Purpose: To analyze the outcome and prognostic factors of a cohort of patients with hepatocellular carcinoma (HCC) and macrovascular invasion (MVI) and establish subgroup categories with different outcomes. Methods: This is a single center retrospective study from March 2001 to December 2005 of patients with newly diagnosed HCC with MVI. The study included patients with HCC and MVI diagnosed by imaging studies (dual phase CT scan or MRI) and reliable clinical variables available. HCC was diagnosed according to the consensus statements established by the EASL and AASLD. Predictors of survival were identified by Kaplan Meyer analysis and Mantel-Cox comparisons. Multivariate Cox proportional hazard analysis was conducted with variables showing significant association with survival at univariate analysis. Results: During the study period, 231 patients out of the 936 HCC patients diagnosed in our center presented with MVI (24.6%). Among them, 199 pts met the inclusion criteria: Seventy were Child Pugh-A (35%), 86 Class B (43%) and 42 Class C (21%). 114 (58%) were ECOG 0 (asymptomatic) and 84 (42%) were symptomatic. HCC was solitary in 110 patients (53.3%). Main portal trunk was involved in 110 (51%), first portal branch in 79 (40%) and a second branch in 18 (9%). Hepatic vein invasion occurred in 39 (20%). Extra hepatic spread was present in 47 patients(23.6%). 143 patients were Barcelona Clinic Liver Cancer Program (BCLC) stage C and 56 BCLC stage D. 115 (57.8%) received treatment after MVI diagnosis, including resection in 34 cases. Median survival for the entire cohort was 4.6 months, the 1 and 2 years survival rate was of 17% and 5%, respectively. Median survival of BCLC C was 6.2 months and BCLC D was of 2.2 months. In BCLC C patients, ECOG 0 (p<0.01), absence of extra hepatic spread (p<0.01) and resection (p=0.01) were independent prognostic factors. Two subgroup of patients with good [asymptomatic patients without extra hepatic spread; n=79] and poor prognosis [n=64] were established. Median survival of these groups was of 8.1 months vs 4.5 months, respectively (p<0.001). Median survival of the 34 patients resected in the good prognosis group was of 10.2 months. Conclusion: HCC patients with macrovascular invasion have a heterogenous outcome. Independent prognostic factors (ECOG and extrahepatic spread) enabled us to recognize two outcome subgroups, and provide the rationale for stratification of patients included in clinical trials. Whether resection might benefit a subgroup of patients with MVI and
TELOMERE AND MITOTIC INSTABILITY AS MARKERS FOR THE PROGRESSION OF HEPATOCELLULAR CARCINOMA AND POSSIBLE IMPLICATIONS IN STEM CELL CARCINOGENESIS

Bong-Kyeong Oh, Haeryoung Kim, Young Nyun Park, Jeong Eun Yoo, Kyung Sik Kim, Chanil Park; 1Cancer Metastasis Research Center, Yonsei University College of Medicine, Seoul, South Korea; 2Department of Pathology, Seoul National University Bundang Hospital, Seongnam, South Korea; 3Department of Pathology, Center for Chronic Metabolic Disease Research, Institute of Gastroenterology and Brain Korea 21 Project for Medical Science, Yonsei University College of Medicine, Seoul, South Korea; 4Department of Pathology, Center for Chronic Metabolic Disease Research, and Brain Korea 21 Project for Medical Science, Yonsei University College of Medicine, Seoul, South Korea; 5Department of General Surgery, Yonsei University College of Medicine, Seoul, South Korea; 6Department of Pathology and Brain Korea 21 Project for Medical Science, Yonsei University College of Medicine, Seoul, South Korea

Purpose: Telomere dysfunction is associated with chromosomal instability, and telomerase reactivation with stabilization of telomere length is crucial in carcinogenesis. However, the role of telomere parameters with respect to chromosomal instability in hepatocarcinogenesis is not clearly understood. In this study, the relationships between telomere parameters, chromosomal instability and progenitor cell differentiation were evaluated in hepatocellular carcinomas (HCCs) along with their impacts on patient prognosis. Methods: Telomere length, telomerase activity, and hTERT mRNA levels were measured in 49 hepatitis B virus-related HCCs and non-HCCs by hybridization with 3'-end DIG-labeled d(TTAGGG)4 probe, TRAP assay and reverse-transcriptase polymerase chain reaction, respectively. The results were compared with clinicopathological data, including differentiation, multipolar mitosis, anaphase bridge, DNA ploidy, immunohistochemical staining results for cytokeratin 19 (CK19), and patient outcome. Results: Telomere lengths of HCCs ranged from 4.7 to 13.1 kb, and 44.4% of HCCs showed telomere lengthening. hTERT mRNA levels and telomerase activities were closely related (p=0.008), and were significantly higher in HCCs than non-HCCs. Telomere length was significantly higher in HCCs with strong telomere activity (p=0.048), high hTERT mRNA levels (p=0.001) and poor differentiation (p=0.041). Poorly differentiated HCCs had more frequent multipolar mitosis (p=0.007). Telomerase activity was positively correlated with multipolar mitosis and anaphase bridges (p=0.019, p=0.017). 13 (28.3%) HCCs were CK19-positive; these demonstrated longer telomeres than CK19-negative HCCs (p=0.046). Overall survival was poor in HCCs with multipolar mitosis>0.4 per field (p=0.016), high telomerase activity (p=0.009), and high telomere length ratio (HCC/non-HCC) >0.8 (p=0.044). Conclusion: Although telomere shortening and chromosomal instability characterize earlier stages of carcinogenesis, cancer progression is associated with telomere maintenance or even elongation. Our results show close associations between high telomerase activity, telomere lengthening, chromosomal instability, and poor prognosis, suggesting that regulation of telomere stabilization may be important for progression to more aggressive HCCs. In addition, the finding that CK19-positive HCCs showed longer telomeres may support previous observations that progenitor cell differentiation in HCCs is associated with a poor prognosis.

PREDICTIVE ABILITY OF HEPATOCELLULAR CARCINOMA STAGING SYSTEMS ACCORDING TO THE TREATMENT MODALITY IN A COHORT OF PATIENTS PROSPECTIVELY FOLLOWED AT A SINGLE REFERRAL CENTRE

Massimo De Giorgio, Stefano Vezzoli, Riccardo Bezza, Maria Grazia Luca, Giovanna Verga, Stefano Okolicsanyi, Maria Grazia Valsecchi, Stefania Galimberti, Michele Colledani, Stefano Fagiuoli, Maria Strazzabosco, Ospedali Riuniti di Bergamo, Bergamo, Italy; 2CeluRe, Ospedali Riuniti di Bergamo, Bergamo, Italy; 3Università di Milano-Bicocca, Milano, Italy; Internal Medicine-Digestive Diseases Liver Center, Yale University, New Haven, CT

Staging systems are essential to assess prognosis of patients with hepatocellular carcinoma (HCC), to guide the therapeutic approach and to design clinical trials. The impact of treatment on natural history of HCC can modify the predictive ability of HCC staging systems. Aim: to evaluate, according to the type of treatment, the predictive ability of the three main HCC staging systems (BCLC, CLIP and TNM), in a large cohort of HCC patients treated and followed prospectively at a single referral Centre. Methods: Demographic, clinical and histological data were prospectively collected, together with liver imaging, at baseline and at 3 month intervals after enrolment, in 332 consecutive HCC patients referred to our Unit from January 2000 to June 2006. HCC was diagnosed according with EASL criteria (histologically confirmed in 68%). Median follow-up was 2 years. 59 pts were resected, 68 pts underwent liver transplantation inside Milan Criteria (age < 65 yrs); 93 pts received ablative treatments (percutaneous ethanol injection or radiofrequency thermal ablation) and 46 pts were treated with chemoembolization (TACE). 66 pts remained untreated, because of advanced disease, refusal of therapy or co-morbidities. The Kaplan-Meyer method and Cox regression models were used to analyse survival and prognosis factors for each staging system. Results: Median age of the cohort was 64 yrs, range 32-87, M:F ratio was 3.9:1; 86.6% of the HCC arose on cirrhotic liver, 60.7% were monofocal at diagnosis. Overall probability of survival at 1, 3 and 5 years was 76.6%, 53.7% and 34.5% respectively. To compare the performance of the three prognostic systems, the χ2 test for trend (discriminatory ability), and the likelihood ratio (LR) χ2 test (homogeneity) and the Akaike's (AIC) information criteria (overall goodness of fit) for the univariate Cox Model were used. Data are shown in the table. (Significant values are in bold). Conclusions: BCLC performs better than other staging systems in predicting overall survival among patients treated with ablative therapies or TACE; survival of untreated patients or of patients treated with resection is predicted more accurately by CLIP rather than TNM. No system accurately predicts prognosis in patients undergoing liver transplantation. These data indicate that in predicting the prognosis of patients with HCC, we should choose the staging system according to the planned treatment modality.

THE EFFECT OF SUSTAINED HBV VIREMIA ON THE RECURRENTENCE OF HEPATOCELLULAR CARCINOMA AFTER CURATIVE RESECTION

Beom Kyung Kim1, Sang Hoon Ahn1,2, Ja Kyung Kim1,2, Do Young Kim1,2, Yong Han Paik1,2, Kwan Sik Lee1,2, Byung Soo Moon1,2, Chae Yoon Chon1,2, Young Myung Moon4, Kwang Hyub Han1,2; 1Internal medicine, Yonsei University College of Medicine, Seoul, South Korea; 2Liver Cirrhosis Clinical Research Center, Yonsei University College of Medicine, Seoul, South Korea; 3Liver Cancer Special Clinics, Yonsei University College of Medicine, Seoul, South Korea; 4Internal medicine, Kwandong University College of Medicine, Kangwon, South Korea

Background: An elevated serum HBV DNA level is a risk factor for developing hepatocellular carcinoma (HCC). Rather than the instantaneous serum HBV DNA, the duration of viremia is more important in carcinogenesis. Nevertheless, most investigations have evaluated the DNA level at study entry as a risk factor. We assessed the effects of sustained HBV viremia on the recurrence of HCC after curative resection. Methods: A total of 230 patients undergoing curative resections between 2000 and 2006 were initially included. Patients who received antiviral therapy at diagnosis or during follow-up, or experienced recurrence within 6 months after resection were excluded. In addition, those who had fluctuating DNA levels (cutoff value: 100,000 copies/mL) were also excluded. Ultimately, 157 patients were enrolled. The serum HBV DNA level, biochemical tests, alpha-fetoprotein, and liver dynamic computed tomography were obtained at 3-month intervals after surgery. The primary endpoint was the recurrence of HCC. Results: With a median follow-up duration of 33.4 months, 75 (47.7%) of 157 patients experienced recurrences. Eighty-nine (non-viremia group) were considered positive when at least one marker had a value above the 75th percentile, the sensibility was 90%, specificity 80%, positive predictive value 92%, negative predictive value 72%, positive likelihood ratio 4.45, and negative likelihood ratio 0.13, and the area under ROC curve 0.9173. Conclusions: Higher expression of serum DCP and GP73 antibody, and low expression of GP73 antigen are new promising markers for the diagnosis of HCC. Combination of these markers provides useful non invasive method for the diagnosis of HCC.

EARLY DIAGNOSIS PANEL OF SERUM BIOMARKERS OF HBV-INDUCED HEPATOCELLULAR CARCINOMA DURING 3 YEARS FOLLOW-UP

Canghai Wang, Bao en Wang, Hong You, Xiaojuan Ou; Beijing Friendship Hospital, Beijing, China

Objective: To investigate the combined value of α-fetoprotein (AFP), des-γ-carboxy prothrombin (DCP), α-feto-protein-L3 (AFP-L3), γ-glutamyl transpeptidase-II (GGT-II), CA125, CA19-9 in patients with liver cirrhosis who had been followed for the development of hepatocellular carcinoma (HCC). And using SELDI-TOF-MS to investigate proteomic markers of these patients. Patients and Methods Eighty-one patients with HBV-induced liver cirrhosis were monitored by serum AFP, DCP, AFP-L3, CA125, CA19-9, GGT-II and ultrasonography every 6 months for 3 years. Proteomic spectra by SELDI-TOF-MS
were generated in 10 patients who were diagnosed as HCC during follow-up. At the same time, all the serum markers were measured in 99 patients with HBV-induced HCC, 30 with secondary liver metastasis, and 20 healthy controls. Results During 3 years following up, 12(15.9%) of the 81 patients with HBV-induced liver cirrhosis were diagnosed as HCC. Each marker’s positive rate in patients who developed HCC during follow-up before HCC was diagnosed showed in table. The diagnostic value of DCP was the highest, with 75.8% sensitivity, 88.6% specificity, and 81.4% accuracy. The accuracy of other markers was reduced in order of AFP, AFP-L3, CA125, GGT-II, and CA19-9. Logistic regression analysis identified DCP, GGT2, AFP, and CA125 as independent markers for HCC. When compared the accuracy with the combination panel of all the serum markers, AFP, DCP plus CA125 showed the highest of 88.2% while the accuracy of AFP alone was only 76.2%. Spearman correlation analysis showed that DCP and CA125 were related with tumor size, DCP, CA125 and CA19-9 were related with Portal vein thrombosis, but no markers were related with extrahepatic metastasis. In addition, the proteomics analysis showed the 4350.8 m/z protein increased from cirrhosis to HCC, while the level of the 6860.5, 7571, 15125, 15893 m/z proteins decreased from cirrhosis to HCC. Conclusions DCP and GGTII emerged earlier in HCC patients than other markers. The best combination of the markers for early diagnosis of HBV-induced HCC was AFP, DCP plus CA125.

Each marker’s positive rate in patients who developed HCC during follow-up before HCC was diagnosed

377 GRADING OF MICROSCOPIC VASCULAR INVASION FOR RESECTED HEPATOCELLLULAR CARCINOMA
Sasan Roayaie, Josep M. Llovet, Iris Blume, Mostafa Gaabour, Swan N. Thung, Myron Schwartz; Mount Sinai Liver Cancer Program, Mount Sinai Medical Center, New York, NY
Purpose: Vascular invasion, usually classified as gross or microscopic (MVI), is a risk factor for recurrence of hepatocellular carcinoma (HCC) after resection; however, MVI represents a wide spectrum between no invasion and gross vascular invasion. The purpose is to determine if any histologic findings can stratify patients with HCC and MVI in terms of recurrence and survival after resection. Methods: We reviewed the records of all resections done for HCC at a single institution between 1/90 and 3/06 to identify those with MVI proven on histology; cases with gross vascular invasion were excluded. Number and size of vessels invaded, invasion of a vessel with a muscular wall, distance from the tumor, and presence of satellite nodules was recorded. Log rank test was used to determine correlation with recurrence and survival. Cox regression analysis was used to identify independent predictors of survival. Results: MVI was present in 131 of 384 resected patients (34.1%). Median follow-up was 28.9 mo. There were 88 recurrences and 54 deaths. On univariate analysis, invasion of a vessel with a muscular wall (p=0.0181), invasion > 1 cm from the tumor (p=0.0378), and invasion of > 5 vessels (p=0.0491) were associated with recurrence; invasion of a vessel with a muscular wall (p=0.002) and invasion > 1 cm from the tumor (p=0.001) were also associated with decreased survival. Both were also significant predictors of survival on multivariate analysis: Vessel w/ muscular wall p=0.018 Exp [B]=2.2 95% CI 1.1-4.2 Vessel >1cm from tumor p=0.015 Exp [B]=2.1 95% CI 1.2-3.7 A risk score assigning one point for the presence of each variable correlated significantly with both recurrence (p=0.0379) and survival (Figure1). Conclusion: Patients undergoing resection for HCC with MVI are a heterogeneous group; the proposed grading system can accurately stratify patients according to their risk of recurrence and survival.

378 SURVEILLANCE CT SCANS FOR RECURRENT OF HEPATOCELULAR CARCINOMA POST-LIVER TRANSPLANT
David Hudesman, Marialsbel Fiel, Sasan Roayaie, Paul Martin, Myron Schwartz; Mount Sinai School of Medicine, New York, NY
BACKGROUND: Recurrent hepatocellular carcinoma (HCC) diminishes overall survival in liver transplant (LT) recipients. Established risk factors for recurrence include larger tumor burden, tumor dedifferentiation and presence of vascular invasion. Excellent tumor free survival has been reported for patients whose tumor burden falls within the Milan criteria. Generally, some form of surveillance is undertaken to detect recurrent HCC for patients within and beyond the Milan criteria, although the optimal strategy remains undefined both in terms of frequency and duration of surveillance. At our center, the current practice is to define whether a LT recipient is at high or low risk for recurrence based on the explant characteristics and to tailor accordingly the intensity of post-LT surveillance. OBJECTIVE: This study was designed to test the hypothesis that surveillance dual phase CT scans for low risk LT recipients is low yield. MATERIAL AND METHODS: 267 adult patients underwent LT for HCC at our institution between January 1998 and December 2005. Patients were stratified into a low risk (within the Milan criteria, well or moderately differentiated tumor, and no vascular invasion) and a high risk (outside the Milan criteria, poorly differentiated, or presence of vascular invasion) group. For the low
risk group, surveillance CT scans were obtained at 3 months post-transplant and then yearly for 5 years. For the high risk group, CT scans were performed every 3 months for the first year, every 6 months for the second and third years, and then yearly for years 4 and 5. Time to recurrence was defined as the point at which a mass was first discovered on dual phase CT scan of the abdomen or CT scan of the chest consistent with recurrent HCC. RESULTS: Of the 267 patients, 110 were designated as low-risk, and 157 as high-risk. HCC recurrences developed in 49 cases (18.4%). 4/110 (3.6%) considered low risk cases, and 45/157 (28.7%) high risk cases recurred. Median time to recurrence was 10.7 months for the entire cohort, and 8.1 months in the high-risk group. 4/49 (8%) of recurrences were beyond 3 years, with only 2% occurring after 4 years. CONCLUSIONS: For patients at low risk for HCC recurrence based on clinical and explant characteristics, regular post-LT surveillance is low yield. For high risk patients, the yield of surveillance with dual-phase CT scans beyond 3 years post-LT is also low. Surveillance for recurrent HCC need not be continued beyond 3 years post-LT.

COMPREHENSIVE GENOME ANALYSIS FOR ETIOLOGY-DEPENDENT AND ETIOLOGY-INDEPENDENT MOLECULAR MECHANISMS IN HUMAN HEPATOCARCINOSIS

Thomas Longerich1, Christoph Schlaeger2, Claudia Schiller1, Peter Bewerunge1, Arianeb Mehrabi4, Roland Eils3, Peter Lichter2, Peter Schirmacher5, Bernhard Radlwimmer2; 1Institute of Pathology, University of Heidelberg, Heidelberg, Germany; 2Division of Molecular Genetics, German Cancer Research Centre, Heidelberg, Germany; 3Division of Theoretical Bioinformatics, German Cancer Research Centre, Heidelberg, Germany; 4Department of General, Visceral and Transplantation Surgery, University of Heidelberg, Heidelberg, Germany

Hepatocellular carcinoma (HCC) represents one of the most common cancers worldwide and is characterized by aggressive tumor formation with poor prognosis. Various etiologies have been linked to HCC development, most prominently chronic hepatitis B (HBV) and C (HCV) virus infections as well as chronic alcohol consumption. About 10% of HCCs are so-called cryptogenic, but likely derive from nonalcoholic steatohepatitis (NASH). In order to identify host changes related to tumor etiology as well as novel driver genes of human hepatocarcinogenesis, we combined high-resolution fine-mapping of genomic imbalances with expression and functional analyses. Array-based comparative genomic hybridization (aCGH) of a panel of etiologically well-defined HCCs (n=68) revealed DNA copy number gains of chromosome arm 8q to be significantly less frequent in cryptogenic HCCs compared to other etiologies. Expression analyses validated MYC as the potential target gene of 8q gains. Moreover, our gene expression data show a upregulation of MYC target genes in these HCCs. In contrast, FGF19, one of the most overexpressed genes in our cryptogenic HCCs, may replace the growth promoting effects of MYC in this etiological subgroup. In addition, we were able to fine-map frequent etiology-independent chromosomal imbalances on 1q32.1 and 20q13.33. From several candidates of these regions, we validated MDM4 and eEF1A2 as the likely candidate genes using expression and functional analyses. In conclusion, molecular hepatocarcinogenesis of cryptogenic HCC differs from the other etiological subgroups at least with respect to 8q gain and MYC activation. Furthermore, activation of the oncogenes MDM4 and eEF1A2 represent an etiology-independent mechanism of human hepatocarcinogenesis in a subset of HCC by presumably overcoming TP53-dependent growth control.

TUMOUR M2-PYRUVATE KINASE HAS A DIAGNOSTIC AND PROGNOSTIC ROLE IN BILIARY TRACT CANCER

James H. Brindle1, Dipok K. Dhar1, Michael Chapman1, James S. Dooley2, Stephen P. Pereira1; 1The Institute of Hepatology, Royal Free & University College London Medical School, London, United Kingdom; 2Centre for Hepatology, Royal Free & University College London Medical School, London, United Kingdom

Background: A reliable tumour marker which could differentiate between benign biliary disease and biliary tract cancer (BTC) would be a useful addition to current diagnostic tests. One such potential marker is the M2 type of the glycolytic isozyme pyruvate kinase (M2-PK), but there are few data on plasma M2-PK in biliary disease. Methods: We used a commercially available ELISA (Schebo-Biotech, Germany) to measure plasma M2-PK levels in 23 patients with benign non-primary sclerosing cholangitis (PSC) biliary diseases (12M, 11F; mean age 50 yr), 11 with PSC (4M, 7F; mean age 59 yr), and 41 with BTC (14M, 27F; mean age 68 yr). Results: The mean ± SD M2-PK level (U/ml) in non-PSC benign disease was 34.3 ± 20.6, compared with values of 71.7 ± 81.6 in PSC (p = 0.031) and 114.8 ± 160.9 in BTC (p = 0.001) (Figure 1). There was also a significant difference in mean M2-PK levels between the 11 patients with PSC alone and three with PSC+BTC (586.7 ± 208.1 U/ml, p = 0.005). Receiver operating characteristics analysis identified a M2-PK cut off of 31 U/ml, corresponding to a sensitivity and specificity of 76% and 61%, respectively, for BTC. However, of the 11 patients with M2-PK levels > 100 U/ml, all but one had BTC. There was a significant correlation between CA19-9 and bilirubin in the PSC and BTC groups, whereas M2-PK was not affected by cholestasis. Patients with BTC who had high levels of both M2-PK and CA19-9 had significantly (p = 0.049) worse survival compared with the other BTC patients; this was the only independent prognostic indicator on multivariate analysis. Conclusions: M2-PK may be a useful diagnostic and prognostic marker in BTC, and warrants further study in the screening of PSC patients for BTC.
Risk factors for HCC occurrence were male gender and absence of diabetes. After a mean follow-up of 50 months, 20 patients developed HCC: 6 in the group treated by beta-blockers alone (n=12) or in association with band ligation (n=35). There was no statistically significant difference between patients treated with beta-blockers or not, in terms of age, sex, alcohol abuse, BMI, platelet counts, presence of diabetes. Recent studies have shown that stress and catecholamine secretion may influence cancer occurrence and progression by modulating the expression of matrix metalloproteinases and vascular endothelial growth factor both inhibited by beta blockers. We assessed the impact of beta-blockers on HCC occurrence in patients with viral C cirrhosis and oesophageal varices periodically screened for HCC Among 420 patients with Child-Pugh A or B viral C cirrhosis, 99 had oesophageal varices and were included in this study, 3 were secondarily excluded due to previous viral eradication. Therefore, the analysis was performed in 96 patients. Clinical and biological data were collected at the time of diagnosis of oesophageal varices and decision to treat Results The mean age of patients was 60.5 ± 12 yrs, 52 men, mean BMI 25.5 ± 4 kg/m2, 60 were diabetics, 38 had alcohol abuse, 52 received a treatment by beta-blockers alone (n=12) or in association with band ligation (n=40). The others (n=44) had no treatment (n= 9) or were treated by band ligation (n=35). There was no statistically significant difference between patients treated with beta-blockers or not, in terms of age, sex, alcohol abuse, BMI, platelet counts, presence of diabetes After a mean follow-up of 50 ± 34 months, 20 patients developed HCC: 6 in the group treated by beta-blocker and 16 in the other group. In univariate analysis, risk factors for HCC occurrence were male gender and absence of beta-blockers use. In multivariate analysis, beta-blockers use was the sole independent risk factor of HCC; HR=0.12 (0.04-0.38) p=0.0003. Conclusion In this retrospective study, Beta-blockers use was associated with a lower incidence of HCC in patients with HCV cirrhosis and oesophageal varices. Beta-blockers may have a preventive effect on the development of HCC that deserve a long term randomised trial.

383 SORAFENIB IN MULTIFOCAL HEPATOCELLULAR CARCINOMA AND ADVANCED LIVER DYSFUNCTION
Matthias W. Pinter1, Wolfgang Sieghart1, Ivo Graziaidei2, Robert Königsberg3, Markus Peck-Radosavljevic1, 1Gastroenterology & Hepatology, AKH & Medizinische Universität Wien, Vienna, Austria; 2Gastroenterology & Hepatology, LH & Medizinische Universität Innsbruck, Innsbruck, Austria; 3Oncology & Hematology, SMZ-Süd - Kaiser-Franz-Josef-Spital, Vienna, Austria

Background: So far, no established treatment for advanced hepatocellular carcinoma (HCC) was available. Encouraging results of a multicenter, placebo-controlled phase III trial using the multikinase inhibitor sorafenib in unresectable HCC suggest a survival benefit and good tolerability in Child-Pugh A patients. No data are available regarding the safety and efficacy of sorafenib in patients with multifocal HCC and advanced liver cirrhosis. Patients and Methods: Between May 2006 and May 2007 patients with unresectable HCC were treated with oral sorafenib (daily target dose: 400 mg bid). Data were collected retrospectively. Survival curves were calculated via the Kaplan-Meier method. Results: Of 32 patients analyzed (m/f = 25/7, age 27 to 82), the predominant etiology of cirrhosis was alcohol (n = 15). Child-Pugh A/B/C was 15/11/6; Barcelona Clinic Liver Cancer (BCLC) stage B/C/D was 2/19/11. The most common side effects were low-grade and manageable. A total of 14 patients died during the observation period (median survival: 1.6 months; range: 0.4 – 7.4); the median overall survival (OS) of the entire intent-to-treat group was 6.5 months (range: 0.4 – 11.4 months). Median follow-up for Child-Pugh A (alive: 14/15) was 3.4 months; median survival was 3.8 months for Child-Pugh B (alive: 4/11) and 1.5 months for Child-Pugh C (alive: 0/6). The differences between Child-Pugh class A, B and C were statistically significant on univariate analysis (log rank, p = 0.0001) (Figure 1). Median follow-up for BCLC stage B/C (alive: 16/21) was 3.8 months; median survival for BCLC stage D (alive: 2/11) was 1.5 months, which is not different from the expected survival in this patient group. The differences between both groups were statistically significant on univariate analysis (log rank, p = 0.0001). Conclusion: Sorafenib is safe in patients with multifocal HCC and advanced liver dysfunction. Diarrhea was the most troublesome side effect in our series similar to the phase III randomized controlled trial (SHARP-trial) of sorafenib in Child A patients. Efficacy could be limited in Child-Pugh C and BCLC stage D patients. Prospective controlled trials are warranted to evaluate the safety and efficacy of sorafenib in large HCC and advanced liver dysfunction.

384 GLOBAL DNA METHYLATION INDEX (GDMI) PROFILE IN PATIENTS WITH CIRRHOSIS: CORRELATION TO UNDERLYING CAUSE OF DISEASE AND ASSOCIATED HEPATOCELLULAR CARCINOMA.
Michel Mendler1, Anthony Anisowicz2, Eric Huang3, Rick Selby3, Richard Del Mastro4, Linda Sher5; 1GI and Liver Diseases, Transplantation Institute, Loma Linda University Medical Center, Loma Linda, CA; 2Cardiovascular Disease Area, Novartis Institute for Biomedical Research, Cambridge, MA; 3Liver Transplant Program and Center for Liver Disease, University of Southern California, Los Angeles, CA; 4GIBCO Cell Culture Systems, Invitrogen Corporation, Grand Island, NY

Background: Changes in hepatic DNA methylation have been demonstrated in specific genes and their promoters in association with cirrhosis due to alcoholic liver disease (ALD) and hepatitis C virus (HCV), and in hepatocellular carcinoma (HCC). We hypothesize that the quantitative global DNA methylation status of peripheral white blood cells (WBC) may reflect epigenetic alterations at the tissue level. Methods: A Global Methylation-Restriction Enzyme Sensitive Assay (GM-RESA) was performed in triplicate on WBC of patients with cirrhosis obtained from a tissue repository from one liver transplantation center, and on commercially available control WBC [n=10]. GM-RESA measures the density of methylated CpG dyads throughout the genome using methyl-sensitive (Hpa II) and insensitive (Msp I) restriction enzymes to calculate the Global DNA Methylation Index (GDMI). The GDMI was correlated to cause of liver disease and presence of HCC. Results: 93 patients were included: 59% male; 48% Hispanic, 38% Caucasian, 8% Asian; 55±11 years old. Etiologies (alone or in combination) included: HCV (53%), ALD (35%), HBV (8%), Cryptogenic (11%) and other (9%). 33% of patients were transplanted, and 56% had a tissue diagnosis. 18 (19%) patients had HCC, 13 with tissue diagnoses. Clinical indices of liver disease were: MELD score 14±6, Child-Pugh score 8±2; albumin (g/dL) 3.1±0.7, INR 1.3±0.3, creatinine (mg/dL) 1.1±1.0, total bilirubin (mg/dL) 3.9±6.6, and platelet count (x1000) 110±75. Mean GDMI of patients (0.24±0.06) was similar to controls (0.22±0.02), but with a greater variance (F test: variance ratio 6.2, p=0.003). GDMI did not correlate with any clinical index. To limit bias from type II error and heterogeneity of etiologies, the GDMI was studied within a subgroup of 77 subjects: 10 controls vs. 24 HCV, 21 ALD, 10 ALD+HCV and 12 HCV+HCC. The GDMI variance of each patient group was significantly greater than that of controls. The GDMI of HCV+HCC (0.27±0.06) was greater than that of controls (p=0.046) and ALD (0.23±0.05; p=0.06); and that of ALD+HCV (0.26±0.05) was greater than controls (p=0.039). Overall, there was an increase in GDMI: ALD < controls < HCV < ALD+HCV < HCV+HCC. Conclusion: This pilot study suggests that compared to the controls, quantitative global DNA methylation (GDMI) of peripheral WBC is lower in patients with cirrhosis due to alcohol alone but higher in HCV associated with HCC. Thus GDMI may provide insight into epigenetic alterations involved in the pathogenesis of liver disease and subsequent carcinogenesis. Larger studies and correlation with tissue GDMI are warranted.

COST-EFFECTIVENESS OF NEW SCREENING STRATEGIES FOR HEPATOCELLULAR CARCINOMA (HCC) COMPARED TO ULTRASOUND (US)

Mark W. Russo1, Richard K. Sterling2, 1Medicine, Carolinas Medical Center, Charlotte, NC; 2Medicine, Medical College of Virginia, Richmond, VA

US is recommended for screening for HCC. However, a positive US is frequently followed by a second imaging study which increases the cost of a screening program. The utility of newer blood tests with better sensitivity and specificity in detecting HCC at relatively low cost for identifying patients who should proceed directly to CT or MRI and reduce the costs of a screening program are unknown. Methods: We conducted a cost-effectiveness analysis of 9 screening strategies to detect HCC in a hypothetical cohort of hepatitis C (HCV) cirrhotics. The outcome was the incremental cost effectiveness ratio (ICER) to detect each additional cancer. Annual screening with US was compared to annual screening with CT, AFP+AFPL3%, DCP+AFP+AFPL3%, and DCP+AFPL3%. Biannual screening strategies that were modeled included US every 6 months (base case), CT every 6 months, US alternating with AFPL3%+DCP, CT alternating with AFPL3%+DCP. We assumed patients with a positive blood test or lesion seen on US would undergo CT. The sensitivity and specificity used were: US 0.6 & 0.8, CT 0.8 & 0.9, AFP+AFPL3% 0.69 & 0.66, AFPL3%+DCP 0.62 & 0.83, AFP+AFPL3%+DCP 0.77 & 0.59. The cost of US, CT, AFP+AFPL3%, DCP+AFP+AFPL3%, DCP+AFPL3% were $200, $590, $90, $180, $180, respectively. Sensitivity analyses were conducted to test the robustness of the model. The annual rate of HCC was assumed at 1.4%. Results: Annual US followed by CT if abnormal was more either more expensive or did not detect more HCC’s than the combination blood screening tests. The most cost-effective strategy was annual screening with AFP+AFPL3% which detected more cancers and cost less than US mostly due to fewer patients proceeding to CT with AFP+AFPL3%. CT detected the most cancers of all the strategies but was the most expensive strategy overall and AFP+AFPL3%+DCP was the blood test that detected the most cancers and was the most expensive blood test. Compared to AFP+AFPL3% the ICER for each additional cancer detected was $85,449 for CT and $147,620 for AFP+AFPL3%+DCP. In sensitivity analysis annual CT would be cost-effective if the cost dropped below $400. The most cost-effective 6 month strategy was CT alternating with AFPL3%+DCP with an ICER of $10,357 for each additional cancer detected compared to biannual US. Conclusion: Annual screening with AFP+AFPL3% is the most cost-effective annual strategy for detecting HCC in HCV cirrhotics; however it detects fewer cancers than AFP+AFPL3%+DCP or CT alone. The most cost-effective 6 month strategy is CT alternating with AFPL3%+DCP; thus, this promising strategy should be prospectively studied in screening of HCC.

10-YEAR ACTUAL LONG-TERM OUTCOME OF HCC AFTER SURGICAL RESECTION: SINGLE CENTER EXPERIENCES

Woo Young Shin1, Kyung-Suk Suh1, Hae Won Lee1, Eung-ho Cho1, Nam-Joon Yi1, Jung-Hwan Yoon2, Kuhn Uk Lee1; 1Surgery, Seoul National University College of Medicine, Seoul, South Korea; 2Internal medicine, Seoul National University College of Medicine, Seoul, South Korea

Background The aim of this study was to evaluate actual 10-year survival and to identify the prognostic factors affecting long term survival and disease-free survival (DFS) in patients with hepatocellular carcinoma (HCC) after surgical resection. Patients and Methods To obtain the actual data, we confined study period from January 1992 to April 1996. Two hundred eighty-one liver resections for HCC were retrospectively reviewed. There were 237 men and 44 women. Median age was 54 years. Univariate and multivariate analyses were performed on 20 clinicopathological variables to analyze factors affecting survival and DFS. Results The median survival time was 4.8 years. The actual 5- and 10-year survival rates were 48.0% and 28.8% respectively. Eighty-one patients survived over 10 years. Preoperative aspartate aminotransferase (AST) level, cirrhosis, number of tumor, Edmondson-Steiner grade and vascular invasion were identified as independent prognostic factors for survival by multivariate analysis. Tumor recurrence appeared in 217 (77.2%) patients. Of these 25 (11.5%) patients had experienced tumor recurrence after 5 postoperative years. The 5- and 10-year DFS rates were 27.1% and 18.4% respectively. Thirty-four patients (12.1%) did not experience tumor recurrence over 10 years. Preoperative AST and alpha-fetoprotein level, cirrhosis, vascular invasion and satellite nodules were identified as the independent prognostic factors of DFS by multivariate analysis. Conclusions Survival decreased continuously until 10 years after surgical resection because of recurrent disease and decompensated cirrhosis. Hence, to improve long-term outcome, other treatment measures to consider background liver such as transplantation or postoperative adjuvant therapies were needed.

LOW SERUM APOLIPOTREIN A1 IS PREDICTIVE OF HCC DEVELOPMENT IN PATIENTS WITH VIRAL C CIRRHOSIS

Gisèle Nkontchou1, Jenny Vaysse2, Amel Mahmoudi1, Valérie Boucier1, Nathalie Ganne Carrié1, Véronique Grand-Le Lemaire1, Jean Claude Trinchet1, Eric Vicaut2, Michel Beauprand1; 1Liver Unit, Bondy, France; 2Biochemistry, Jean Verdier Hospital, Bondy, France

Low levels of Apolipoprotein A1 (Apo A1) have been reported in patients with extensive liver fibrosis and recently, a genomic study suggested it was predictive of the occurrence of HCC in patients with HCV cirrhosis. This study was aimed to assess the predictive value of serum Apo A1 for the occurrence of HCC in a cohort of 185 patients with HCV cirrhosis, prospectively followed and screened for HCC by US examination performed every 6 months. Sera were sampled and clinical and biological parameters were recorded at the time of inclusion. Results All patients had well compensated cirrhosis. The mean age was 58.5 ± 13.2 yrs, 111 were male, 55 diabetics and 60 have cirrhosis related to HCV + alcohol. The mean BMI was 25.7 ± 3.9 kg/m2., 33 (18%) have a low serum level of Apo A1. After a mean follow-up of 3.3 ± 2.0 yrs, 30 patients developed a
HCC. In univariate analysis, risk factors for HCC occurrence were male gender, high BMI, low level of Apo A1 and low platelet counts. In multivariate analysis, low level of Apo A1 (p<0.02), high BMI (p<0.004), male gender (p=0.01) and platelet counts (p=0.04) were independent risk factors. Conclusion Decrease of serum level of Apo A1 is associated with HCC occurrence in patients with HCV cirrhosis.

388 A COMPREHENSIVE PROSPECTIVE STUDY FOR THE VALUE OF 11C-ACETATE AND 18F-FDG PET-CT IN THE DETECTION OF HEPATOCELLULAR CARCINOMA

Ji Hoon Kim1, Joong-Won Park1, Seok Ki Kim2, Keon Woak Kang2, Kyung Woo Park1, Jun-II Choi1, Sang Jae Park1, Woo Jin Lee1, Eun Kyung Hong1, Chang-Min Kim1; 1Center for Liver Cancer, National Cancer Center, Goyang, South Korea; 2Department of Nuclear Medicine, National Cancer Center, Goyang, South Korea

Background: The value of 18F-FDG positron emission tomography (PET) was found to be low in the detection of hepatocellular carcinoma (HCC) because of a high false negative rate. Recently, 11C-Acetate PET studies showed a relatively high sensitivity for the detection of HCC but there was no sufficient data. Therefore, we evaluated the value of 11C-Acetate and 18F-FDG PET-CT in the detection of HCC. Methods: Between June 2006 and February 2007, 99 patients who had either a newly diagnosed HCC or a new distant metastasis after surgical resection of HCC 6 months prior to this study, were prospectively enrolled. A biopsy was performed on all patients and they all underwent 11C-Acetate and 18F-FDG PET-CT study free of charge before treatment. Results: 1) The number of patients was 5, 37, 16, 13, 28 in modified UICC stages I, II, III, IVa, IVb respectively. 2) Analysis of intrahepatic tumors: A total of 110 countable and above 1 cm-sized intrahepatic tumors from 90 patients were analyzed. The sensitivity of 18F-FDG, 11C-Acetate, and 18F-FDG + 11C-Acetate was 60.9%, 75.4%, and 90% in 11C-Acetate (p<0.001), respectively. The sensitivity according to the size of tumor (<2/2-5/5-10/10-20 cm) was 27.2%/47.8%/85.7% in 11C-Acetate (p<0.001) and 31.8%/78.2%/95.2% in 11C-Acetate (p<0.001), respectively. The standardized uptake value (SUVD) according to the size of tumor (<5/5-10/10-20 cm) was 4.7±1.7/8.0±5.2 in 18F-FDG (p=0.001) and 5.5±2.1/5.5±2.4 in 11C-Acetate (p=0.499). The sensitivity according to the grade of tumor differentiation (Grade 1,2/Grade 3,4) was 50%/90% in 18F-FDG (p=0.001) and 80%/90% in 11C-Acetate (p=0.05). 3) Analysis of distant metastases: We analysed 35 distant metastatic tumors by indexing the largest tumor in each separate organ. The sensitivity of 18F-FDG, 11C-Acetate, and 18F-FDG + 11C-Acetate was 85.7%/77%, and 85.7%, respectively. The sensitivity according to the size of tumor (<2/≥2 cm) was 80%/93% in 18F-FDG (p=0.365) and 65%/93% in 11C-Acetate (p=0.101), respectively. The SUV according to the size of tumor (<2/≥2 cm) was 3.6±2.5/4.6±2.4 in 18F-FDG (p=0.276) and 2.2±2.1/4.1±3.2 in 11C-Acetate (p=0.089). The sensitivity according to the grade (Grade 1,2/Grade 3,4) was 90.9%/76.9% in 18F-FDG (p=0.337) and 90%/53.8% in 11C-Acetate (p=0.032). Conclusions: Both 11C-Acetate and 18F-FDG PET-CT showed low sensitivity in the detection of small intrahepatic HCC but relatively high sensitivity in the detection of extrahepatic metastases. Addition of 11C-Acetate to 18F-FDG PET-CT increases the sensitivity in the detection of intrahepatic HCC tumors, not of extrahepatic HCC metastases.

Disclosures: The following people have nothing to disclose: Shunsuke Ura, Masao Honda, Teruyuki Ueda, Ryuehi Nishino, Hajime Takatori, Mikiko Nakamura, Shuichi Kaneko; Gastroenterology, Graduate School of Medical Science, Kanazawa University, Kanazawa, Japan

Background & Aims: MicroRNAs (miRNAs) are small non-coding RNAs that represent an important mechanism for posttranscriptional gene silencing and have recently been recognized to play important roles in tissue development, cell differentiation and proliferation and apoptosis processes in human diseases and cancers. We have previously reported gene expression profiles of chronic hepatitis (CH)-B and CH-C differ [Gastroenterology. 2001, 120, 955, Hepatology. 2006, 44, 1122]. This study examined miRNA expression profiling in chronic viral hepatitis (CH) and hepatocellular carcinoma (HCC) liver tissues. Methods: We applied real-time detection (RTD)-PCR to detect miRNAs. We used Loopeal-primed RTD-PCR with Taq-Man® MicroRNA Assays Human Panel Early Access Kit (Applied Biosystems), which contains a 180-assay panel covering most known human miRNAs. We analyzed tumor and non-tumor liver tissues from 12 patients with HBV-related HCC (HCC-B), 14 patients with HCV-related HCC (HCC-C) and 9 patients with normal liver (N). Candidate target genes by miRNAs were predicted by Miranda Pro 3.0. To evaluate the regulatory effect of miRNAs on target genes in these samples, whole gene expression profiling was obtained from these samples using an in-house cDNA microarray comprising 9614 clones. Data analysis was performed by BRB Array Tool (NCBI). Results: Hierarchical clustering analysis (unsupervised learning methods) and supervised learning methods using compound covariate predictor revealed significant classification of N, CH and HCC respectively (N vs. CH: 97% accuracy, p<0.001; CH vs. HCC: 79% accuracy, p<0.001). Differences were larger between N and CH than between CH and HCC. Interestingly, miRNA profiles differentiated CH-B and CH-C, and HCC-B and HCC-C (CH-B vs. CH-C: 92% accuracy, p<0.001; HCC-B vs. HCC-C: 77% accuracy, p=0.02), although statistical values for HCC-B and HCC-C were less. Out of differentially expressed miRNAs among these classifications (p<0.01), 18 miRNAs from N vs. CH and 8 miRNAs from CH and HCC regulated target gene expression in host tissue samples, as determined by group comparison using whole gene expression profiling data from cDNA microarrays. Similarly, 4 miRNAs from CH-B vs. CH-C and 2 miRNAs from HCC-B vs. HCC-C were determined and expressions could differentiate HBV- or HCV-infected liver. Conclusions: Expression of miRNAs clearly differentiated N, CH and HCC as well as HBV- and HCV-infected liver. Functionally active miRNAs determined by combined gene expression data can reveal pathogenesis and identify therapeutic targets for liver disease.

FOCAL NODULAR HYPERPLASIA BUT NOT IN FNH-LIKE

Sandra Rebouissou1, Gabrielle Couchy1, Sandrine Imbeaud2, Louis Libbrecht3, Charles P. Balabaùd4, Tania Roskams5, Paulette Bioulac-Sage5, Jessica Zucman-Rossi1; 1U674, Inserm, Paris, France; 2CNRS, Villejuif, France; 3Department and Laboratories of Pathology, University Hospitals of Leuven, Leuven, Belgium; 4Hospital Saint André, CHU Bordeaux, Bordeaux, France; 5Hospital Pellegrin, CHU Bordeaux, Bordeaux, France

Focal nodular hyperplasia (FNH) is the second most common benign liver tumor after hemangioma. A central stellate fibrous region containing malformed vascular structures characterizes FNH nodules, which are considered as the result of a hyperplastic response to increased blood flow rather than a neoplastic process. In contrast to typical FNHs that usually develop in normal liver, FNH-like nodules occur in cirrhotic liver but share similar histopathological features. To better understand the pathophysiology of FNH, we searched for deregulated genes in FNH, using a transcriptome analysis exploring more than 15,000 different genes in 8 FNHs compared to 4 non-tumoral liver samples. Selected genes were validated using quantitative RT-PCR in a larger series of 72 benign liver tumors including FNH, adenoma, cirrhotic nodules and FNH-like lesions. Among the 524 genes significantly deregulated in FNH, we identified 20 genes of which the expression is zonated in the normal liver lobule. All 6 genes that are normally highly expressed in the perivenous area were up-regulated in FNH nodules, while 14 genes physiologically expressed in the perportal area were down-regulated. Using immunohistochemistry, we found that overexpression of the β-catenin-activated glutamine synthetase (GS) in FNH extended up to 5 to 10 hepatocytes away from the veins leading to a marked enlargement of the peri-veneinous areas, while in normal liver its expression is restricted to the immediate venous surrounding. In all hepatocytes, β-catenin was membranous without significant cytoplasmic or nuclear over-expression. However, quantitative RT-PCR analyses identified a slight but significant β-catenin mRNA overexpression closely related to the overexpression of β-catenin targeted genes in FNH suggesting an increased gradient of β-catenin expression without activating mutations. We further analysed the expression of 15 genes in a series of 72 benign liver nodules. Interestingly, FNH-like lesions demonstrated an expression profile similar to other related cirrhotic samples but different from the profile observed in typical FNH. However, in FNH-like the two perivenous genes encoding GS and GPR49 were significantly down regulated when compared to normal liver, adenomas and FNH nodules. Consistent with this result, little or no GS staining was observed in FNH-like nodules using immunohistochemistry. In conclusion, our data reveals the presence of an increased zonated expression of β-catenin targeted genes in FNHs, but not in FNH-like nodules. Although they have the same morphological features, our findings indicate that these two types of lesions have a different pathogenesis.

LIVER RADIODEMOBILIZATION EFFECTIVELY CONTROLS TUMOR GROWTH OF MACROSCOPIC BUT NOT MICROSCOPIC DISEASE IN PATIENTS WITH HEPATOCELLULAR CARCINOMA

Mercedes Iturriaga1, Felix Alegría1, Jose Ignacio Bilbao2, Antonio Martínez de la Cuesta2, Alberto Benito2, Javier Arbizu2, I Ignacio Herrero1, Jorge Quiróga1, Jesus Prieto1, Bruno Sangro1; 1Liver Unit, Clinica Universitaria of Navarra, Pamplona, Spain; 2Radiology, Clinica Universitaria of Navarra, Pamplona, Spain; 3Nuclear Medicine, Clinica Universitaria of Navarra, Pamplona, Spain

Radioembolization (RE) is a new form of brachytherapy in which radiation is delivered by microspheres labeled with radioisotopes injected into the hepatic artery or its branches. Although anti-tumor effect results from preferential embedding of microspheres in tumor vasculature, non-tumoral parenchyma in targeted areas of the liver also receive a certain dose of radiation that might affect the growth of microscopic disease. Aim: to establish the efficacy of RE in preventing the growth of microscopic lesions in targeted areas, and evaluate possible factors influencing this effect. Patients and Methods: Patients with advanced HCC and preserved liver function were evaluated for RE using resin microspheres labeled with yttrium-90. Previous assessment included MRI or CT to detect extrahepatic disease and to measure liver and tumors volumes, and a hepatic angiogram with radiolabeled macroaggregates of albumin to identify shunt to distant organs and for activity calculation. Patients were followed every 3 months and received no further treatment until progression. RECIST criteria were used for evaluation of tumor response in targeted areas of the liver, where target tumor lesions and new lesions were evaluated separately. Results: Fifty-nine patients with HCC were evaluated for liver RE. Treatment was contraindicated in 19 (32%) mainly due to intense shunting to the lung or to a low efficiency in particle entrapment within the tumor nodules. Forty patients received 43 treatments. Mean age was 60 years (range: 39-75). CLIP scores were distributed as follows: 1 in 25%, 2 in 40%, 3 in 12% and 4 in 5%. Mean tumor volume was 787 mL. Lobar treatments were performed in 65% of cases. The median activity delivered was 2.00 GBq (range 0.75 to 3.25 GBq). A rough estimation of the median dose of radiation received by tumors and liver was 106 Gy (range: 22-1371) and 35 Gy (range: 6-1200), respectively. Mean follow-up was 643 days (range: 65-1314 days). At 3 and 6 months, disease control rates of target lesions were 97% and 94%, respectively. However, new lesions had appeared in the targeted area of the liver in 22% and 27% of the cases, respectively. Patients that developed new lesions did not receive a lower activity in GBq either absolute or relative to targeted liver volume or tumor involvement. One- and 2-y survival rates were 42% and 42% for CLIP-1, 37% and 12% for CLIP-2 and 15% and 0% for CLIP-3 patients, respectively. Conclusion: RE allows an effective control in the treated lesions in the vast majority of cases but did not prevent the emergence of new lesions in the targeted area. This suggests that microscopic lesions are not effectively treated by RE.

THE SIGNIFICANCE OF OSTEOPONTIN PROMOTER SNPS AT NT-155 AND FOXD3 AS HOST FACTORS TO REGULATE THE DEVELOPMENT OF HEPATOCELLULAR CARCINOMA IN FEMALE PATIENTS WITH HCV INFECTION

Kazuhiro Hamaoka1, Sumiko Nagoshi2, Kayoko Sugawara1, Mie Inao1, Kayoko Naiki1, Masayuki Naito1, Nobuaki Nakayama1, Kenji Fujiwara2, Satoshi Machida1; 1Division of Gastroenterology and Hepatology, Saitama Medical University, Moroyama-Machi, Japan; 2Yokohama Rosai Hospital for Labor Welfare Corporation, Yokohama, Japan

Osteopontin is a cytokine essential for the initiation of Th1 immunity. We identified 4 SNPs (nt-155, -433, -616, -1748) in promoter region of osteopontin gene, and demonstrated that SNP at nt -433 reflected hepatitis grading in chronic hepatitis C patients, while the other 3 SNPs showed linkage disequilibrium to each other. Also, osteopontin is shown to be an extracellular matrix promoting hepatocellular carcinoma (HCC) invasion. Thus, osteopontin promoter SNPs may affect the development of HCC. In the present paper, we tested this hypothesis. [Methods & Results] 1) Clinical examination: 291 patients with chronic liver disease due to HCV infection received ultrasound at 3 months intervals, and HCC was detected in 115 patients (Male 80, Female 35). Osteopontin promoter SNPs at nt -155 and -443 were determined by Invader assay using DNA from blood samples. Mean peripheral platelet levels (×104/mm3) at detection of HCC was less in female than in male (8 vs 11, p<0.05), but the levels in female were higher in those with deletion homozygotes at nt -155 and C/C or C/T at nt -443 than in those showing the other alleles (11 vs 7, p<0.05). 2) Promoter Assay: DNA samples were PCR-amplified between nt -1 and -658. There existed 3 haplotypes, and the alleles at nt -155 and -443 were deletion and C in haplotype-1, deletion and T in haplotype-2 and G and T in haplotype-3, respectively. Each cDNA was subjected to dual-luciferase reporter assay following transfection into HepG2 cells. Promoter activity was greater in haplotype-1 than in haplotype-2, and haplotype-3 cDNA showed minimal activities. 3) Gel-Shift Assay: The assay was performed using nuclear extracts from male HepG2 and female Hela cells. SRY, transfer factor encoded on Y-chromosome, were shown to bind to oligonucleotide around nt -155 irrespective the alleles, but FoxD3 can bind to such region only when the SNP showed deletion mutation. [Conclusion] HCC may develop in female showing deletion homozygotes at nt -155 and C/C or C/T at nt -443 even when progression of liver fibrosis was mild. Promoter activity was greater in case of cDNA showing such haplotype than in those with other haplotypes, and FoxD3 can promote translation by cDNA showing deletion mutation at nt -155 even in female cells. Thus, osteopontin promoter SNP at nt -155 may play a role in the development of HCC through interaction with FoxD3 especially in female patients with HCV infection.

Introduction: Cholangiocarcinoma (CCA) is the second most common primary liver tumor and its incidence is on the rise. The predictors of survival have not been well defined in patients with CCA. The aims of this study were to evaluate the predictors of survival in patients diagnosed with CCA. Methods: This is a case series of patients with CCA seen in our center from January 2003 to December 2006. CCA was diagnosed by cytology or histopathology. CCA was divided into extrahepatic (ECC) and intrahepatic (ICC). Laboratory and tumor data were obtained at diagnosis and tumor staging was performed according to TNM. Lifetime alcohol and tobacco exposure was quantified as > 1500 gram-years and > 20 pack years, respectively, based on review of the medical record. Kaplan-Meier and Cox regression were utilized for univariate and multivariate analysis, respectively. Results: A total of 123 patients were seen. The median age was 64 years and 70 (57%) were male. Only 15 patients had chronic liver disease (12 PSC and 3 HCV). The median CA 19-9 was 182 U/mL. A total of 55 (45%) had ECC and 68 (55%) had ICC. There was a median of 1 lesion with a median maximum tumor diameter of 6.2 cm, 54 (45%) had vascular involvement and 42 (34%) had extrahepatic metastases. At diagnosis there were 18 stage I, 18 stage II, 42 stage III and 45 stage IV. A total of 29 patients underwent surgical resection, 67 underwent chemotherapy, radiation or combination of these, and 27 did not undergo therapy. The median survival was 8.1 months with a 1-, 3- and 5-year probability of survival of 44%, 17% and 13%, respectively. The 1-year survival for those with stage 1 tumor was 70%. On univariate analysis, CA 19-9 > 100 U/mL, extrahepatic metastases, smoking, alcohol, TNM staging, undergoing therapy and total bilirubin > 1.5 ng/mL were significant predictors of mortality. No difference in survival was observed between patients with ICC and those with ECC. On multivariate analysis, the independent predictors of survival were undergoing therapy (0.44, 95%CI:0.26-.76), CA 19-9 > 100 U/mL (2.8, 95%CI:1.5-4.1) and smoking > 20 pack-years (2.3, 95%CI:1.4-3.7). Presence of underlying liver disease was not a significant factor. Conclusions: In this cohort of CCA patients, 70% had stage III or IV tumors at presentation and median survival was 8.1 months. Smoking, high CA19-9 and undergoing therapy were predictors of survival. Further studies should evaluate whether addition of these factors to tumor burden may improve the prognostic staging of patients with CCA.

PERSPECTIVE EVALUATION OF ABERRANT P16 METHYLATION IN SERUM OF PATIENTS BEFORE AND AFTER THERAPY FOR LOCALIZED HCC

Francesca Ferrara1,2, Francesca Lodato1, Pasquale Chieco2, Vilma Mantovani2, Antonio Colecchia1, Enrico Roda1, Stefano Brillanti1; 1Dept. of Internal Medicine & Gastroenterology, University of Bologna, Bologna, Italy; 2CRBA, Azienda Ospedaliero-Universitaria, Bologna, Italy

Hepatocellular carcinoma (HCC) is a frequent complication of liver cirrhosis and a leading cause of mortality worldwide. Localized HCC in cirrhotic patients may be safely treated with locoregional therapies, but early recurrence is frequent, probably due to dissemination. Aberrant methylation of the tumor suppressor gene p16 plays an important role in hepatocarcinogenesis, and may be detected in serum by methylation-specific PCR (MSP). In this study we evaluated the significance of serum p16 methylation in predicting early HCC recurrence after locoregional therapy. Methods: Twenty-five consecutive adult patients, with HCV-related liver cirrhosis and single HCC nodule < 5 cm in diameter with no macrovascular invasion, underwent percutaneous radiofrequency ablation (RFA) or trans-arterial chemoembolization (TACE). They were evaluated for the presence of p16 methylation in serum by MSP the day before HCC treatment and one month after RFA or TACE. Patients were prospectively followed for at least 24 months with abdominal CT scan, performed one month after therapy and every 3 months thereafter, to assess HCC recurrence. Results: p16 methylation was detected in sera of 8 out of 25 patients (32%) before RFA or TACE. One month after treatment, CT scan showed apparent complete ablation or no residual HCC activity in all of these patients. MSP showed disappearance of p16 methylation in 5/8 HCC patients. No evidence of HCC recurrence was found during follow up in these 5 patients. On the contrary, early recurrence of HCC occurred in the 3 patients who remained positive for p16 one month after therapy (2 RFA and 1 TACE). No correlation was found between p16 methylation and tumor response levels. Conclusions: Results of this pilot prospective study indicates that using MSP, aberrant p16 methylation may be found in one third of patients with localized liver HCC. Patients who achieve an apparent complete destruction of HCC and do not experience early HCC recurrence become negative for p16 methylation in serum one month after successful locoregional therapy. On the contrary, persistence of p16 methylation in serum predicts early recurrence of HCC, despite CT scan evidence of apparent successful treatment. Larger studies are warranted to confirm the clinical implications of our findings.

POLYMORPHISMS OF DNA REPAIR GENES XRCC3, ERCC5/XPG AND RISK OF HEPATOCELLULAR CARCINOMA IN KOREAN WITH CHRONIC HEPATITIS B INFECTION

Neung Hwa Park1, Bo Ryung Park1, Jung Woo Shin1, Seok Won Jung1, Chang Woo Nam2, Yang Won Na2, Jae Hee Seo2, Hyun Duk Shin4, Se Hwan Lee4, Danbi Lee4, Sung Eun Kim4, Jung A Kim4, Young-Hwa Chung1; 1Internal Medicine, Ulsan University Hospital, Ulsan, South Korea; 2Surgery, Ulsan University Hospital, University of Ulsan College of Medicine, Ulsan, South Korea; 3Pathology, Ulsan University Hospital, University of Ulsan College of Medicine, Ulsan, South Korea; 4Internal Medicine, Asan Medical Center, University of Ulsan College of Medicine, Seoul, South Korea

Backgrounds: DNA repair mechanisms are important for maintaining DNA integrity and preventing carcinogenesis. Genetic variations in DNA repair genes are thought to modulate DNA repair capacity and are suggested to be related to hepatocellular carcinoma (HCC) risk. Methods: We investigated the effects of the XRCC3 Thr241Met and ERCC5/XPG His1104Asp polymorphisms on the risk of developing HCC in a case-control study. The XRCC3 Thr241Met and ERCC5/XPG His1104Asp polymorphisms were assayed by PCR-RFLP method for 541 cases with HCC and 405 controls without HCC among hepatitis B virus (HBV) carriers. Allele frequencies of polymorphism were compared between patients with HCC and patients without HCC among HBsAg positives by logistic regression. Results: The observed genotype frequencies of polymorphisms in both cases and controls conformed to the Hardy-Weinberg equilibrium. The frequencies of the ERCC5/XPG His/His, His/Asp and Asp/Asp genotypes of among cases (21.6, 63.9 and 14.5%, respectively) were significantly different from those among controls (9.6, 74.6 and 15.8%, respectively; P<0.001). The ERCC5/XPG His/His genotype was more frequent in cases than in controls, whereas the His/Asp genotype was less frequent in cases than in controls (P<0.001 and P<0.001, respectively). With the adjustment for age and gender, the ERCC5/XPG His/His genotype was associated with a significantly increased risk of HCC (adjusted OR, 2.62; 95% CI, 1.75-3.91; P<0.001) with the combined His/Asp and Asp/Asp genotypes as the reference. However, the XRCC3/XPB Thr241Met genotype was not associated with HCC risk (adjusted OR, 1.24; 95% CI, 0.65-2.37; P=0.52). Conclusions: These results suggest that the ERCC5/XPG His1104Asp polymorphism contributes to genetic susceptibility to HCC, while XRCC3 Thr241Met polymorphism is not associated with HCC risk, in Korean patients with chronic HBV infection.

Background/Aims: The pathogenesis of frequent-intrahepatic recurrence of hepatocellular carcinoma (HCC) after locoregional therapies remains uncertain. Risks and patterns for intrahepatic distant recurrence (IDR) of single, primary HCC after radiofrequency (RF) ablation were examined. Methods: Ninety patients with a single primary HCC less than 3 cm who had complete RF ablation were enrolled the study. Risk factors for IDR and the patterns of IDR after RF ablation were analyzed. Results: The median follow-up was 37.4 months. IDR was observed in 44 (48.9%) patients. Univariate analysis revealed pretreatment serum α-fetoprotein (AFP) level ≥50 ng/ml (P = 0.0324), des-γ-carboxy prothrombin (DCP) level ≥40 mAu/ml (P = 0.006) and prothrombin time (PT) <70% (P = 0.0188) related to IDR. A multivariate stepwise Cox proportional hazards regression model revealed pretreatment serum AFP and DCP levels to be independent risk factors for IDR. The local tumor progression (P = 0.023) and serum DCP level ≥40 mAu/ml (P = 0.025) were related to multiple IDRs. Conclusions: HCC patients with high serum AFP or DCP before RF ablation should be carefully followed up to monitor any IDRs. Multiple IDRs frequently occur in patients with high DCP levels or local tumor progression making complete local control of HCC mandatory.

patients had perinatally-acquired HBV infection and none had received treatment for HBV. Nested PCR of the full HBx genome was performed on the sera of all cases and PCR products were sequenced to look for mutations. Nested PCR was similarly performed on tumor and non-tumor tissues of the HCC group and PCR products sequenced. Results: In the HCC group, 9/10 had mutations in HBx gene in the sera (6 were PCR negative) compared to 19/21 in the control group (11 were PCR negative), p=NS. The most common mutations in both groups were similar, ie HB6R and I127T. All tumor tissues (16/16) yielded mutations in the HBx gene compared to 13/16 in non-tumor tissues. Concordance of the signature HBx gene mutations between tumor and non-tumor tissues was 43.8% (7/16) and 12.5% (2/16) between sera and tumor tissues (p<0.05). Conclusions: HBx gene mutations are common in the serum of patients with chronic HBV infections with or without HCC. However, in patients with HCC, HBx gene mutations are more common in the liver tissues and further mutations may occur when they integrate into liver tissues, leading to development of HCC.

401 TRENDS IN THE INCIDENCE OF HEPATOCELLULAR CARCINOMA IN SINGAPORE 1968-2002
Mark L. Fernandes1, Yong Huak Chan2, Seng Gee Lim3; 1Gastroenterology and hepatology, National University Hospital, Singapore, Singapore; 2Biostatistics Unit, Faculty of Medicine, National University of Singapore, Singapore, Singapore

Background and Aims: To describe the trends in the incidence of hepatocellular carcinoma (HCC) in the three main ethnic groups in Singapore over the last 35 years and the prevalence of associated risk factors. Methods: The incidence of HCC was obtained from the Singapore Cancer Registry. Data on the prevalence and incidence of hepatitis B and hepatitis C was obtained from the Ministry of Health Singapore and the prevalence of other risk factors were obtained from published national population surveys. Results: Between 1968 and 2002, 2913 cases of HCC were registered by the Singapore Cancer Registry. The age standardized incidence (ASR) of HCC in the population fell by 58% in men and 47% in women from 1968-1972 to 1998-2002 from 17.1 to 7.1 per 100,000 men (p = 0.004) and from 2.8 to 1.5 per 100,000 women (p = 0.01). Amongst the three main ethnic groups, the incidence for HCC was highest in Chinese compared with Malays (p = 0.048) and Indians (p = 0.023). The overall prevalence of hepatitis B in Singapore fell from 9-10% in 1980-81 to 4% in 1999. The incidence of acute hepatitis C was 0.6 per 100,000 in 2005. The prevalence of regular alcohol consumption rose by 0.8% from 1976-77 to 1998. From 1976 to 2004 the prevalence of smoking dropped by 10%. The prevalence of obesity increased from 4.3% in 1982-85 to 6.9% in 2004 and the prevalence of diabetes mellitus rose from 2% in 1975 to 8.2% in 2004. Conclusions: There has been a significant decrease in the incidence of HCC in Singapore over the last 35 years associated with a decrease in the prevalence of hepatitis B in the population. This is likely to be due to the introduction of hepatitis B vaccination in Singapore in the early 1980’s and the compulsory vaccination of babies born to carrier mothers. The difference in the incidence between different racial groups is likely to be due to the differing prevalence of hepatitis B. The trends in other risk factors suggest that they are unlikely to have contributed significantly.

402 THE CHANGING EPIDEMIOLOGY AND ETIOLOGY OF HEPATOCELLULAR CARCINOMA FROM 1969 THROUGH 2006 IN ALASKA NATIVE PEOPLE
Marc Connelly1, Michael Bruce2, Nicholas Kassebaum2, Lisa Bulkow3, Mary Snowball4, Brian J. McMahon2,3; 1Department of Surgery, Alaska Native Medical Center, Anchorage, AK; 2Arctic Investigations Program, Centers for Disease Control and Prevention, Anchorage, AK; 4Liver Disease and Hepatitis Program, Alaska Native Tribal Health Consortium, Anchorage, AK

Alaska Native people have an increased rate of primary hepatocellular carcinoma (HCC) compared to the overall US population. Hepatitis B virus (HBV) has been identified as a major etiologic agent in Arctic Indigenous people. With the introduction of HBV immunization in 1982, as well as the emergence of hepatitis C virus (HCV) in this population, the epidemiology and etiology of HCC in Alaska may be changing. Methods: We reviewed all cases of viral and non-viral associated HCC in Alaska Native persons from 1969 through 2006. Using ICD-9 codes from the Alaska Native Medical Center, the Alaska Native Tumor Registry, and records from the Liver Disease and Hepatitis Program, all cases of HCC that occurred from 1969 through 2006 were identified and reviewed for demographic and clinical features and etiology. Etiology was categorized as viral (HBV, HCV) and non-viral. Incidence rates per 100,000 population were calculated for HCC overall and by etiologic category. Body mass index (BMI) was compared between non-viral and viral HCC cases. Results. Over the study period, 115 cases of HCC were identified in 110 persons. The age distribution for HCC was bimodal with peaks in the second and sixth decades of life (early peak due to HBV). The overall HCC rate was 3.63 per 100,000 and did not change significantly over the study period (p = 0.54). However, HCV-associated HCC increased from zero cases prior to 1985 to 23 since 1995, representing 30% of viral associated HCC (p = 0.01). The rates of HBV-associated HCC varied widely over time (1.26-3.79 per 100,000) but did not show a significant trend over the study period (p = 0.52). The age distribution of HBV-associated HCC demonstrated a shift towards presentation later in life. From 1969 to 1999, 29% of HBV associated HCC cases were under 20 years of age; after 2000, no cases were under age 20 (p = 0.028). Non-viral HCC rates ranged from 0.3 to 2.04 cases per 100,000 but demonstrated no significant trend over the study period (p = 0.90). Mean BMI was greater in non-viral HCC compared to viral HCC (38.8 vs 26.6, p = 0.002). Conclusions. HCC rates in Alaska Natives remained stable over the study period, but the epidemiology and etiology are changing. HCV has emerged as an important cause of HCC since 1995. Two decades after mass hepatitis B immunization, the HCC age distribution has shifted to cases presenting later in life. This is consistent with the presence of an aging HBV-infected population with few new chronically infected young persons entering the population. The significantly increased BMI in non-viral HCC cases compared to viral HCC cases suggests nonalcoholic fatty liver disease as a likely etiology.

PROGNOSTIC FACTORS AFFECTING 3 YEARS SURVIVAL IN PATIENTS WITH HEPATOCELLULAR CARCINOMA (HCC)

Massimo De Giorgio1,2, Stefano Vezzoli2, Riccardo Bezzo2, Maria Grazia Luca1, Giovanni Verga1, Stefano Okolicsanyi2, Maria Grazia Valsecchi2, Stefania Galimberti2, Michele Colladan1, Stefano Fagiuoli1, Mario Strazzabosco1,2

HCC is heterogeneous cancer with different risk factors, and response to therapy. Overall survival at 3 years is poor, but a subset of patients shows a survival, comparable to that achieved after liver transplantation. The ability to identify these patients would facilitate decision making and organ allocation. 

AIMS: To evaluate the influence of pre-treatment parameters on 3-year survival in a cohort of non-transplanted HCC patients.

METHODS: Out of 400 patients with HCC diagnosed according to the EASL criteria treated and prospectively followed-up at a single referral centre, we selected 228 consecutive patients that did not undergo liver transplantation and were either alive (group A, 91 pts) or dead (group B, 137 pts) three years after diagnosis. Patients were treated with: resection (26 pts in group A, 27 pts in group B), ablative treatments (49 in A and 28 patients in B), TACE (13 pts in A and 28 in B) while 3 patients in A and 55 in B remained untreated because of refusal of therapy, co-morbidities or advanced disease. Qualitative and quantitative variables were first analyzed with the χ² test qualitative or Wald test, respectively, and then with a logistic regression model (multivariate analysis, with stepwise method).

RESULTS: Median survival was 53.4 months (range: 36.2-105.2) in A and 10.7 months (range: 0-35.5) in B. At univariate analysis, ascites, encephalopathy, portal vein thrombosis, HCV, HBsAb/HBeAb, overall tumour burden, number of nodules, ALT, ALP, γGT, Bilirubin, Albumin, PT-INR, Hematocrit, AFP, MELD, Child Pugh, BCLC, TNM and CLIP were significantly different between A and B (p < 0.05). After multivariate analysis, tumor burden, OR:1.332, bilirubin(OR:3.053), portal vein thrombosis (OR:13.208) and HBsAb/HbcAb (OR:3.201) were significant independent predictors of survival. These were used to generate a logistic regression model able to predict the probability of death and survival 3 years after HCC diagnosis. The predictive ability expressed as the Area Under the Curve of the ROC Curve was 83.4%, showing a good accuracy of the model. Depending on the cut-off probability, sensitivity (survival shorter than 3 years correctly classified) of 90.91% and 1-specificity (survival longer than 3 years incorrectly classified) of 16.95% were reached.

CONCLUSION: Prognosis of patients with HCC can be predicted using a mathematical model factoring tumor burden, macrovascular invasion, liver function and previous contact with HBV as independent factors. The ability of the model to stratify patients according to their estimated prognosis three years after the diagnosis may be of help in decision making and organ allocation.

THE CLINICOPATHOLOGICAL AND PROGNOSTIC SIGNIFICANCE OF ALPHA-FETOPROTEIN EXPRESSION IN INTRAHEPATIC CHOLANGIOCARCINOMA. A POSSIBLE PROGENITOR CELL ORIGIN

Junpei Soeda, Takenari Nakata, Shiro Miwa, Shinichi Miyagawa; 1st. Department of Surgery, Shinshu University, Matsumoto, Japan

Recent studies suggest that some types of human cancers may arise from cancer stem cells. A hepatic progenitor cell which can differentiate into hepatocytes and biliary lineage, has also been suggested to give rise to hepatocellular carcinoma and combined hepatocellular-cholangiocarcinoma. Alpha-fetoprotein (AFP) has been shown to be expressed in liver cells and human progenitor cells and there are some cases of intra hepatic cholangiocarcinomas (ICCs) with seropositive for AFP. Aims: In this study, we investigated the expression of AFP in ICCs. Method: Expression of AFP was examined in 53 patients with ICC by double immunohistochemical and immunofluorescence staining using the antibody against AFP and cytokeratin (CK) 7 or 19 (biliary differentiation marker). The relationship between their positive or negative expression and clinicopathological variables including survival rate after initial hepatectomy was analyzed. Results: Fifty three cases were diagnosed pure ICC because of both morphological aspects, mucus production, and diffuse positivity for CK 7 or 19. Of 53 cases of ICCs, 9 (17.0%) were positive for AFP. In each case, some tumor cells were double positive for CK19 and AFP and showed oval cell like morphology (small size, high nuclear to cytoplasmatic ratio and an oval-shaped nucleus). There were no significant differences between expression of AFP and clinicopathological variables except for elevated serum AFP levels. Although there is no significant difference in survival rate between the patients with AFP positive cases and AFP negative cases, ICCs expressing AFP had a higher rate of recurrence (P = 0.012) after initial hepatectomy compared with AFP negative tumors. Conclusion: In our series, 17% of ICCs contained cells expressing AFP and these ICCs showed higher recurrence rate. Existence of AFP positive oval cell like cells suggests that AFP positive ICCs might originate from hepatic progenitor cells.

THE INTERACTIVE EFFECT OF PROGNOSTIC FACTORS AND PI-88 USE ON THE DELAY OF HEPATOCELLULAR CARCINOMA (HCC) RECURRENCE FOLLOWING CURATIVE PARTIAL HEPATIC RESECTION

James Garner, Justus Homburg; Progen Pharmaceuticals Limited, Brisbane, QLD, Australia

Purpose: Proposed indication for PI-88 is the prevention of cancer recurrence following partial hepatic resection in patients with HCC. PI-88 is a first-in-class mimetic of heparan sulfate (HS) which targets two biological processes critical to the growth & progression of solid tumors: angiogenesis & metastasis. It antagonizes HS interaction with angiogenic growth factors & inhibits cleavage of basement membrane by heparanase. Methods: Efficacy & safety of PI 88 as post-resection adjuvant therapy in pts with HCC was evaluated in a recently completed randomized Phase II study. The primary end point was tumor non-recurrence rate at 48 wks with disease-free survival forming a secondary endpoint. Tumor recurrence rate at 48 weeks was 50% in the control group, 63% in the PI-88 160 mg group & 41% in the PI-88 250 mg group. Time to
recurrence was 78% longer for the treated group than for controls (48 weeks vs. 27 weeks) at the 70th percentile. Literature supports the key prognostic factors affecting HCC recurrence following curative partial hepatic resection including tumor size, number of liver tumors, histopathological differentiation of the tumor, presence of microvascular invasion, & hepatitis serology. In an effort to further delineate the effect of PI-88 on pts with varying degree of HCC recurrence risk as determined by these prognostic factors, a stepwise cluster analysis was conducted for all trial control arm pts. Results: On the basis of this analysis, assessment of HCC recurrence risk for pts in the 160mg & 250mg arms was made, & subsequent Kaplan-Meier disease-free survival analysis was completed for those pts determined to have higher risk of HCC recurrence. Amongst the control arm pts for whom complete 48-week data was available, tumor size is the most powerful predictor of HCC recurrence. Those pts with a (primary) tumor of less than 2.5 cm are unlikely to recur within one year of curative partial hepatic resection, while those with tumors larger than or equal to 2.5 cm are much more likely to recur (approximately 10% versus 60%, respectively). On the basis of tumor size alone, it is possible to correctly predict recurrence in 69% of cases, up from the 43% 12-mth overall recurrence rate. By adding prognostic variables of microvascular invasion & hepatitis serology, it is possible to increase this overall predictive power. Conclusion: This study is consistent with literature on prognostic factors of HCC recurrence following curative partial hepatic resection. Furthermore, the data supports the conclusion that PI-88 has a significant effect on those pts that are likely to recur within 12-mths.

COPY NUMBER ANALYSIS OF HEPATOCELLULAR CARCINOMA USING TEN GENES DERIVED FROM GENECHIP DATA SET OF HEPATOMA CELL LINES

Yasuo Tanaka1,2, Fumihiko Kanaï1,2, Motohisa Tada1,1, Ryosuke Tateishi1, Shuichiro Shina1, Haruhiko Kobashi1, Takao Kawabe1, Osamu Yokosuka4, Seishi Ogawa1, Masao Omata1; 1Department of Clinical Drug Evaluation, University of Tokyo Hospital, Tokyo, Japan; 2Department of Gastroenterology, University of Tokyo, Tokyo, Japan; 3Department of Clinical Drug Evaluation, University of Tokyo Hospital, Tokyo, Japan; 4Department of Regeneration Medicine for Hematopoiesis, University of Tokyo, Tokyo, Japan; 5Department of Medicine and Clinical Oncology, Chiba University, Chiba, Japan

Background/Aim: Hepatocellular carcinoma (HCC) is one of the leading causes of cancer deaths worldwide, and chromosomal copy number alterations could result in aberrant oncogenes activation and tumor suppressor genes inactivation in HCC. In this study, we analyzed 17 hepatoma cell lines for areas of DNA copy number changes (gain, amplification and deletion) and LOH through genome-wide analysis with Affymetrix GeneChip Human Mapping 50 K Set. Moreover, we investigated the copy number of genes that we have chosen from GeneChip data of hepatoma cell lines in HCC clinical samples, and analyzed the association with clinicopathological parameters. Materials/Methods; We analyzed 17 hepatoma cell lines (PLC/PRF/5, Huh-1, Huh-6, Huh-7, HepG2, HepSB, HLE, HLF, SK-Hep-1, JHH-1, JHH-4, JHH-7, SNU398, SNU449, HT17, SSP-25 and RBE) with GeneChip and Copy Number Analyzer for GeneChip (CNAG) (Nannya et al. Cancer Res. 2003) for data analysis. We selected one gene each from highly amplified regions in at least two cell lines, and analyzed copy number of 70 formalin-fixed paraffin-embedded HCC samples using quantitative real-time PCR. Results; Ten high grade amplification regions (n > 4) within 3 Mbp were detected in at least two cell lines, and the size of minimal common amplified region was 129 Kbp. Nineteen homozygous deletion regions were identified in at least one cell line, and the size of minimal deletion was 13 Kbp. Furthermore, LOH at chromosome 4q, 8p, 9p and 13q was observed with high frequency. In regards to clinical samples, copy number was almost normal in liver cirrhosis, and frequently amplified in Edmondson grade II (Ed II) HCC compared with Ed I HCC. Logistic Regression revealed that Gene 1 in 8q22.3 [Ed/I/II 8.3%/39.1%] and Gene 2 in 14q12 [Ed/I/II 4.2%/21.7%] were significantly amplified in Ed II HCC (p<0.05). Multivariate analysis using stepwise variable selection showed that gain of Gene 1 appeared to be associated with HCC recurrence. Conclusion; GeneChip and CNAG enabled us to narrow down the region of copy number changes in hepatoma cell lines. Gain of Gene 1 and 2 were associated with malignant phenotypes of HCC, and gain of Gene 1 might be predictive for recurrence free survival in HCC patients.

PRETRANSPLANT CHEMOEMBOLIZATION FOR HEPATOCELLULAR CARCINOMA ≤ 3 CM DOES NOT INFLUENCE THE OUTCOME AFTER LIVER TRANSPLANTATION

Mohamed Amer, Mohammed Yousri, Fatma Barakat, Yehia Naga, Fatma Barakat, Yoko Kono, Lisa M. Richards, Elliot Alpert, Claude B. Sirlin, Rose Steven, Marquis Hart, Ajai Khanna, Tarek Hassenin; University of California, San Diego, San Diego, CA

Liver transplantation (OLT) is the favored option of therapy for patients with hepatocellular carcinoma (HCC) who fulfill Milan criteria. Transarterial chemoembolization (TACE) is one of the most widely used treatments for HCC patients awaiting liver transplantation to prevent tumor growth. Aim: To evaluate the impact of pre-transplant TACE in patients with tumor size ≤3 cm on the outcome after liver transplantation regarding HCC recurrence and patient survival. Methods: The explants of 66 consecutive patients with HCC who were transplanted between 2001 and 2007 were reviewed. 15 patients had HCC > 3 cm while 51 patients had HCC ≤3 cm. Patients with HCC of ≤3 cm are the subjects of this analysis. Patients were divided into Group A (n=30) who received TACE pre-OLT and Group B (n=21) who did not receive TACE. Patient charts were reviewed and data was collected. Results: The mean age was 55.2 ± 6.9 and 86% were male. 49% were Caucasian, 43% Hispanic and 8% other. 84% had Hepatitis C Virus, with no significant difference between both groups in terms of etiology of liver disease (p=0.64). Patients in group B had higher MELD score than patients in group A (16.8 ± 5.3 and 12.4 ± 5.2, respectively; p<0.01); 39% of Group B patients had a Child Pugh class C versus 11% of Group A patients (p=0.03). Examining the liver explant showed that there were no differences between both groups in tumor characteristics (Table). 30% of patients in group A who received TACE had complete tumor necrosis. 27% of patients in group A had poorly or moderately differentiated tumor versus 57% in group B (p=0.75). The median duration between diagnosis of HCC and liver transplantation was 146 (8-1313) days with no significant difference between both groups (p=0.44). The median post liver transplant follow-up was 16 (1-54) months for both groups (p=0.87). There was no statistical significant difference between both groups in terms of HCC recurrence or survival. 1 patient in each group had recurrence (p=0.79). 24 (80%) of patients in group A versus 17
408 BILARY INSULIN LIKE GROWTH FACTOR-1 (IGF1) IS A SENSITIVE MARKER FOR THE DIAGNOSIS OF EXTRA-HEPATIC CHOLANGIOCARCINOMA

Domenico Alvaro1, Gianpiero Macari2, Maria Grazia Mancino3, Marco Marzioni2, Maria Consiglia Bragazzi1, Paolo Onori3, Stefano Ginanni-Corradini1, Pietro Invernizzi1, Antonio Franchitto1, Eugenia Gaudio1, Antonio Benedetti2; 1Clinical Medicine, University of Rome “La Sapienza”, Rome, Italy; 2Dept. of Gastroenterology, Polytechnic University of Ancona, Ancona, Italy; 3Dept. of Experimental Medicine, State University of L’Aquila, L’Aquila, Italy; 4Division of Internal Medicine, University of Milan, Milan, Italy

Cholangiocarcinoma is a malignant tumour with an incidence and mortality progressively increasing worldwide and, characterized by poor prognosis and scarce response to current therapies. Unfortunately, diagnostic markers for an early diagnosis are virtually lacking. Human and experimental studies showed that cholangiocarcinoma cells express and secrete IGF1 and VEGF (vascular endothelial growth factor). Our aim was to measure IGF1 and VEGF in bile and serum of patients with extrahepatic cholangiocarcinoma and to evaluate their performance as diagnostic markers. Bile samples were collected from 73 patients consecutively submitted to endoscopic retrograde cholangiopancreatography (ERCP) including extrahepatic cholangiocarcinoma (n=29), pancreatic cancer (n=19) and benign biliary pathologies (n=25; bile duct stones (n=16), primary sclerosing cholangitis (n=8), cholangitis (n=1)).

Definitive diagnosis was based on conventional radiology, ERCP and follow-up. IGF1 and VEGF were measured by ELISA, biliary bile salt by 3α-hydroxysteroid dehydrogenase. Biliary IGF1 concentration was 15-20-fold higher (p<0.00001) in extrahepatic cholangiocarcinoma than in pancreatic cancer or benign biliary pathologies, the latter two groups showing similar results. By using ROC analysis and an optimized cut-off point, biliary IGF1 concentration higher than 114 ng/ml showed, as a single marker, a sensitivity and specificity equal to 1 (100%) in the diagnosis of extrahepatic cholangiocarcinoma with respect to either pancreatic cancer or benign biliary pathologies. Biliary VEGF concentration, in contrast, was similar between cholangiocarcinoma, pancreatic cancer and benign biliary pathologies. The serum levels of IGF1 were similar while, serum levels of VEGF were significantly higher (p<0.05) in cholangiocarcinoma and pancreatic cancer with respect to benign biliary pathologies. In conclusion, we demonstrated that the determination of biliary IGF1 concentration in patients submitted to ERCP for biliary obstruction definitively differentiates extrahepatic cholangiocarcinoma from either pancreatic cancer or benign biliary pathologies, suggesting a role in the clinical work-up.

(81%) in group B had disease free survival (p=0.93) during the follow-up period post OLT. Conclusion: Pre-OLT TACE of <3 cm tumor size does not influence rate of recurrence of HCC or survival post-OLT in patient fulfilled the Milan Criteria.

409 RADIOFREQUENCY ABLATION FOR HEPATOCELLULAR CARCINOMA AND INTRATUMORAL PRESSURE

Chiaki Kawamoto, Atsushi Yamashita, Yoko Baba, Koji Yakabi; Department of Gastroenterology and Hepatology, Saitama Medical Center, Saitama Medical University, Kawagoe-shi, Japan

[Background and Aims] Radiofrequency ablation (RFA) is considered to be a less invasive therapeutic technique for hepatocellular carcinoma (HCC). However, sporadic cases of unexpected recurrence, such as intrahepatic dissemination, peritoneal dissemination and extrahepatic metastasis, have been described. Some of these types of recurrences might be caused by increased intratumoral pressure. We therefore examined basic and clinical studies on the association between RFA and intratumoral pressure. [Subjects and Methods] A Basic study: Under general anesthesia, laparotomy was performed on 19 pigs and a 20-mm LeVeen needle electrode was inserted into the liver for RFA. Intrahepatic pressure was monitored by placing a 21-G percutaneous ethanol injection therapy (PEIT) needle near the LeVeen needle and using an invasive blood pressure monitor. RFA was performed as follows: 1) Single-step method (standard ablation); After fully deploying the electrode, the power was initially applied at 30 W, then increased in increments of 10 W/min until power roll-off. 2) Multi-step method; The array was gradually deployed in 8 steps. At each step, the power was fixed at 30 W until power roll-off. B. Clinical study: Subjects were 32 patients with HCC. Mean tumor size was 14.7±1.1 mm. Under local anaesthesia, after inserting a 20-mm LeVeen needle percutaneously into the liver, a 21-G PEIT needle was placed near the LeVeen needle, and intratumoral pressure was monitored using an invasive blood pressure monitor. Based on the results of the basic study, RFA was performed using the multi-step method (30 W 8-step deployment). CT was performed postoperatively to ensure that ablation was performed sufficiently. [Results] A. Basic study: Mean time to reach power roll-off and hepatic parenchymal pressure were 163.1±40.4 s and 154±30.9 mmHg for the single-step method and 116.4±30.8 s and 24.1±18.2 mmHg for the multi-step method, respectively. Maximum diameter of ablated area for the single- and multi-step methods was 25.1±5 and 23.0±2.8 mm, respectively. B. Clinical study: Mean time for roll-off was 372.7±175.8 s and mean increase in intratumoral pressure was 39.1±28.7 mmHg. Postoperative CT showed that all HCCs were sufficiently ablated. Also, with the multi-step method, pain could be alleviated during treatment. [Conclusions] With the single-step method, hepatic parenchymal pressure rapidly increased just before power roll-off. Conversely, the multi-step method allowed suppression of increases in intrahepatic pressure in both basic and clinical studies. Because the patients did not experience much pain during RFA, the multi-step method should be used for RFA.

410 TREATMENT OF RECURRENT HEPATOCELLULAR CARCINOMA AFTER CURATIVE RADIOFREQUENCY ABLATION

Ryosuke Tateishi1, Shuichiro Shinya1, Takamasa Ohki1, Takahisa Sato1, Ryota Masuzaki1, Jun Imamura2,1, Noriyo Yamashiki1, Tadashi Goto1, Hideo Yoshida1, Shuntaro Obi2,1, Haruhiko Kobashi1, Masao Omata1; 1Department of Gastroenterology, University of Tokyo, Tokyo, Japan; 2Department of Hepatology, Kyouda Hospital, Tokyo, Japan

BACKGROUND: Radiofrequency ablation (RFA) is widely applied as an initial treatment for unresectable hepatocellular carcinoma (HCC). AIMS: To elucidate the characteristics of recurrence after curative RFA, treatment modalities for recurrence and the prognosis. METHODS: We treated 667 naïve patients with HCC by RFA between 1999 and 2004. Patients were followed up according to our follow-up strategy after RFA with dynamic CT/MRI and tumor markers (alphafetoprotein, des-gamma-carboxy prothrombin and AFP-L3 fraction) every 4 months. Tumor recurrence was identified in 423 patients during the follow-up period until December 31, 2005. We enrolled 420 patients of them excluding 3 in whom recurrence was identified at other institutes to assess the following variables at the diagnosis of the recurrence: the size and number of recurrent nodules, presence of extrahepatic metastasis and portal venous invasion, and treatment modalities for recurrence. Survival analysis was performed according to the Kaplan Meier methods by following up patients until the end of 2006. Univariate and multivariate Cox proportional hazard model was applied to assess the risk factors for survival. Age, gender, the size and number of original and recurrent nodules, tumor markers at recurrence, etiology of background liver diseases and Child-Pugh class were adopted for the analysis. RESULTS: There were 264 men and 156 women, with a median age at recurrence, 70 years (range, 44-91). HCV antibody was positive in 343 and HBs antigen was positive in 47. Mean ± SD of Child-Pugh score was 6.3 ± 1.3, which increased by 0.3 as compared with that at initial treatment. Size of nodules at recurrence were < 2 cm in 268, 2.1-3 cm in 108, 3.1-5 cm in 36 and > 5 cm in 7. Extrahepatic metastasis and portal venous invasion were identified in 112 (2.6%) and 92 (2.1%) respectively. Patients were treated by RFA in 371 (88%), TACE in 49, radiotherapy in 4, systemic chemotherapy in 3, arterial infusion chemotherapy in 2, resection in 3 and best supportive care in 5 (including overlap). Cumulative survival rates at 1, 3 and 5 years after recurrence were 90.3%, 62.9% and 36.3%, respectively. Multivariate analysis with Cox proportional hazard model revealed that size of original tumor, number of recurrent nodules, presence of extrahepatic metastasis and portal venous invasion were independent risk factors for poor prognosis. Conclusion: Our strategy could identify recurrent nodules small in size and RFA was indicated 88% of patients. The change in liver function was minimal and unfavorable mode of recurrence was rare. RFA can be the first choice for recurrent HCC as well as naïve HCC.

411 POLYMORPHISM OF INTERLEUKIN-18 IS A RISK FACTOR FOR THE CLEARANCE OF HEPATITIS B VIRUS INFECTION AND HEPATOCELLULAR CARCINOMA DEVELOPMENT

Jaeyoun Cheong1,2, Sungwon Cho1,2; 1Gastroenterology, Ajou University School of Medicine, Suwon, South Korea; 2Ajou Genome Research Center, Suwon, South Korea

Background/Aim: The outcomes of hepatitis B virus (HBV) infection are probably related to host immune factors. Interleukin-18 (IL-18) plays significant roles in immune defense. This study was undertaken to investigate the association between persistence of HBV infection or HCC occurrence and single nucleotide polymorphisms (SNPs) of IL-18 gene. Methods: Between March 2002 and December 2002, a total of 1,050 Korean patients were enrolled in three different groups; 'HBV clearance (n=320)' and 'chronic hepatitis (CH) / liver cirrhosis (LC) (n=637)' and 'hepatocellular carcinoma (n=93)'. We assessed polymorphisms at four polymorphic sites in IL-18 gene at position -9731G>T, -9212G>C, -140G>C, +4861A>C in subject studies. Results: IL-18 -9212C allele (OR = 0.25, P = 0.01), -140G allele (OR = 0.36, P = 0.02) and +4861C allele (OR = 0.25, P = 0.01) were significantly associated with HBV clearance in a recessive model. Additionally, IL-18 -9212G allele (OR = 2.18, P = 0.01) and 'dominant model, OR = 2.11, P = 0.03 in dominant model), -140C allele (OR = 1.97, P = 0.03 in dominant model, OR = 1.98, P = 0.04 in dominant model) and +4861A allele (OR = 1.91, P = 0.04 in co-dominant model) showed susceptible effect on the HCC development. Conclusions: This study suggested that SNPs at various sites of IL-18 gene were associated with HBV clearance and HCC occurrence.

412 LONG TERM RESULTS OF RFA VS SURGICAL RESECTION FOR HCC IN PATIENTS WITH WELL PRESERVED LIVER FUNCTION

Chang-Min Cho, Hyun-Cheol Lee, Min-Kyu Jung, Seong-Woo Jeon, Won-Young Tak, Young-Oh Kweon; Internal Medicine, Kyungpook National University Hospital, Daegu, South Korea

Background/Aims: Surgical resection is considered optimal for potential treatment of hepatocellular carcinoma (HCC). However, only 20% of HCCs can be resectable due to the severity of cirrhosis or the multiple nodules. Radiofrequency ablation (RFA) has recently shown comparable results to surgical resection for the treatment of HCC. We compared the clinical results between surgical resection and RFA. Methods: From January 2000 to December 2002, 116 patients who had Child-Pugh class A and underwent surgical resection (n=61) or RFA (n=99) for HCC (single nodule < 5 cm in diameter, or less than 3 nodules with < 3 cm in diameter) were analyzed retrospectively. We compared the survival rates, the recurrence rates and the complication rates between two groups. Results: In Surgical resection group, the local and distant recurrence rates were 11.5% and 42.6%. Recurrence free survival rates at 1, 3 and 5-year were 73.1%, 45.1% and 39.2%, respectively and overall cumulative survival rates were 98.3%, 83.4% and 75.1%. In RFA group, the local and distant recurrence rates were 19.2% and 39.4%. Recurrence free survival rates at 1, 3 and 5-year were 72.4%, 40.4% and 33.7%, respectively and overall cumulative survival rates were 95.8%, 78.3% and 73.1%. There were no significant differences in the overall and
recurrence free survival rates between two groups (p=0.77 and p=0.58). The incidence of complication was similar between the two groups. Conclusions: RFA shows comparable results to surgical resection for the treatment of HCC and may be considered as an alternative to surgical resection for the treatment of HCC.

A PROPOSAL OF NOVEL TREATMENT-ASSIST TECHNIQUE IN THE SONAZOID-ENHANCED ULTRASONOGRAPHY: VALUE OF DEFECT RE-PERFUSION IMAGING

Masatoshi Kudo, Kinuyo Hatanaka, Yasunori Minami, Hiroshi Tei, Kiyoshi Maekawa; Dept. Gastroenterology and Hepatology, Kinki University School of Medicine, Osaka, Japan

Background and Aim: Sonazoid (GE Healthcare) is a second generation ultrasound contrast agent, that has been approved for routine clinical use on January 10, 2007. Sonazoid-enhanced harmonic imaging (Sonazoid CEUS) provides extremely superb real-time vascular imaging as well as Kupffer imaging at 10 min. after intravenous injection of 0.015 mL/kg of Sonazoid. The local ablation therapy such as radiofrequency ablation (RFA) for hepatocellular carcinoma (HCC) is usually performed by ultrasound (US) guidance. However, RFA for sonography ill-defined HCC nodules or local recurring nodules after RFA is extremely difficult because of the difficulty of identification of the nodule on B-mode US. Aim of this study is to clarify the usefulness of newly innovated contrast US technique, “Defect Re-perfusion Imaging” by using Sonazoid re-injection method at the post-vascular (Kupffer) phase. Materials and Methods: From January to May, 2007, there were a total of 10 sonography ill-defined HCC nodules, all of which were not identified by B-mode US. A total of 0.015 mL/kg of Sonazoid were injected and Kupffer image was obtained at 10-20 min. after injection. Typical HCC nodules should show Kupffer defect since typical HCC has no Kupffer cells. Therefore, when defect area was observed at the post-vascular phase, 0.015 mL/kg of Sonazoid was re-injected and whether or not arterial flow is present within the Kupffer cell defective portion. Results: In all of 10 sonography ill-defined HCC nodules, positive enhancement was obtained within the Kupffer cell defective portion by Sonazoid re-injection, thereby, the diagnosis and localization of HCC was possible. Subsequently, RFA was successfully performed in all of 10 sonography ill-defined HCC nodules. Conclusion: Defect Re-perfusion Imaging is an extremely useful method to diagnose and identify the sonography ill-defined HCCs, which facilitates easy and correct insertion of RFA needle inside the HCC nodules, which were not possible by any other modalities before this technique was innovated.

DISCOVER A NEW BIOMARKER FOR EARLY DETECTION OF HEPATOCELLULAR CARCINOMA USING MALDI-TOF MS AND CLINPROTOOLS

Yang Liu1, Masahiko Sunaga2,3, Kazuyuki Sagawa2,3, Mamoru Satah2,3, Hiroshi Umemura2, Masaharu Yoshikawa1, Osamu Yokosuka1, Takeshi Tomonaga2, Fumio Nomura2; 1Department of Medicine and Clinical Oncology, Graduate School of Medicine Chiba University, Chiba city, Japan; 2Department of Molecular Diagnosis, Graduate School of Medicine Chiba University, Chiba, Japan; 3Clinical Proteomics, Chiba university Hospital, Chiba city, Japan

Objectives: Detection of HCC at early stage is often difficult in chronic hepatitis C patients especially in cirrhosis. Once the diagnosis of HCC established, the overall 5-year survival rate remains less than 5%. The poor prognosis of HCC due to that the disease frequently diagnosed at an advanced stage, when the disease is too far for effective treatment. In order to reduce HCC mortality, early identification of hepatocellular carcinoma from is needed. MALDI-TOF (matrix assisted laser desorption/ionization time-of-flight) is a proteomic technique that enables the profiling of proteins present in any biological material. We used this approach to identify new biomarkers of hepatocellular carcinoma (HCC) in the sera of patients with HCV-associated cirrhosis. Patients and Method: Serum samples (5 uL) from the 16 of HCV-associated cirrhosis patients with hepatocellular carcinoma and the 15 of HCV-associated cirrhosis patients without HCC were prefractionated using magnetic Magnetic Beads based Weak Cation Exchange Chromatography resins (Bruker Daltonics, Germany) by ClinProTools automatic machine according to recommendatory protocol. We analyzed each spectrum obtained from MALDI-TOFMS with flexAnalysis™ software in automatic mode and ClinProTools(the data interpretation software of the mass spectrometry-based ClinProt solutions for biomarker analysis), the former to detect the peak intensities of interest and the latter to compare the peaks across the spectra obtained from all samples. The inter- and intra- reproducibility (IMAC Cu beads) assay of the MALDI spectra was subjected. Result After MALDI-TOF MS spectra and flexAnalysis™ analysis, there were 23 peaks increased 25 peaks decreased in group of HCV-associ- ciated cirrhosis with HCC. The representative spectra of peptide, it was of note that an 8568 Da peak, significantly increased in HCC group. 8568 Da peak increased in 11 samples in group of HCC in the context of HVC-related liver cirrhosis, on contrast, there are only 3 samples increased in group of HCV-associated cirrhosis without HCC. ClinProTools was used to check the difference between two groups of 8568 Da, the result of P values is: 1.08e-006. After purified on-chip, and cut out of gel followed trypsin digested, the peptide was identified by LC MS/MS, and confirmed that there is a significant difference indeed in LC and HCC groups by western blotting. We observed no associated level with AFP or PIVKAII and tumor size. Conclusion: These results demonstrated a novel approach to discover a new biomarker for early detection of hepatocellular carcinoma using MALDI-TOF MS and ClinProTools.

415 GENETIC POLYMORPHISMS ASSOCIATED WITH CLEARANCE OF HEPATITIS B VIRUS INFECTION AND HEPATOCELLULAR CARCINOMA OCCURRENCE DETECTED BY SNP CHIPS

Jaeyoun Cheong1, KyuBum Kwack2, SeungKu Lee2, Jason J Kang3, Sungwon Cho4; 1Gastroenterology, Ajou University School of Medicine, Suwon, South Korea; 2Pochon CHA University, Seongnam, South Korea; 3Department of Internal Medicine, Ajou University School of Medicine, Suwon, South Korea; 4Department of Internal Medicine, Ajou University School of Medicine, Suwon, South Korea

Hepatitis B virus infection (HBV) associated chronic liver disease (CLD) and hepatocellular carcinoma (HCC) are major causes of death in HBV endemic areas. Expression of collagens is related progression and suppression in CLD and/or HCC. We investigated whether polymorphisms of collagen type III, alpha 1 (COL3A1) associated with genetic susceptibility of CLD and HCC. Three hundred and forty-two patients (230 CLD, 112 HCC) and 117 healthy controls were performed association study using Illumina’s SNP chip by allele specific extension method. Selected polymorphisms and haplotypes were analyzed by logistic regression controlling age and gender as covariables. In statistic analysis, SNP CHA-1 was high significantly association with control verse CLD, control verse HCC, and control verse CLD with HCC in allelic model, codominant, dominant (p=0.01 to 0.002). Haplotype 1 (ht1), ht 2, and ht 5 significant associated with to control verse CLD (p=0.021, p=0.030 p=0.0037, respectively), control vs HCC (ht 1: p=0.046), and control verse CLD with HCC (ht 1: p=0.013 and ht 5: p=0.046). In conclusion, we showed that SNP CHA-1 polymorphism and ht1 may increase the clearance of HBV infection, whereas ht2, ht5 may increase the susceptibility to disease progression, by using SNP chip analysis.

416 LIVER TRANSPLANTATION IN PATIENTS WITH HEPATOCELLULAR CARCINOMA ACROSS MILAN CRITERIA

I Ignacio Herrero1, Mercedes Inarraiaegui1, Bruno Sangro1, Fernando Pardo2, Jorge Quiroga1, Felix Alegre1, Fernando Rotellar2, Custodia Montiel2, Jesus Prieto1; 1Department of Medicine, Liver Unit, Universidad de Navarra, School of Medicine, Pamplona, Spain; 2Department of Surgery, Clinica Universitaria, Pamplona, Spain

Milan criteria are the most frequently used limits for liver transplantation (LT) in patients with hepatocellular carcinoma (HCC), but our previous experience with expanded criteria showed encouraging results. Aim: To investigate whether our expanded (CUN) criteria (one nodule up to 6 centimeters or 2-3 nodules up to 5 centimeters each) could be used to select patients with HCC for LT. Patients and methods. Eighty-five patients with HCC fulfilling CUN criteria were included as candidates for LT. We were excluded of the waiting list if they exceeded CUN criteria. Survival and recurrence rates were compared according to tumor staging. Results: Twenty-six out of 85 (30%) patients exceeded Milan criteria. Twelve patients had tumor progression on the waiting list. Four patients (7%) fulfilling Milan criteria and 8 patients (30%) exceeding them progressed exceeding CUN criteria (p=0.001). One, 3-, 5-, 7- and 10-year survival rates of the 73 transplanted HCC patients were 86%, 74%, 70%, 61% and 50%, respectively. According to radiological staging, 47 patients were within Milan criteria at the moment of transplantation and 26 (35%) exceeded them, but were within CUN criteria. Tumor recurrence and survival rates were similar for patients fulfilling Milan and CUN criteria. Tumor recurrence rates were significantly higher in patients whose pathological staging exceeded CUN criteria. Conclusion: CUN criteria (one nodule up to 6 centimeters or 2-3 nodules up to 5 centimeters each) increases the number of HCC patients who could benefit from LT, without worsening the results.

417 REGULATION OF THE NKG2D IMMUNORECEPTOR BY SOLUBLE MICA DURING TRANSCATHETER ARTERIAL EMBOLIZATION FOR HEPATOCELLULAR CARCINOMA

Keisuke Kohga1, Tetsuo Takehara1, Hayato Hikita1, Akira Sasakiwa1, Akio Uemura1, Ryotaro Sakamori1, Shinjiro Yamauchi1, Tomohide Tatsum1, Kazuyoshi Okawa1, Tatsuya Kanto1, Naoki Hiramatsu1, Kazuhiro Katayama1, Michio Kato1, Norio Hayashi1; 1Department of Gastroenterology and Hepatology, Osaka University Graduate School of Medicine, Suita, Japan; 2Department of Gastroenterology and Hepatology, Osaka Koseinenkin Hospital, Osaka, Japan; 3Department of Gastroenterology and Hepatology, Osaka National Hospital, Osaka, Japan

Background & Aim: The immunoreceptor NKG2D is an activating molecules expressed on natural killer cells. MHC classI-related chain A (MICA) is the ligand of NKG2D and is over-expressed in injured cells or transformed cells. Recent studies indicate that MICA could be released as its soluble form (sMICA) from those cells and capable of downregulating NKG2D expression, leading to the attenuation of innate immune response to potentially malignant cells. Although sMICA has been shown to increase in sera of some cancer patients, the presence and significance of sMICA in liver diseases are not fully established. The present study examined soluble MICA in chronic liver disease and hepatocellular carcinoma (HCC) and their involvement in the immune cell expression of NKG2D during transcatheter arterial embolization (TAE) for HCC. Patients & Method: Serum levels of sMICA was differentially determined by ELISA from 581 individuals including 104 healthy volunteers (HV), 141 patients with chronic hepatitis (CH), 104 patients with cirrhosis (LC), and 232 patients with hepatocellular carcinoma (HCC). Peripheral blood mononuclear cells (PBMC) were collected before and 2 weeks after TAE therapy from 38 patients with HCC. Twenty-one untreated patients with HCC, matching the TAE group with respect to TNM stage and Child-Pugh stage were also enrolled as controls. NKG2D expression on NK cells and CD8-positive T cells were analyzed by flow cytometry, whereas sMICA was also evaluated by ELISA simontaneously. Difference between pretreatment and post-treatment values were tested by paired t test. Result: Levels of sMICA differed statistically (p<0.01) among each 4 groups (HV: median=50 pg/ml, CH: median 342 pg/ml, LC: median 586 pg/ml, HCC: median 648 pg/ml). The elevation of sMICA level was observed associated with the progression of fibrosis. In LC, significant correlation was observed between the Child-Pugh classification and the level of sMICA. In HCC the progression of liver disease and that of the tumor were independent determinants for sMICA level. The TAE therapy significantly decreased serum levels of soluble MICA, and increased the NKG2D expression on NK cells and CD8-positive T cells; there was an inverse correlation between changes in soluble MICA levels and in NKG2D expression. Conclusion: Although sMICA are produced from both HCC and premalignant cirrhotic livers, therapeutic intervention for HCC can reduce the levels of sMICA and thereby upregulate the expression of NKG2D. Cancer therapy may
have a beneficial effect on the NKG2D-mediated anti-tumor immunity.

HIGHER EXPRESSION OF MICROSMAL PROSTAGLANDIN E SYNTHASE-1 IN NON-TUMOROUS LIVER TISSUES ASSOCIATES WITH SHORTER RECURRENCE-FREE SURVIVAL OF PATIENTS WITH HEPATOCELLULAR CARCINOMA

Hikaru Fujioka, Koichi Nonaka, Atsumasa Komori, Seigo Abiru, Shinya Onizuka, Kiyoshi Migita, Masahiro Ito, Hiroshi Yatsuhashi, Hiromi Ishibashi; Clinical Reserach Center, NHO Nagasaki Medical Center, Omura, Nagasaki, Japan

Microsomal prostaglandin E synthase-1 (mPGES-1) is the terminal enzyme for the production of prostaglandin E2 from cyclooxygenase-derived prostaglandin H2. Microsomal PGES-1 is linked to the conditions that result in high PGES biosynthesis, which has been reported to be associated with various types of cancer. However, little is known about the prognostic value of mPGES-1 in non-tumor liver tissues after curative hepatectomy for HCC patients. We examined the expression of mPGES-1 protein by immunohistochemistry in 64 patients with HCCs who were underwent curative hepatectomy. Samples from seven histologically normal liver tissues were also examined. The level of mPGES-1 expression was higher in the hepatitic or cirrhotic liver tissues than in the normal liver tissues and the cirrhotic livers expressed more mPGES-1 than hepatitic livers (p < 0.05). All differentiated types of HCC expressed mPGES-1. Although there was no correlation between the mPGES-1 expression in HCC tumor tissues and prognosis, a close correlation was found between the mPGES-1 expression in non-tumor liver tissues and the shorter disease-free survival of the HCC patients (p < 0.01). Moreover, higher mPGES-1 expression in non-tumor liver tissues was associated with the presence of active inflammation (p < 0.05). In conclusion, the mPGES-1 expression in non-tumor tissues may play an important role in early recurrence of HCC after curative hepatectomy.

SERUM ANTIBODY TO HEPATITIS B CORE ANTIGEN IS NOT ASSOCIATED WITH INCREASED RISK OF HEPATOCELLULAR CARCINOMA IN PATIENTS WITH HCV-RELATED CIRRHOSIS

Tommaso Straffolini1, Piero L. Almasio2, Marcello Persico3, Giovan Battista Gaeta4, Savino Bruno5; 1Department of Gastroenterology, AO San Giacomo, Rome, Italy; 2Gastroenterology and Hepatology Unit, Palermo, Italy; 3Department of Internal Medicine, Naples, Italy; 4Viral Hepatitis Unit, Naples, Italy; 5Department of Medicine, AO Fatebenefratelli e Ospedali, Milan, Italy

The impact of previous exposure to HBV as a risk factor associated with tumour occurrence in subjects with HCV-related cirrhosis has not been fully investigated. We assessed whether serum anti-HBc is associated with HCC development in HCV-RNA+ve, HBsAg-ve patients with cirrhosis. 693 patients (432 men, mean age 54.8 years) with HCV-related histologically-proven cirrhosis and anti-HBc testing, surveilled with ultrasound examinations every six months, was analysed. All patients were treated with Interferon (IFN) between January 1992 and December 1997. Independent predictors of HCC were assessed by Cox multiple regression analysis. Results. Mean follow-up was 96.2 months; 303 (43.8%) patients were anti-HBc positive. There was no difference in the incidence of HCC between anti-HBc+ve and anti-HBc-ve patients. In a subgroup with sustained viral response we observed a slight increase of incidence of HCC per 100 person-years in anti-HBc+ve patients as compared to anti-HBc-ve patients.
compared to negative ones (1.17, 95% C.I. 0.32-2.98 vs. 0.64, 95% C.I. 0.13-1.87). Conclusions. Serum anti-HBc+ve/HCV+ve cirrhosis treated with IFN irrespective to the achievement of response did not show an increased risk of HCC in comparison with anti-HBc+ve subjects. These results indicate that in everyday clinical practice patients with HCV-related cirrhosis and past exposure to HBV infection do not require a tailored surveillance for HCC.

421
LEF TO LOBE LOCATION OF HEPATOCELLULAR CARCINOMA AS A RISK FACTOR OF COMPLICATIONS OF RADIOFREQUENCY ABLATION
Olivier Seror1, Gisèle Nkontchou2, Medhat Ibraheem1, Corinne Barrucand1, Nathalie Ganne Carrie2, Emanuelle Coderc1, Jean Claude Trinchet2, Michel Beaugrand3, Nicolas Sellerier1; 1Radiology Unit, Jean Verdier Hospital, Bondy, France; 2Liver Unit, Jean Verdier Hospital, Bondy, France

As the small volume of the left lobe might increase the risk of complication of radiofrequency ablation (RFA) in patients with hepatocellular carcinoma (HCC), we compared in a retrospective study the tolerance of RFA performed for the ablation of HCC located in the left vs the right lobe. Patients and Methods: Over a 5-year period, 197 consecutive patients with cirrhosis and HCCs located either in the left (n=38) or in the right lobe (n=159) underwent RFA for the treatment of 47 and 198 tumours, respectively. Patient's characteristics were similar between the two groups excepted a higher percentage of subcapsular tumours in the left lobe: 31% vs 17% (p=0.03) Results: Treatment of tumours located in the left and right lobes required a mean of 1.05±0.2 and 1.02±0.14 procedures (p=0.34), including a mean of 1.8±1.2 and 2±1.5 (p=0.43) applications, respectively. Complication rates per procedure performed in the left and right lobes were 7/38 (18%) vs 6/159 (4%) (p=0.01), including capsular haematoma (3 vs 2), transient ascites (1 vs 0), pseudoaneurysms (1 vs 1), portal thrombosis (1 vs 0), liver abscess (0 vs 1), stomach burn (1 vs 0), biliary tract stenosis (1 vs 1), pleural effusion (0 vs 1) respectively. In multivariate analysis, left lobe location OR=3.16 (1.05-9.53) p=0.04, multifocal HCCs, OR=3.45 (1.14-10.38) p=0.03 subcapsular location OR=3.45 (1.14-10.38) p=0.03 and platelet counts < 100000 (100000/ ml OR=3.45 (1.14-10.38) p=0.03 were independent risk factors of complications. Conclusion the left lobe location of HCC is a major risk factor of complication after percutaneous RFA.

EFFECT OF INTRAPERITONEAL SALINE INFUSION FOR PERCUTANEOUS RADIOFREQUENCY ABLATION OF HEPATOCELLULAR CARCINOMA
Yun-Jin Chung, Won-Young Tak, Young-Dae Park, Se-Young Lee, Seok-Jin Yoon, Soo-Young Park, Eun-Soo Kim, Min-Kyu Jung, Seong-Woo Jeon, Chang-Min Cha, Young-Oh Kweon, Sung-Kook Kim, Yong-Hwan Choi; Hepatology, Kyungpook National University Hospital, Daegu, South Korea

INTRODUCTION: Percutaneous radiofrequency ablation (RFA) is effective therapeutic modality for hepatocellular carcinoma. But the procedure is not always successful, because of tumor location, possibility of surrounding tissue damage, and poor ultrasonographic image. AIMS & METHODS: This study was performed to evaluate the efficiency and safety of saline infusion into peritoneal cavity for difficult RFA cases such as hepatic dome or surface located tumor and ill defined tumor on ultrasonogram because of covering omentum. Total of 71 patients were included from June 2001 to April 2007. The reason of intraperitoneal saline infusion is to secure approach route for hepatic dome located tumor (n=35), minimize the injury of adjacent organs for surface tumor (n=27), and to detect the tumor more clearly by moving aside of omentum (n=9). We assessed the success rate and complication of procedure. We also assessed improvement of ultrasonographic image in cases that the tumor was not sharply or clearly defined on ultrasonogram (n=48). RESULTS: The percutaneous RFA with intraperitoneal saline infusion was effective in 65 cases (91.5%). The success rate was 94.3% in hepatic dome tumor, 85.1% in surface tumor, and 100% in tumor with poor ultrasonographic image. Intraperitoneal saline infusion made tumors defined more clearly on ultrasonogram in 37 cases (77.1%), and the improvement of ultrasonographic image of tumors was significant (p<0.001). There was no adjacent tissue injury on spiral CT image after RFA and no significant hemoglobin change related to procedure. Procedure related complications were developed in 33 cases (46.5%). But no major complications were developed and most common complication was pleural effusion (38%). CONCLUSION: Intraperitoneal saline infusion is effective and safe method for percutaneous RFA of hepatocellular carcinoma located at hepatic dome or surface. In addition, the tumors can be detected more clearly on ultrasonogram after intraperitoneal saline infusion.

ELUTING BEADS FOR HEPATOCELLULAR CARCINOMA - TRANSARTERIAL CHEMOEMBOLISATION USING DRUG ELUTING BEADS FOR HEPATOCELLULAR CARCINOMA - RESPONSE AND SIDE EFFECT PROFILE

Briohny W. Smith1, Jonathan Tibballs2, John Ferguson2, Bastiaan DeBoer3, Gary P. Jeffrey1,4, Leon Adams1,4, Luc Delriviere3, Andrew Mitchell3, Gerry C. MacQuillan1,4, 1Western Australian Liver Transplantation Service, Sir Charles Gairdner Hospital, Perth, WA, Australia; 2Department of Radiology, Sir Charles Gairdner Hospital, Perth, WA, Australia; 3Department of Anatomical Pathology, Pathwest, Perth, WA, Australia; 4Department of Medicine and Pharmacology, University of Western Australia, Perth, WA, Australia; 5Western Australian Liver and Kidney Transplant Surgery, Sir Charles Gairdner Hospital, Perth, WA, Australia

BACKGROUND: Transarterial chemoembolisation (TACE) prolongs survival in hepatocellular carcinoma (HCC) though still remains a palliative treatment. Drug eluting bead transarterial chemoembolisation (DEB TACE) utilises chemotherapy loaded beads to deliver chemotherapy and embolise the tumour arterial supply. This allows higher doses of chemotherapy to be retained in the tumour whilst minimising systemic side-effects. This is likely to cause a different side effect profile (post embolisation syndrome) to conventional TACE. AIMS: To evaluate the radiological and pathological response and side effect profile of HCC treated with DEB-TACE in our institution. METHODS: All patients were treated with a maximum of 4ml DC beads (Biocompatibles) loaded with epirubicin 37.5mg/ml until embolisation was judged to be complete. Follow up MRI or CT scan occurred 4 weeks post treatment. Patients with residual tumour vascularity were re-treated. Pathological response was assessed in patients who underwent HCC resection or transplant. Side effects and adverse events were recorded retrospectively at outpatient clinic reviews. RESULTS: 19 patients (17 males, mean age 65.0 +/-11.6 years) underwent 22 episodes of DEB-TACE. Underlying liver disease was alcohol (7), Hepatitis B (5), NASH (2) and hepatitis C (1). 11 patients were Childs A cirrhosis, 2 were Childs B cirrhotic and 6 were noncirrhotic. Of the 19 patients, 12 had no previous conventional TACE, radiofrequency ablation or percutaneous alcohol injection. Of these 8 had 100% tumour devascularization, 1 50-99% devascularization, 2 <50% devascularization and 1 defaulted follow-up. Histopathology of 4 specimens (2 tumour resection, 2 explanted livers) demonstrated beads causing vascular obstruction and variable tumour necrosis. 73% of patients experienced post embolisation syndrome (abdominal pain and fever) following TACE. This lasted for a median of 6 days. Of the three patients who had previously received Lipiodol TACE, all described the side effects of DEB-TACE to be more severe. Two patients required re-hospitalisation, one due to an abscess requiring drainage and prolonged IV antibiotics. CONCLUSIONS: Early radiological and pathological responses to DEB-TACE is promising. Post embolisation syndrome is common, more severe in patients with larger tumours and is more prolonged than that following standard TACE. This probably reflects increasing tumour necrosis.

424 THERAPEUTIC OUTCOMES OF RADIOFREQUENCY ABLATION UNDER GENERAL ANESTHESIA FOR HEPATOCELLULAR CARCINOMA - PROPENSITY ANALYSIS OF RFA VERSUS SURGERY

Akiko Saito1, Michiyo Chiba1, Tomoko Komiya1, Yuki Yoned1, Keiko Shiratori2, Shunichi Ariizumi2, Satoshi Katagiri2, Hideo Katuragawa1, Masakazu Yamamoto1, Ken Takasaki1, Toshio Morizane2, 1Institute of Gastroenterology, Tokyo Women’s Medical University, Tokyo, Japan; 2Department of Medicine, Kanagawa Dental College, Kanagawa, Japan

INTRODUCTION: In recent years, RFA has become the first choice among non-surgical treatments for HCC. However, there are few reports focusing on RFA as an alternative to hepatic resection. As randomized controlled trials are difficult to perform in Japan, we conducted a propensity analysis to compare the outcomes of RFA versus surgery. METHODS: From September 1999 through December 2005, 520 HCC cases with nodules ≤5cm underwent RFA (216 cases) or surgery (304) as the initial curative treatment. Overall and recurrence-free survivals were calculated for all cases, and the RFA and surgical groups were compared by Kaplan-Meier method and Proportional hazards analysis. The Propensity analysis was then performed. RFA was performed under general anesthesia, employing percutaneous ultrasound-guidance. A RITA 500PA was used during the first year, and thereafter a Cool-tip needle, as the electrodes for RFA. RESULTS: 1) In all patients, the overall survival rates at 5 years after RFA or hepatic resection were 66.4% and 72.4%, respectively (p=0.493). The respective recurrence-free survival rates at 5 years were 36.0% and 25.9% (p=0.017). However, multivariate analysis showed the absence of differences between the two groups. Surgery vs RFA: HR1.078 (95%CI 0.849-1.376) (p=0.540) for overall survival, 1.158 [0.997-1.347] (p=0.065) for recurrence-free survival. 2) Six factors (Age, HCC location, form, diameter, Prothrombin time and ICG-R15) determining treatment selection, RFA or surgery, were identified using multiple logistic regression analysis. Ninety pairs of RFA and surgery cases were selected (180 in total) as propensity-score-match cases. Propensity analysis confirmed that there were no significant differences in either overall or recurrence-free survival between the two groups. 3) Among the 220 RFA cases, only one experienced a major complication (bleeding into the abdominal cavity) and two developed refractory ascites. CONCLUSION: There was no difference in either overall or recurrence-free survival between patients undergoing RFA and those treated surgically. RFA under general anesthesia is a safe and effective method of treating HCC.

425 ELEVATED SERUM HYALURONIC ACID MAY IDENTIFY VINYL CHLORIDE WORKERS AT HIGH RISK FOR THE SUBSEQUENT DEVELOPMENT OF HEPATIC ANGIOSARCOMA

Matthew C. Cave1, Royce Groce1, Arpna Mahalingashetty1, Swati Joshi-Barve1, Lark Reynolds1, Craig J. McClain1,2, 1Medicine/Gastroenterology, University of Louisville, Louisville, KY; 2Louisville VAMC, Louisville, KY

Purpose: Vinyl chloride (VC) exposure is a well-documented risk factor for angiosarcoma of the liver (ASL). This association was first made in 1974 at a Kentucky chemical plant. To date, 25...
employees from this plant have developed ASL, and this is the largest single site cluster in the United States. Nationally, 80,000 chemical workers have been exposed to VC. Due to a long latency period, many are still at risk for ASL. A biomarker is needed for the early detection of this deadly tumor. ASL arises from sinusoidal endothelial cells (SECs) which also metabolize hyaluronic acid (HA). We review our experience with ASL and test the hypothesis that serum HA is elevated in VC workers who have subsequently developed ASL. Materials and Methods: A cohort of 103 workers with high VC exposure has been followed clinically since 1974 for the development of ASL. Using a nested case control approach, serum HA levels were measured in stored samples from workers with ASL or from those who went on to develop ASL, and in control groups with either high or low VC exposure who did not develop ASL. Results: The mean age at time of diagnosis of ASL was 58.6 years. The mean cumulative vinyl chloride exposure was 17,500 PPM-Yr. Angiosarcoma presented following an average latency period of 22.2 years after reaching a threshold exposure of 7000 PPM-Yr. The average values of routine liver function tests were surprisingly normal at the time of diagnosis of ASL: ALT 24 U/L (±20, s.d.), AST 36 IU/L (±9), alkaline phosphatase 70.7 IU/L (±44.6), total bilirubin 1.2 mg/dL, (±0.15), albumin 4.3 g/dL (±0.21). All 25 patients died of hepatic angiosarcoma despite aggressive treatment in the majority of cases. One employee lived 14.5 years after surgical resection. The mean survival for the other 24 was only 1.24 years after diagnosis. The mean HA level in 2 patients after the hepatic resection. The mean HA level in 11 workers at 11.1+6.90 years prior to the diagnosis of ASL was 71.6 µg/L (±58.1). This was greater than HA levels in both the high VC exposure control group (30.0±24.9 µg/L, p = 5.57 x 10^-5) and the low VC exposure control group (32.0±26.7 µg/L, p = 0.00703). Conclusions: ASL develops after a long period of high occupational VC exposure and has been uniformly fatal. At the time of diagnosis of ASL, routine liver chemistries were normal while HA was markedly elevated. In workers with high VC exposures who went on to develop ASL one decade later, the average HA level was twice that of workers who did not develop ASL. Elevated HA may identify VC workers at risk for the subsequent development of ASL.

426 COMPARISON OF FIBROSCAN, APRI, AST/ALT AND CLINICAL SIGNS AS NON INVASIVE PREDICTORS OF CIRRHOSIS
Raza Malik, Rory Farnan, Michelle Lai, Hannalisa Freitag, Detlef Schuppan, Nezam H. Afdhal - Grant/Research Support: Other

Background and Aims: Noninvasive identification of compensated cirrhosis is important. We therefore compared Transient Elastography (Fibroscan), APRI score, AST/ALT ratio, hyaluronic acid and clinical signs to determine which modality performs best in predicting compensated cirrhosis. Methods Patients were stratified into cirrhotic and non-cirrhotic. Fibroscan measurements were correlated with clinical (spider naevi & palmar erythema), serological, radiological, endoscopic and histology which served as gold standard. An intention to treat analysis was applied to compare the cohorts using the ANOVA test with differences reported if p<0.05. ROC curves were generated to assess the diagnostic value of each test. Results A total of 833 patients were recruited into the study of whom 73 patients were excluded as a Fibroscan measurement could not be obtained (8% drop out). Fibroscan >12 kPa was diagnostically superior to the other parameters (sensitivity, specificity, PPV and NPV > 80%) yielding an AUROC measurement of 0.87 when compared to HA>45 (0.74), APRI score>1 (0.74), AST/ALT ratio>1 (0.64) and clinical signs (0.63) (p<0.01). In sub group analysis, Fibroscan performed as well. In 524 Hepatitis C patients (272 cirrhotic and 252 non-cirrhotic), Fibroscan>12 kPa yielded an AUROC of 0.86 compared to APRI>1 (0.75), HA>45 (0.73), AST/ALT ratio>1 (0.62) and clinical signs (0.63) (p<0.01). In the 236 non-hepatitis C patients in the study of whom 106 had cirrhosis and 130 were non-cirrhotic Fibroscan was also diagnostically superior at identifying cirrhosis. Fibroscan yielded an AUROC of 0.89 compared to APRI>1 (0.70), HA>45 (0.66), AST/ALT ratio>1 (0.70) and clinical signs (0.62) (p<0.01). Importantly, Fibroscan performed best at identifying cirrhosis in 146 biopsy proven Childs Pugh A cirrhosis with no clinical, biochemical or radiological features of cirrhosis or portal hypertension. Here, Fibroscan >12 kPa yielded an AUROC of 0.86 compared to APRI>1 (0.74), HA>45 (0.72), AST/ALT>1 (0.60) (p<0.01). Conclusion Fibroscan accurately identified compensated cirrhosis using a liver stiffness cut off of 12 kPa, confirming it as the best non invasive method to identify cirrhosis.

427 PROSPECTIVE STUDY OF NEOPLASTIC SEEDING IN PATIENTS UNDERGOING ULTRASOUND GUIDED PERCUTANEOUS DIAGNOSTIC OR THERAPEUTIC PROCEDURES OF HEPATIC TUMORS
Gian Ludovico Rapaccini, Laura Riccardi, Manuela Nestola, Fulvia Elia, Nicoletta de Matteis, Antonio Grieco, Giovanni Gasbarri, Maurizio Pompili; Internal Medicine, Catholic University, Rome, Italy

Neoplastic seeding along the needle track is a possible complication after percutaneous diagnostic and therapeutic procedures. In the retrospective studies the incidence of seeding of neoplastic cells after echoguided percutaneous biopsy ranges between 0.003 and 2%. Pancreatic neoplasms have a higher risk of neoplastic seeding. The risk increases using cutting needles. Percutaneous ablation treatments, like percutaneous ethanol injection (PEI) and radiofrequency thermal ablation (RFA), are safe and effective techniques to treat non resectable hepatic tumors. The referred risk of percutaneous seeding of neoplastic cells is 0.66-6.2% for PEI, 0.6% for RF. Aim of the study was to give a prospective evaluation of seeding occurrence in patients undergoing echoguided percutaneous diagnostic and therapeutic procedures. We included the patients undergone to fine needle biopsy (FNB) or ablation therapies for neoplastic lesions of liver; for each patient the needle entry point was marked on the skin with a tattoo. The seeding has been then searched with quarterly ultrasound examinations. From January 2001 to January 2005 we studied 270 patients, undergoing 574 procedures. On the whole 368 hepatic nodules were subjected to ultrasound-guided percutaneous procedures. During this period a total of 264 diagnostic fine needle biopsies have been performed: 164 in nodules detected in cirrhotic patients (97 cytological and 67 histological examinations), 100 in liver metastasis (64 cytological and 36 histological examinations). 310 ablation therapies have been
performed in 255 hepatic nodules (246 HCCs and 9 metastasis) detected in 149 patients. We have observed 3 cases of seeding in the studied population (1.1%). The first case was observed in a patient with HCC after FNB. The other 2 cases occurred in 2 patients with HCC after FNB and PEI. This first prospective longitudinal study about incidence of neoplastic seeding after hepatic echo-guided diagnostic or therapeutic procedures, has demonstrated a low rate of the complication. The contemporary emergence of the seeded nodules with recurrence of the neoplasms in other sites, doesn’t suggest an influence of this complication on the patients prognosis.

428 CORRELATION OF LAPAROSCOPIC LIVER BIOPSY TO ELASTICITY MEASUREMENTS (FIBROSCAN®) IN PATIENTS WITH CHRONIC LIVER DISEASE

Carmin G. Nudo¹, Lennox Jeffers², Pablo A. Bejarano², Luis A. Servin-Abad², Zvi Leibovici¹, Maria de Medina¹, Eugene R. Schiff²; ¹Division of Hepatology, Center for Liver Diseases, University of Miami, Leonard M. Miller School of Medicine, Miami, FL; ²Department of Pathology, University of Miami, Leonard M. Miller School of Medicine, Miami, FL

Background: Transient elastography is a noninvasive method to assess liver fibrosis by measuring liver stiffness. Studies have compared elastography to percutaneous liver biopsy. Laparoscopic liver biopsy is associated with decreased sampling error since biopsies are obtained from both lobes and the presence of gross nodularity can be directly visualized. Aim: To assess the relationship between liver elasticity (E) measured with shear elasticity probe (FibroScan®) and liver fibrosis (F) and activity (A) assessed by histopathological and laparoscopic findings. Methods: Patients undergoing laparoscopic liver biopsy were enrolled. Gross appearance of the liver was assessed. Transient elastography (FibroScan®, Echosens) was used to measure liver stiffness. Spearman correlation analysis, multiple regression analysis and receiver operating characteristics (ROC) curve were used to analyze the data. Results: 95 patients were included, 50 +/− 9.4 years old (48% male). The indication for liver biopsy was HCV (64%), elevated enzymes (11%), NAFLD (9%), HBV (7%), AIH (4%), and other (5%). The distribution of fibrosis was F0 12.6%, F1 8.4%, F2 34%, F3 25%, F4 20% and activity G0 3%, G1 11.6%, G2 23.2%, G3 37%, G4 25.3%. E was normalized using a decimal logarithmic transformation (logE). In the correlation analysis, F was related to the E (r = 0.65; p < 0.0001), as was A (r = 0.46, p < 0.0001). A was also related to F. In a multiple regression analysis of logE, activity and fibrosis, E was strongly associated with advanced stages of F (stage 3 and 4) (r = 0.42; p < 0.001). The ROC curve for E to identify patients with F ≥ 3 and F4 had an area under the curve (AUC) of 0.84 and 0.86 respectively. For activity G2 ≥ 3 and G4 the AUC was 0.74 and 0.71. The table demonstrates the performance of various cutoffs of E. Conclusions: Shear Velocity (E) increases with liver fibrosis (F). The stage of fibrosis was associated with the grade of activity and must be considered in evaluation of elasticity to predict fibrosis. A cutoff of 11.9 kPa has moderate sensitivity and high specificity to identify patients with F ≥ 3. FibroScan® could be a useful noninvasive tool to detect advanced stages of fibrosis. Different models should be considered for different etiologies of liver disease.

429 COMPUTATIONAL FLOW DYNAMICS SIMULATION OF PORTAL BRANCHES IS USEFUL FOR ANALYZING THE MECHANISM OF NON-UNIFORM REGIONAL LIVER REGENERATION AFTER SURGICAL RESECTION

Yuju Iimuro, Shinichi Saito, Junichi Yamanaka, Tadamichi Hirano, Nobukazu Kuroda, Toshihiro Okada, Takaaki Sugimoto, Yasukane Asano, Naoki Uyama, Yugo Udo, Jiro Fujimoto; Surgery, Hyogo College of Medicine, Nishinomiya, Japan

Portal blood flow has been implicated in a critical factor regulating liver regeneration after surgical resection, while there has been no definitive evidence supporting this hypothesis. Whether the remnant liver regenerates uniformly or some specific region of the remnant liver preferentially regenerates is also unknown. We hypothesized that changes in blood flow in each portal branch regulate the regional regeneration, and tested this hypothesis employing computational simulation systems.

Methods: Out of 116 HCC patients who received hepatic resection during recent three years, 13 patients who underwent anterior or posterior segmentectomy and 7 patients who received lateral segmentectomy were analyzed. According to preoperative MD-CT, 3-D structure of portal branches was constructed, and each segment volume was accurately calculated using 3-D virtual hepatectomy simulation software (Hitachi Image Processing System) as we reported before (Hepatology 2005). Same procedure was performed 3 months after the operation, and regeneration volume in each segment was determined. Direct measurement of prompt changes in blood flow in each portal branch after surgery is technically difficult, so we used computational flow dynamics (CFD) software (Fluent 6.2, Fluent Inc.) for flow simulation. For the CFD analysis, mesh models of portal branches were constructed using a 3-D image processing and editing software (Mimics, Materialise). On the Fluent 6.2, changes in blood flow in the remnant portal branches were simulated by virtual cutting of an interested portal branch, and correlation between those changes and regeneration volume was investigated. Results: Actual hepatic resection volumes well correlated with the simulated volumes (r2 = 0.96), implying the accuracy of the virtual hepatectomy simulation software. In patients with right-side hepatectomy, degree of liver regeneration during 3 months was significantly greater in the right lobe compared with the left lobe (p < 0.05). On the other hand, liver regeneration was significantly greater in the left lobe when lateral segmentectomy was performed (p < 0.05). According to the CFD software, the increase in blood flow after virtual portal resection was significantly greater in a portal branch adjacent to the resected branch, and the regional regeneration volume tended to be greater in that portal branch area. These data possibly account for the greater regeneration volume in the resection-side of the remnant liver. Conclusions: Liver regeneration after surgical resection does not uniformly
According to genotype/phenotype criteria, hepatocellular adenomas (HCA) have been classified into four subgroups: HNF1α-mutated, inflammatory/telangiectatic, β-catenin mutated (half being also inflammatory/telangiectatic), and a group without any specificity. In this study we analysed retrospectively MRI of HCA before resection and classified using immunohistochemistry (IHC) [Hepatology 2007 in press]: LFABP negativity for HNF1α-mutated HCA (14 cases); SAA positivity for inflammatory/telangiectatic HCA (18 cases, 3 cases being also β-catenin mutated), β-catenin and glutamine synthetase overexpression for β-catenin activated HCA (1 case) and 5 unclassified cases. MRI were reviewed in consensus by two abdominal radiologists, without knowledge of IHC results. HNF1α HCA: most lesions had an homogeneous aspect on all sequences. The signal intensity on T1 weighted sequences was iso or slightly hyperintense with homogeneous signal dropout with fat-suppression sequences. The signal intensity was iso or slightly hyperintense on T2 weighted sequences and most lesions showed moderate enhancement on arterial, portal and delayed phases after gadolinium administration. Inflammatory/telangiectatic HCA: signal intensity on T1 weighted sequences was homogeneous with iso or slightly hyperintensity and no signal dropout with fat suppression sequence. Heterogeneous aspect was frequent on T2 weighted sequences but all lesions presented a markedly hyperintense component. All lesions showed a strong arterial enhancement with persistant enhancement on delayed phase. Good correlation was found between high signal area on T2 weighted sequence, delayed enhancement and peliotic zones on pathologic examination. The three lesions with both SAA expression and β-catenin activation showed the same MRI features. β-catenin mutated HCA: part of the lesion looked like inflammatory/telangiectatic lesion with high hyperintensity on T2 weighted sequence and delayed enhancement after gadolinium administration. Rest of the lesion was isointense on T2 weighted sequence and slightly hypointense on T1 weighted sequence with no signal dropout on fat suppression sequence. Unclassified HCA: inflammatory/telangiectatic MRI features were found in two lesions. The three others had characteristics of benign hepatocellular nodules with no specific MRI feature and among them, two had intratumoral hemorrhagic zones. Conclusion: The two main subgroups of HCA are associated with specific MRI patterns dependent on homogeneous steatosis for HNF1α-mutated HCA and peliotic component for inflammatory/telangiectatic HCA. No specific MRI feature was found to be associated with β-catenin mutated HCA.
The diagnosis of FNH is made using imaging techniques in 70% of the cases. A role for liver biopsy can become essential in FNH when imaging cannot establish firmly the diagnosis. However, in some cases of FNH histopathological diagnosis remains difficult, even in a resected specimen. Recently it has been shown that glutamine synthase (GS) was a useful marker in tumoral pathology including HCA (Hepatology, in press) and nodules from cirrhotic patients (Hepatology, 2007;45:725-34). The aim of the current study is to use GS as a marker in our practice to evaluate its ability to differentiate FNH from HCA or even hepatocellular carcinoma (HCC). FNH resected from normal or occasionally steatotic livers were retrieved from our collection. Seven groups were analysed as a: 15 cases with a firm preoperative diagnosis; b: 5 cases without a firm preoperative diagnosis (FNH or HCA or HCC); c: 2 cases with a preoperative diagnosis of HCA; d: 5 cases occurring in men with a suspicion of HCC; e: 10 cases associated with HCA (single, multiple or adenomatosis); f: 3 cases in patients with a past history of malignant tumors and g: 10 HCC on non cirrhotic liver, 5 expressing b-catenin. For all cases several blocks were available. Sections were stained using H&E, trichrome, reticuline, PAS, perls, and were immunolabelled for CK7 and 19, and GS. The diagnosis of FNH was established based on classical pathological standards. In case of uncertainty, additional immunostainings included IFABP, SAA and b-catenin. Controls included group e and g. In non tumoral liver, GS staining was strictly limited to 1 or 2 hepaticoportal plates around hepatic veins. In all FNH groups (a-f) GS staining was identical, intense, and included group e and g. In non tumoral liver, GS staining was never detected in all FNH samples tested. In b-catenin mutated HCA and HCC, GS was detected but its labelling was more diffuse, without the “map-like” pattern characteristic of FNH. In non b-catenin mutated HCA, GS was occasionally detected at the periphery and around some hepatic veins inside the tumor. Conclusion. In FNH, typical or not, independent of the size and its possible steatotic content, GS gave the same typical pattern and consequently represents the best marker to date which discriminates FNH from other hepatocellular nodules. The usefulness of this marker in liver biopsy needs however to be confirmed. The reason why GS immunostaining is increased in FNH remains presently unknown.

IMPACT OF PREOPERATIVE VIRTUAL SEGMENTAL VOLUME ON LIVER RESECTION FOR HEPATOCELLULAR CARCINOMA IN PATIENTS WITH IMPAIRED LIVER FUNCTION

Junichi Yamanaka, Shinichi Saito, Yuji limuro, Tadamichi Hirano, Nobukazu Kuroda, Toshihiro Okada, Takaaki Sugimoto, Yasukane Asano, Naoki Uyama, Jiro Fujimoto; First Department of Surgery, Hyogo College of Medicine, Nishinomiya, Japan

BACKGROUND & AIM: Liver resection offers a potential cure for hepatic malignancies when the resection margin is negative. In cases of hepatocellular carcinoma (HCC), however, impaired hepatic function due to accompanying chronic liver disease restricts liver resection volume. Hence, accurate assessment of liver resection volume and resection margin is mandatory in preoperative planning for safe and curative hepatectomy. We have reported usefulness of virtual hepatic resection via three-dimensional (3D) image analysis software based on hepatic circulation (Hepatology, 2005). The aim of this study was to assess the feasibility and accuracy of multidetector CT scan based simulation in patients with impaired liver function undergoing hepatectomy for HCC. PATIENTS & METHODS: Hepatectomy simulation software was programmed to reconstruct detailed 3D vascular structure and to calculate liver volume based on portal vein perfusion. In 151 patients with HCC, liver resection volume was estimated preoperatively by both simulation and conventional planimetry. For validation, predicted resection volumes were compared with actual resected specimen weights. The resection margin as estimated by the simulation was compared with the margin in the specimen. RESULTS: Of the 151 patients enrolled in the study, 148 (98%) had complete simulation data. These patients showed impaired hepatic function with mean indocyanine green retention rate at 15 min (ICG R15) of 20%. Histology of the liver parenchyma showed bridging fibrosis or cirrhosis in 79%. Impaired hepatic function resulted in segmental or more limited resection in 52% of patients. No patients died within 30 days of resection. One patient deceased on postoperative day 67 due to postoperative liver failure and the mortality rate was 0.7%. There were no major complications requiring additional surgery. Minor complications such as ascites, pleural effusion, or bile leakage occurred transiently and were managed conservatively. Simulation showed higher correlation and smaller discrepancy (r=0.96; 9.3 mL) between predicted and actual liver resection volume than conventional planimetry (r=0.74; 174 mL). Simulation showed correlation (P < 0.01) between estimated and actual segmental volume, which was not measurable by planimetry. Simulation showed a correlation (r = 0.84) between predicted and actual margin, with a difference of 1.6 mm. CONCLUSIONS: Hepatectomy simulation in 3D predicted segmental liver volume and the resection margin accurately. This virtual method should contribute to preoperative planning to achieve safe and curative resection in HCC patients, whose hepatic function is compromised.

434 ASSESSMENT OF HEPATIC FUNCTIONAL RESERVE USING FUNCTIONAL LIVER MR IMAGING: CORRELATION WITH LABORATORY AND PATHOLOGIC FINDINGS IN ANIMAL MODEL

Jin-Woo Lee1, Soon Gu Cho2, Jung Il Lee3, Seok Jeong1, Kye Sook Kwon1, Don Haeng Lee1, Hyung Gil Kim1, Yong Woon Shin1, Young Soo Kim1, Eun Joo Kim1, Hyun-Joo Park1, In-Sea Park2; 1Department of Gastroenterology and Hepatology, Inha University College of Medicine, Incheon, South Korea; 2Department of Radiology, Inha University College of Medicine, Incheon, South Korea; 3Department of Pathology, Inha University College of Medicine, Incheon, South Korea

Background and Aim: Surgical intervention in patients with abnormal liver function carries a higher morbidity and mortality. It is crucial to assess the risk before operation. However, there is no single reliable method for measuring hepatic functional reserve (HFR) until now. Thus, this study aimed to evaluate the reliability of functional liver imaging (FLI) in measuring HFR.

Materials and Methods: The FLI is a method of measuring HFR by calculating the percentage of functional volume that consisted of viable hepatocytes in a certain liver, compared with that in normal one using Mn-DPDP enhanced MR imaging and volumetry. We evaluated the change of HFR using serial FLI before and after acute hepatic necrosis (AHN) in the liver of 15 beagle dogs. AHN was induced by intraperitoneal injection of carbon tetrachloride. The MR images were obtained with 1.5T GE Signa Horizon system using EFGRE-3D sequence (TR/TE = 4.7/1.1 msec; FA, 20.0°) and torso-coil. The post-processing of the FLI was performed at a SUN Sparc workstation. All of the subjects were sacrificed immediately after the acquisition of second FLI, and percent of viable hepatocytes in pathologic specimens was determined using image analyzer. The correlation between the change of HFR measured with FLI (HFR-FLI) and the parameters of liver function tests (AST, ALT, albumin, bilirubin, prothrombin time), and the retention rate of indocyanine green 15 minutes after administration (ICG-R15) before and after induction of AHN were assessed. The correlation between the enhancement rate in the livers with AHN compared with that in corresponding normal ones (R(E AHN/ENL)) and the percent of viable hepatocytes in pathologic specimens was also determined. Results: The mean ± standard deviation of HFR-FLI in the livers with AHN was 59.7 ± 9.0 % in comparison with that of the normal ones. The change of HFR-FLI was well correlated with that of all the laboratory findings (serum level of AST, ALT, albumin, bilirubin, prothrombin time) and ICG-R15 (β = -0.858 or > 0.959, p < 0.05). The R(E AHN/ENL) showed strong positive correlation with percent of viable hepatocytes in pathologic specimens (β = 0.982, p < 0.05). Conclusion: The change of HFR-FLI was well correlated with that of the findings of laboratory liver function tests, and the R(E AHN/ENL) well represented the percent of viable hepatocytes validated by pathologic examination. Therefore, we suggest that the FLI could be used as a reliable method for measuring HFR.

435 ULTRASONOGRAPHIC ANALYSIS OF HAVMS IN A LARGE COHORT OF HEREDITARY HEMORRHAGIC TELANGIECTASIA PATIENTS: DEFINITION OF A NEW HIGHLY-ACCURATE INTRAHEPATIC PARAMETER

Patrizia Suppressa1, Paolo Buonamico1, Giovanna Pasculli1, Gennaro M. Lenato1, Franco D'Ovidio2, Maurizio Memeo1, Luigi Castorani1, Carlo Sabbas1; 1Internal Medicine and Public Health, University of Bari, Italy, Bari, Italy; 2Statistics, University of Bari, Italy, Bari, Italy

Background: Hereditary hemorrhagic telangiectasia (HHT) is a rare genetic disorder (1:5000) whose diagnosis is based on 3/4 of the following criteria: familiar history, epistaxis, mucocutaneous telangiectases, visceral arteriovenous malformations. Hepatic arteriovenous malformations (HAVMs) have been found in more than 70% HHT patients by multislice CT (MSCT). Due to its noninvasivity and low cost, echo-color Doppler has recently been considered a valuable tool for long-term of HHT-related HAVMs; however, only open studies of selected patient cohorts using mainly extrahepatic ultrasonographic criteria are currently available. Aim of Study: To perform a blind controlled study with echo-color Doppler as a screening procedure for HAVMs in a large cohort of unselected HHT patients for investigation of the accuracy of “color spots” (a new intrahepatic echo-color Doppler parameter) and to compare its accuracy together with that of previously-reported extrahepatic ultrasound criteria (1) for diagnosis of HAVMs. Methods: 153 HHT patients (80 males and 73 females, mean age 47±15, range 15-75 yrs) were systematically screened with abdominal MSCT (considered as the gold standard) and echo-color Doppler (HDIL-9ATL System) by two independent operators to evaluate the presence of HAVMs. Both intrahepatic parameters (“color spots” with high velocity and low resistance index) and extrahepatic parameters (diameter, flow velocity and tortuosity of hepatic artery and portal vein) were utilized. The sensitivity and specificity for both classes of criteria were assessed (Cramer’s V index). Results: MSCT was positive in 128/153 (84%) HHT patients. Doppler color spots were found in 130/153 patients (see Table). The sensitivity, specificity and diagnostic accuracy of color spots compared to MSCT were 95%, 68% and 91%, respectively, and the “color spot criterion” showed a greater correlation to MSCT (Vindex = 0.655; p<0.0001) than the extrhepatic criteria (V = 0.39) (1). Conclusions: A new echo-color Doppler intrahepatic parameter (“color spot”) was identified showing an optimal accuracy for detecting HAVMs in HHT, thus permitting a non-invasive, ideal strategy for periodical screening of HHT patients. These data support the superiority of intrahepatic compared to extrahepatic criteria for identification of HAVMs. 1) Caselitz et al. Hepatology 2003;37:1139-46.

Efficacy of Positron Emission Tomography CT for Metastatic Hepatocellular Carcinomas

Tomokazu Kawaoka, Hiroshi Aikata, Shoichi Takahashi, Kazuaki Chayama; Graduate School of Biomedical Science Hiroshima University, Hiroshima, Japan

Background/Aim: Since the patients suffering from hepatocellular carcinoma (HCC) live longer than before, thanks to improvement of diagnostic and therapeutic modality, the patients who possess remote metastasis of HCC are increasing. This study aimed to evaluate the efficacy of Positron Emission Tomography (PET) CT as a detection tool for metastatic HCCs compared with MDCT and bone scintigraphy. This included visual correlations of PET-CT and MDCT imaging in the detection of HCC using receiver operating characteristic (ROC) analysis. Materials and Methods: Thirty patients who have metastatic HCC at Hiroshima university hospital were enrolled in this study from Jan. 2005 to Jan. 2007. Those patients had 128 metastatic nodules, among which lung metastases were 80, bone metastasis were 29 and lymph node metastasis were 19 cases. In terms of tumor size, median size of lung metastasis was 6 mm (2-33 mm) in diameter, that of bone metastasis was 18mm (8-120 mm) and that of lymph node metastasis was 30mm (15-67mm). For the ROC analysis, 128 nodules were diagnosed as metastatic HCC by one experienced abdominal radiologists. And same numbers of segments that did not include HCC were prepared as negative image. Another three physicians independently reviewed both positive and negative images. Each physician read two or three sets of images such as MDCT, PET-CT and bone scintigraphy for bone metastasis. Each reader scored each image for the presence of metastatic HCC lesions and assigned confidence levels to his observations (1=definitely negative, 2=probably negative, 3=possibly positive, 4=probably positive, 5=definitely positive). Results: The mean sensitivity and the mean specificity were 94%, 81% with MDCT, 31%, 96% with PET-CT in lung metastasis, 41%, 93% with MDCT, 55%, 93% with PET-CT, 36%, 85% with bone scintigraphy in bone metastasis and 95%, 89% with MDCT, 89%, 68% with PET-CT in lymph node metastasis. The mean positive predictive values were 83%, 89% with MDCT or PET-CT in lung metastasis, 83%, 89% with MDCT, PET-CT or bone scintigraphy in bone metastasis and 90%, 74% with MDCT or PET-CT in lymph node metastasis, respectively. The mean Az values were 0.93, 0.49 with MDCT or PET-CT in lung metastasis, 0.72, 0.84, 0.68 with MDCT, PET-CT or bone scintigraphy in bone metastasis and 0.96, 0.65 with MDCT or PET-CT in lymph node metastasis, respectively. Conclusion: According to ROC analysis, MDCT was more useful for detection of lung and lymph node metastasis of HCC, while PET-CT was more useful for detection of bone metastasis of HCC.

Positron Emission Tomography (PET/CT) Using Fluoro-Choline Allows to Differentiate Between Adenoma and Focal Nodular Hyperplasia

Franck Bumse1, Virginie Huchet2, Lionel Arrivé3, Dominique Wendum2, Francois Paye4, Raoul Poupon1, Jean-Noel Talbot5, Olivier Rosmorduc1; 1Hepatology, AP-HP, Hôpital Saint-Antoine, Faculté de Médecine Pierre et Marie Curie, Paris, France; 2Pathology, AP-HP, Hôpital Saint-Antoine, Faculté de Médecine Pierre et Marie Curie, Paris, France; 3Surgery, AP-HP, Hôpital Saint-Antoine, Faculté de Médecine Pierre et Marie Curie, Paris, France; 4Radiology, AP-HP, Hôpital Saint-Antoine, Faculté de Médecine Pierre et Marie Curie, Paris, France; 5Nuclear Medicine, AP-HP, Hôpital Tenon, Faculté de Médecine Pierre et Marie Curie, Paris, France

Background and aim: Despite the high performance of current imaging techniques, the differential diagnosis between hepatic adenoma and FNH could remain difficult in particular for nodules of small size, often inaccessible to the liver biopsy. PET/CT using F-18fluoro-2-D-glucose (FDG) is well established as a non-invasive diagnostic tool for the detection of a variety of malignant tumours. However, because of its low sensitivity, this technique is not used for the diagnosis of hepatocellular carcinoma (HCC). We have recently shown that F-18fluoro-methylcholine (FCH) was more sensitive than FDG for HCC detection. The aim of this study was to evaluate the uptake of FCH by hepatocellular benign tumours. Patients and Methods: 14 patients were prospectively explored for one or more nodules developed in a non cirrhotic liver and compatible with adenoma or focal nodular hyperplasia (FNH). The nodules were investigated by RMN and CT. An histological confirmation of the lesions was obtained in all patients except four because of the characteristic imaging features of FNH. Two PET/CT were carried out in each patient after injection of FDG and of FCH (4 MBq/kg of body weight) at four days of interval. The uptake of FCH and of FDG by the tumours was evaluated by the standardized uptake value (SUV). Results: 12 women and 2 men were included and presented with the following hepatic lesions: FNH (n=8), adenomas (n=4) including 2 adenomatosis, telangiectatic FNH (TFNH) (n=1) and association of a TPNF and a FNH (n=1). All FNH had an intense and early uptake of FCH (SUV: 7.86±1.4). This uptake gradually decreased at late time. In contrast, there was no FCH uptake by adenoma and TPNF. Concerning the patient presenting with TPNF and FNH, an intense uptake of FCH was only observed for the nodule having the features of FNH. None of these tumours (adenoma and FNH) showed an abnormal uptake of FDG. Conclusions: Our results show that the TEP/TDM using FCH is a sensitive and specific technique able to differentiate between FNH and adenoma.

The Hepatic Transcriptome of HCV Infection and Interferon Treatment in Hepatocytes Recovered from Chimeric Mice

Donna Douglas, Gordon Broderick, Jamie Lewis, Yutaka Yasui, David Bond, Norman Kneteman; University of Alberta, Edmonton, AB, Canada

Differential viral loads and sensitivity to IFNα treatment occurs with HCV-1A and HCV-3A infections in chimeric mice (Kneteman, N.M., et al Hepatology, 2006. 43(6): p. 1346-53); an
outcome that parallels the clinical setting for the therapeutic administration of IFNα to chronically infected patients. The chimeric mouse model was used to study IFN-stimulated genes (ISGs) in the early innate immune response to HCV infection since it lacks an adaptive immune system. Human hepatocytes were recovered from HCV-1A and -3A infected mice (+/- IFNα treatment) and used for transcriptional profiling by microarray analysis. Hepatocytes from naive mice (+/- IFNα treatment) served as controls. IFNα treatment of naive mice was associated with a significant upregulation of the hepatic transcriptome (3.8% of 54,675 interrogations) and many of the upregulated transcripts were established ISGs but only 2 of these are known to have antiviral activities (GBP2 and IFNAR1). Also included were ISGs of unknown function (GIP3, IFI13, IFI27, IFI30, IFITM2). We observed very few genes associated with HCV infection, and none were found to be ISGs. Antecedent HCV infection had a negative impact on the induction of genes by administered IFN (from 3.8% to 0.2% and 3.3%, for 1A and 3A, respectively), including GBP2 and IFNAR1. Interestingly, antecedent HCV infection had no impact on unknown ISGs GIP3, IFI24 and IFI30. Thus far, we have identified the hepatic transcriptome induced by (i) by HCV-1A and -3A infection (ii) IFNα-2b monotherapy, and (iii) IFNα-2b monotherapy in the setting of HCV-1A and -3A infection.

HEPATITIS C VIRUS CORE PROTEIN SELECTIVELY ACTIVATES CELL GROWTH FACTOR SIGNALING

Andrew Kim, Shigenobu Kawai, Waihong Chung, Eun Kim, Jack R. Wands, Jisu Li; Liver Research Center, Rhode Island Hospital and The Warren Alpert Medical School of Brown University, Providence, RI

Background and Aims: Primary hepatocellular carcinoma (HCC) is the fifth most common cancer worldwide. At least five growth factor signaling pathways have been implicated in the development and progression of HCC, including HGF, Wnt, IGF-II, TGFβ and TGFβ. Hepatitis C virus (HCV) is one of the principal etiological agents that dramatically increase the lifelong risk for HCC, and its core protein has been proposed to be a key contributing factor. To determine whether the HCV core protein modulated growth signaling pathways, we employed a cell culture system of inducible core protein expression (Huh-7/Tet-on) to investigate the transcriptional and functional changes of the signaling network. Methods: Gene transcriptional alterations in response to core protein expression were documented by microarray analysis. Activation of growth factor signaling was evaluated by reporter assay that monitored growth factors or downstream targets. The effect of growth factors on Huh-7 cell proliferation was examined by transient transfection of the cDNA constructs. Results: Microarray analysis of 39,000 human genes (Affymetrix U133) revealed that both Wnt and HGF signaling were activated as evidenced by marked up regulation of the ligands and downstream components of the pathway. In addition, the MAPK, Hedgehog, VEGF and PPAR signaling pathways were also found up regulated. In contrast, genes involved in the TGFβ, Notch, insulin signaling pathways were mostly down regulated. These data indicate that HCV core protein selectively up regulates certain growth signaling pathways. Since Wnt and HGF pathways have been implicated in >50% HCC cases, further experiments were performed to validate their contribution to cell growth. We found that overexpression of either Wnt-1 or HGF by transient transfection significantly increased Huh-7 cell proliferation, and the promoter activities of HGF and TCF (downstream target of the Wnt signaling) were marked increased by HCV core protein. Transfection with HGF or incubation of cells with HGF conditioned medium markedly increased TCF reporter gene expression, indicating crosstalk between HGF and Wnt signaling, with HGF signaling upstream of Wnt signaling. Conclusion: HCV core protein selectively up regulates the Wnt-1 and HGF growth signaling pathways. Interaction and crosstalk between these two pathways may contribute to the development of HCC.

APOLIPOPROTEIN C-IV EXPRESSION IS REGULATED BY KU ANTIGEN AND CORRELATES WITH TRIGLYCERIDE ACCUMULATION IN HCV INFECTED LIVER
Eun Kim, Jack R. Wands, Jisu Li; Liver Research Center, Rhode Island Hospital and The Warren Alpert Medical School of Brown University, Providence, RI

Background: Hepatic steatosis is frequently associated with persistent hepatitis C virus (HCV) infection. We recently found that HCV core protein upregulated transcription of genes related to fat/lipid metabolism, in particular apolipoprotein C-IV (ApoC-IV, ~10.7-fold increase). Sequence -122 to +41 (163bp) of the ApoC-IV promoter was defined as the core protein responsive element and Ku70/Ku80 complex (known as Ku antigen) was identified as the major nuclear proteins associated with the 5' end of this element. In the present study, we examined correlation between ApoC-IV expression and triglyceride accumulation in human liver of chronic HCV infection, and began to identify transcription factors important for regulation of ApoC-IV transcription. Methods: Nine HCV infected cirrhotic livers and four normal livers were compared for the levels of ApoC-IV mRNA using RT-real time PCR and triglyceride by enzymatic assay. The Ku70 coding sequence was amplified from Huh-7 cells by RT-PCR and cloned into the expression vector pcDNA3.1/Zeo+. The role of Ku70 overexpression in ApoC-IV promoter activity was examined by luciferase reporter assay. The transcription factors that bind to position -122 to -54 of the ApoC-IV promoter were predicted by TRANSFAC database search, and their role in ApoC-IV promoter activity was examined by site-directed mutagenesis of the 163-bp promoter. Results: The average ApoC-IV mRNA level was higher in HCV infected liver (6.2 ± 4.2) than in the control group (3.7 ± 2.6). Interestingly, the ApoC-IV transcript level strongly correlated with the concentration of intracellular triglycerides in the HCV infected liver (R² = 0.78), but not in the control group (R² = 0.57). Overexpression of Ku70 in Huh-7 cells increased steady-state level of Ku80 and also the ApoC-IV promoter activity, thus complementing our previous finding using Ku70 siRNA. Mutational analysis revealed that binding sites for transcription factors HNF4, C/EBPβ, and PPAR/RXR located at the 5' half [-122 to -54] of the 163-bp promoter were critical for core protein induced promoter activity. Conclusion: ApoC-IV may be the major regulator of triglyceride level in HCV infected cirrhotic liver, and it is controlled at the transcriptional level by Ku antigen, possibly through recruitment of other liver specific transcription factors. Further understanding of its regulation may help identify novel targets for intervention of hepatic steatosis.

ESCAPE IN AN HLA B8-RESTRICTED CD8 EPITOPE IN HCV NS3 IS ASSOCIATED WITH VIRAL FITNESS COSTS
Cesar Oniangue-Ndza1, Shadi Salloum1, Christoph Neumann-Haefelin2, Anna Eckart1, Robert Thimme2, Sergei Viazov1, Michael Roggendorf2, Joerg Timm1; 1Department of Virology and Lab Medicine, Tulane University of Health Sciences, New Orleans, LA; 2Virology II, National Institute of Infectious Diseases, Tokyo, Japan

Background: A convenient and reliable assay system is needed to be examined directly using fluorescence microscopy. Recently, a unique HCV clone derived from a Japanese FHF patient has been demonstrated to replicate efficiently in cell culture and produce infectious HCV particles. Aim: We sought to develop chimeric clones between green fluorescence protein (GFP) with full-length and subgenomic JFH-1 clones such that HCV replication and infection can be examined directly using fluorescence microscopy. Methods: Chimeric full-length (JFH-1) and replicon (pSGR-JFH-1) clones were prepared by inserting the GFP coding sequences in frame with the coding sequences of HCV NS5A protein of JFH-1 clone. HCV RNA transcripts were prepared from each clone by T7 RNA polymerase and transfected to Huh-7.5 cells by the electroporation method. The success of HCV transfection and replication was examined by developing stable replicon cell lines and in vitro infectivity of fluorescent virus particles using Huh-7.5 cells. Results: Both the replicon and full-length chimeric clone showed a clearly visible GFP expression of NS5A/GFP fusion protein that visualized by fluorescence microscopy and fusion protein can be detected by Western blot analysis. The replication of chimeric clones was confirmed by detecting positive strand HCV RNA by ribonuclease protein assay and the ability...
to form G418 cell colonies. We have now established several stable cell lines that support high-level replication of GFP-tagged sub-genomic HCV RNA. The level of viral replication between the wild type and chimeric clone is comparable. Huh-7.5 cells transfected with GFP tagged viral genomes produced infectious virus particles since expression of GFP was demonstrated in naive Huh-7.5 cells after virus infection. As a practical validation, we showed that replication and infectivity totally abolished by treatment with alpha interferon. Conclusion: We established a HCV cell culture system using GFP tagged viral genomic and sub-genomic clones that allow direct visualization of infected cells by fluorescence microscopy. These systems provide a powerful tool for the understanding of host-virus interactions and may provide a reliable model system to test varieties of anti-HCV substances. 444 ARREST OF NATURAL KILLER (NK) CELL DEVELOPMENT IN THE EARLY STAGES OF ACUTE HCV INFECTION MAY REPRESENT A DIRECT EFFECT OF HCV CORE PROTEIN

Lucy Golden-Mason1,2, Nicole Castelblanco1, Young S Hahn3, Hugo R. Rosen1,2; 1Division of Gastroenterology & Hepatology, Hepatitis C Center & Department of Medicine, University of Colorado Health Sciences Center, Denver, CO; 2Integrated Program in Immunology, University of Colorado Health Sciences Center & National Jewish Hospital, Denver, CO; 3Department of Microbiology & Pathology, University of Virginia Health Sciences Center, Charlottesville, VA

Background: NKs recognize conserved structures that signal viral invasion, thus providing an important first line of defense. In humans, relative expression of CD56 identifies functionally distinct subsets (CD56bright CD56dim) of NKs. An increased proportion of immature CD56bright NKs has been reported in patients with chronic HCV infection, however, little is known of NKs in the acute setting. HCV proteins, including core, demonstrate immuno-modulatory properties, however, the effect of core on NK cells has not previously been investigated. Aim: To characterize NKs in the early and late stages of acute HCV infection and examine the effect of core protein on NK development and function. Methods: Treatment naïve acute HCV patients (n=22), including 10 with spontaneous recovery, were studied. Flow cytometry was used to phenotype NKs directly ex vivo and after culture. Functional readouts included natural cytotoxicity and cytokine production (IFN-γ). FACS-sorted CD56bright and CD56dim NK subsets from healthy controls (n = 5) were cultured with control βgal protein or in the presence of HCV core protein and stimulated with IL-15 to drive NK cell maturation. Results: Direct ex vivo analysis of patients with acute HCV demonstrated there was an increased proportion of CD56bright NKs early in acute HCV infection per se which returned to normal levels on resolution but remained elevated in chronically evolving infection (p=0.0037). Divergent NK CD16 expression in resolving compared to chronically evolving patients late in acute HCV infection (p=0.03) provides further evidence of maturational arrest. Natural cytotoxicity was reduced in both the early and late stages of infection and did not recover to normal levels after viral clearance (follow-up 6 months). HCV resolution was characterized by lower than normal TNF production (p=0.01) by NK cells whereas IFN-γ production was unaffected. In vitro culture with HCV core protein in normal subjects maintained a significant proportion of immature NKs in the CD56bright state, whereas cells cultured with control protein all achieved a CD56dim phenotype. Culture with core protein induced TNF production by effector NKs. Conclusions: Maturational arrest of NKs occurs early in acute HCV but is transient in patients who spontaneously resolve infection. HCV-core protein has an immunomodulatory effect on NK cells. The in vitro effect of core-mediated NK dysregulation closely correlates with NK characteristics measured directly ex vivo in the setting of acute infection. Our data suggest that arrest of NK development in HCV infection may be a direct effect of core protein and may affect the outcome of acute infection.

445 HEPATITIS C VIRUS REPLICATION SENSITIZES HUMAN HEPATOMA CELLS TO TRAIL-INDUCED APOPTOSIS

Richard Fischer1, Sebastian Gorke1, Lin Lan1, Sibylle J. Rau1, Takaji Wakita2, Hubert E. Blum3, Mirjam Zeisel1, Thomas F. Baumert3; 1Department of Gastroenterology and Hepatology, University of Freiburg, Freiburg, Germany; 2Department of Virology II, National Institute of Infectious Diseases, Tokyo, Japan; 3Inserm U748, Université Louis Pasteur, Hopitaux Universitaires de Strasbourg, Strasbourg, France

Backgrounds and Aims: Several hepatitis C virus (HCV) proteins have been implicated to modulate apoptosis of HCV target cells. However, the molecular mechanisms leading to the death of hepatocytes during hepatitis C virus infection are only poorly understood. TRAIL, the TNF-related apoptosis-inducing ligand, has recently been implicated in the death of hepatocytes under inflammatory but not normal conditions. To determine the potential role of TRAIL in HCV-induced hepatitis and viral clearance, we studied the effect of HCV replication on TRAIL-induced apoptosis of human hepatoma cells. Methods: Huh7.5 cells were transfected with JFH-1, JFH-1/deltaE1E2, JFH-1/GND full-length and SGR/JFH-1 subgenomic HCV RNA. Apoptosis of Huh7.5 cells was studied by cleaved poly (ADP-ribose) polymerase-1 (PARP-1), caspase-8 and -9 activation and TUNEL assay. Results: Transfection of Huh7.5 cells with replication-competent JFH-1 but not with replication-deficient JFH-1/GND RNA resulted in apoptosis of Huh7.5 cells as shown by enhanced PARP cleavage, caspase activation and positive TUNEL staining. Following incubation with TRAIL, induction of apoptosis was markedly enhanced in Huh7.5 cells transfected with JFH-1 RNA compared to cells transfected with replication-deficient JFH-1/GND RNA or mock-transfected cells. A similar enhancement of TRAIL-mediated apoptosis was observed following transfection of hepatoma cells with JFH-1/deltaE1E2 and SGR/JFH-1 subgenomic HCV RNA suggesting that sensitization to TRAIL-induced apoptosis is independent of HCV structural protein expression but requires active viral replication. Conclusions: Our data suggest that HCV replication sensitizes hepatoma cells to TRAIL-induced apoptosis. These findings may have important implications for pathogenesis of hepatitis and mechanisms of viral clearance.

446 NEUTRALIZING ANTIBODY INDUCTION IN MONOTYPIC HEPATITIS C VIRUS INFECTIONS IN CHIMPANZEE DOES NOT CORRELATE WITH OUTCOME

Hisayoshi Watanabe1, Frances Wells2, Pei Zhang2, Marian E. Major1; 1Laboratory of Hepatitis Viruses/Division of Viral Products, CBER/FDA, Bethesda, MD; 2Division of Hematology, CBER/FDA, Bethesda, MD

Recent publications have suggested a correlation between neutralizing antibody (NAb) to HCV and clearance of virus. In order to test NAb to HCV in the context of the complete viral particle we constructed a 1a/2a chimera virus containing the H77 (1a) coreE1E2 region and the JFH1 (2a) non-structural region. Following a lag phase we observed rapid spread of the virus in cells with CPE at d7 (MOI=0.1) or peak titers at d14, 3x10^4 ffu/mL (MOI=0.01). Using this chimera, we tested NAb using sequential acute phase plasma from monotypic H77-infected chimpanzees, rechallenged chimpanzees, and chimpanzees vaccinated with rE1E2 protein. The kinetics of NAb production showed weak increases during the acute phase (wks 6-10) mainly in animals that eventually developed persistent infections and substantial increases during the chronic phase (post wk 30, 90% neutralization) in these same animals, while the kinetics of NAb production fluctuated during the acute phase in cleared animals. In contrast, we observed decreases in neutralization using late chronic phase plasma (wk 150), this may indicate mutations in the circulating virus that no longer stimulate antibody able to recognize the original sequence. When we compared the average number of foci with untreated control in the acute phase by Hest, there was a significant neutralization of virus at a number of time points although inhibition was <50%. This was observed at an earlier time point in the cleared animals than in the persistently infected group, but there was an absence of higher levels of NAb production in the cleared animals during the acute phase. In addition, we found that NAb does not play a role in controlling HCV during re-exposure to the virus after clearance, as no substantial levels of NAb could be detected in plasma from 3/3 animals rechallenged with monotypic virus. Vaccination of chimpanzees with rE1E2 protein elicited NAb (titers >1:1000). However, although this antibody recognized a highly conserved neutralizing antibody epitope (amino acids 412-419) it did not exhibit substantial levels of cross neutralization using the 2a genotype virus indicating that reactivity to this epitope alone is not an indicator of broad neutralizing ability. In conclusion, our data suggest that these antibodies do not play an important role in determining the outcome of infection.

447 SOCS-3 EXPRESSION AND HCV RELATED CHRONIC HEPATITIS: INSULIN RESISTANCE AND RESPONSE TO ANTIVIRAL THERAPY

Marcello Persico1, Mario Capasso2, Eliana Persico1, Monica Svelto1, Roberta Russo2, Daniela Spano2, Lori Crocè2, Vincenzo La Mura1, Francesco Maschella1, Flora Masutti1, Roberto Torella1, Claudio Tiribelli1, Achille Iolascon2

The response to antiviral therapy is lower in HCV patients with genotype 1 than in those with genotype 2. Overexpression of the suppressor cytokine signalling 3 (SOCS-3) gene in liver tissue was associated to a poorer treatment outcome in patients with chronic hepatitis C, viral genotype 1. Also insulin resistance has been implicated in non-response to anti-HCV treatment. To understand why HCV genotype 1 patients respond differently, we investigated SOCS-3 gene expression, the metabolic syndrome (MS) and the response to therapy in a cohort of patients with HCV-related hepatitis. A total of 198 patients (108 with genotype 1, and 90 with genotype 2) treated with pegylated-interferon plus ribavirin were consecutively enrolled in the study. We measured SOCS-3 expression in Epstein-Barr-virus-transformed lymphoblastoid cell lines derived from peripheral lymphocytes of a subset of 130 patients. The MS was more frequent in genotype-1 patients than in genotype-2 patients (p<0.01). Non responders (NR) (p<0.01), MS (p<0.001) and genotype 1 (p<0.001) were significantly related to SOCS-3 over-expression. However, SOCS-3 levels were higher in NR also irrespective of genotype (p<0.01). At univariate analysis, genotype (p<0.001), age (p<0.001), SOCS-3 (p<0.001) and MS (p<0.001) were significantly related to response to therapy. However, at multivariate analysis, SOCS-3 was the only independent predictor of response (OR: 6.7; p<0.005). Conclusions: We speculate that SOCS-3 expression per se may influence the response to antiviral therapy and that genotype 1b virus might induce its up-regulation. This may account for the different response to therapy between genotype-1 and genotype-2 infected patients.

448 COMPREHENSIVE ANALYSES OF HCV-RELATED CELL SIGNALING PATHWAYS USING CELLS WITH OR WITHOUT EXCLUSION OF HCV REPLICON AND THEIR CURED CELLS

Yuki Sakurai1, Naoya Sakamoto2,1, Mina Nakagawa2,1, Yoko Sekine-Osajima1, Megumi Tasaka1, Yasuhiro Iitsu2, Cheng-Hsin Chen1, Mamoru Watanabe1; 1Gastroenterology and Hepatology, Tokyo Medical and Dental University, Tokyo, Japan; 2Hepatitis Control, Tokyo Medical and Dental University, Tokyo, Japan

Background: HCV replication is closely associated with several host factors. In this study, we have analyzed cellular effects on HCV replication and host genes that may regulate the virus replication by comprehensive gene expression analyses in two types of replicon cells, their cured cells and the parental HuH7 cells. Material and Method: Chimeric gene of YFP and neomycin phosphotransferase (Yeo) was inserted into HCV-1b and -2a replicon, and HuH7 cell lines that express the Yeorepli- con were established. YFP expression was detected by fluorescence microscopy and by FACS analysis. The cured cell lines, which are highly permissive for replicon expression, were established from the replicon cell lines by eliminating replicon by interferon-alpha treatment. The high YFP-replicon expressing cells were separated using FACS Vantage SE cell sorting system. 54,461 gene expression profiles of those cell populations were analyzed by DNA microarray (Gene Chip, Affimetrix). And we conducted a comprehensive molecular pathway analyses using our gene expression data by using a functional mapping tool, MetaCore (GeneGo). Results: Comparison of replicon cells with cured cells showed that 83 and 196 genes were up- and down-regulated in replicon cells (>2-fold and <0.5 fold). Comparison of cured cells with parental HuH7 cells showed that 335 and 181 genes were up- or down-regulated in cured cells. In molecular network analyses, replicon cells showed activation of NF-kappa B, AP-1, PPAR-alpha-related
449 INFECTION OF PRIMARY HUMAN HEPATOCYTES WITH RECOMBINANT HEPATITIS C VIRUS

Attachment of the virus to the cell surface followed by viral entry is the first step in a cascade of events required for initiation of infection. Results obtained with surrogate model systems for HCV infection using human hepatoma cell lines suggest that HCV entry is most likely a multi-step process which requires a set of initial binding molecules such as glycosaminoglycans, as well as (co)-receptors for viral entry such as CD81, SR-BI and claudin-1. However, it still remains elusive which host cell factors are required for HCV entry into its natural target cell, the human hepatocyte. In this study, we used the recently established HCV/JFH-1 based-infectious tissue culture model system to generate high titer virion preparations (HCVcc) for infection of primary human hepatocytes (PHH). Cells were incubated with cell culture adapted JFH-1 with proven in vivo viability in the presence or absence of an NS3 protease inhibitor. Infection was assessed by measuring HCV RNA by quantitative RT-PCR at different time-points post infection. PHH could be reproducibly infected with HCVcc as shown by a time-dependent increase of HCV RNA in infected hepatocytes which was not observed when cells were treated with the NS3 protease inhibitor. Studies to assess the impact of CD81, SR-BI and claudin-1 as host entry factor for HCV infection of primary human hepatocytes are ongoing. In conclusion, our results suggest that PHH can be infected with cell culture grown HCV. This model system will allow further dissecting molecular mechanisms of HCV infection of its natural target cell - the human hepatocyte.

450 AN ASSESSMENT OF THE ROLE OF SREBP1C IN THE PATHOGENESIS OF HCV-RELATED STEATOSIS

Stuart McPherson1,2, Julie R. Jonsson2, Helen D. Barrie3, Andrew D. Clouston2, Elizabeth E. Powell1,2; 1Hepatology, Princess Alexandra Hospital, Brisbane, QLD, Australia; 2Southern School of Medicine, University of Queensland, Brisbane, QLD, Australia; 3University of Newcastle, Newcastle upon Tyne, United Kingdom

Background: Hepatic steatosis occurs in 50% of subjects with hepatitis C virus (HCV) infection and is a risk factor for more rapid disease progression. Both metabolic and viral factors are involved in the pathogenesis of HCV-associated steatosis, which remains incompletely understood. Sterol regulatory element binding protein 1c (SREBP1c) is a transcription factor that regulates the expression of lipogenic genes, increasing fatty acid and triglyceride synthesis. SREBP1c is elevated in the fatty liver of obese, insulin resistant mice and has been implicated in the pathogenesis of hepatic steatosis. The role of SREBP1c in the pathogenesis of HCV-related steatosis is unknown. Aim: To investigate the role of SREBP1c in the pathogenesis of HCV-related steatosis. Methods: Expression of SREBP1c mRNA was measured by real-time (RT)-PCR in liver biopsy samples from 123 patients with chronic HCV (80 male), 12 with chronic Hepatitis B (HBV) (3 male) and 14 HCV/HBV-negative subjects with histologically normal liver (NDL). Fasting serum was collected at the time of liver biopsy and assessed for levels of insulin and glucose. Results: Increased hepatic expression of SREBP1c was seen in patients with chronic HCV (p=0.007) and chronic HBV (p=0.002) compared with NDL. There was no difference in SREBP1c expression between subjects with HCV and HBV (p=0.11). In the patients with HCV, a statistically significant negative correlation was seen between hepatic SREBP1c expression and stage of fibrosis (r=-0.375, p<0.001), severity of hepatic inflammation (r=-0.313, p<0.001) and grade of steatosis (r=-0.28, p=0.002). There was a trend towards increased hepatic SREBP1c expression in subjects with HCV genotype 1 compared to genotype 3 (p=0.06). Overall in subjects with HCV, no relationship was seen between hepatic SREBP1c expression and BMI, HOMA score, or alcohol intake. Following multivariate analysis (adjusting for age, gender, viral genotype, BMI, HOMA, fibrosis, steatosis and hepatic inflammatory score), hepatic SREBP1c expression remained independently associated with fibrosis (p=0.003), viral genotype (p=0.006) and hepatic inflammation (p=0.01). Conclusions: Hepatic expression of SREBP1c was elevated in subjects with chronic HCV and chronic HBV compared with HCV/HBV-negative control subjects. However, unexpectedly, increasing grade of steatosis and stage of fibrosis was associated with a decrease in the expression of SREBP1c, suggesting that it may not play a prominent role in the pathogenesis of hepatic steatosis in HCV.

IN Volvement OF IL-7 AND Thymic Stromal Lymphopoietin IN Functional Impairment OF Myeloid Dendritic Cells IN Chronic Hepatitis C Virus Infection

Hideki Miyatake1, Tatsuya Kanto1, Michiyu Inoue1, Mitsuaki Sakakibara1, Ichio Ilose1, Masanori Miyazaki1, Naruyasu Kakita1, Naoki Hiramatsu1, Tetsuo Takehara1, Akinori Kasahara2, Norio Hayashi2; 1Department of Gastroenterology and Hepatology, Osaka University Graduate School of Medicine, Suita, Japan; 2Department of General Medicine, Osaka University Graduate School of Medicine, Suita, Japan

BACKGROUND AND AIMS: It has been reported that impaired functions of CD4 or CD8 T cells or dendritic cells (DC) are involved in HCV persistence, however, the precise mechanisms remains unclear. IL-7 is a lymphopoietic cytokine that acts on differentiation and maintenance of activity of lymphocytes or DC. Lesser expression of IL-7R on T cells has been reported in acute hepatitis C patients who eventually progressed to chronicity, suggesting the critical role of IL-7/IL-7R system in HCV infection. Thymic stromal lymphopoietin (TSLP), an IL-7-like hematopoietic cytokine, is a potent activator of myeloid DC (MDC) and activated CD4 T cells. The involvement of TSLP in allergic diseases has been reported, however, its role in HCV infection is poorly understood. To elucidate the role of IL-7/TSLP in chronic hepatitis C (CHC), we examined serum levels of these cytokines and their influences on the function of blood MDC. SUBJECTS AND METHODS: Sixty CHC patients and age-matched 60 healthy volunteers (HV) were enrolled in this study. Plasma levels of IL-7 and TSLP were measured by ELISA. MDC were magnetically separated from PBMC and were cultured in the presence of IL-7 (IL-7-DC), TSLP (TSLP-DC), or medium alone (med-DC). After 24h, we compared their phenotypes and stimulatory capacity of naive CD4 T cells between the groups. The ability of MDC to induce Th1 or Th2 was analyzed by cytokines released from DC-primed T cells. RESULTS: The levels of IL-7 and TSLP are lower in CHC compared with those in HV (p<0.05, respectively). In some CHC patients who cleared HCV by 48 weeks of peg-IFN-α and ribavirin combination therapy, TSLP levels elevated to the normal range after the completion of therapy, suggesting that HCV is involved in lower level of TSLP. In contrast, such restoration by HCV clearance was not observed in IL-7 levels. Both in CHC patients and HV, IL-7- and TSLP-DC displayed higher expression of CD86 and CD80 compared with med-DC (p<0.05, respectively). In HV group, IL-7- or TSLP-DC were more capable of CD4 T cell proliferation than med-DC. In CHC patients, IL-7-DC ability to stimulate T cell proliferation was less than that of IL-7-DC from HV or TSLP-DC either from CHC or HV (p<0.05), suggesting that MDC from CHC have lesser capacity of responding to IL-7. In DC ability to induce Th1/Th2 response, IL-7-DC from CHC primed T cells to produce more IL-13 than those from HV (p<0.05), while there was no difference in IL-13 release from TSLP-DC-primed T cells between the groups. CONCLUSION: Low level of IL-7/TSLP and lesser Th2-prone ability of MDC to stimulate CD4 T cells in response to IL-7 may be involved in functional impairment of MDC in HCV infection.

INSULIN RESISTANCE IN CHRONIC HEPATITIS C: A PROSPECTIVE STUDY SHOWING AN ASSOCIATION OF INSULIN RESISTANCE WITH GENOTYPES 1 AND 4, VIRAL REPLICATION AND LIVER FIBROSIS

Rami Moucari1,2, Tarik Asselah1,2, Dominique Cazals-Hatem3, Hélène Voitot1, Nathalie Bayer1, Marie-Pierre Ripaill1, Rodolphe Sobesky1, Michèle Martinot-Peignoux4, Sarah Maylin2,4, Marie-Hélène Nicolas-Chanoine2, Dominique Valla1,2, Michel Vidal3, Pierre Bedossa1,2, Patrick Marcellin1,2,5, Hépatologie, Beaujon Hospital, Clichy, France; 2Pathology, Beaujon Hospital, Clichy, France; 3Biochemistry, Beaujon Hospital, Clichy, France; 4Microbiology, Beaujon Hospital, Clichy, France; 5INSERM U773-CRB3, Beaujon Hospital, Clichy, France

Background and Aims: There is growing evidence of an association between chronic hepatitis C and insulin resistance. However, the influence of viral factors such as HCV genotypes and viral replication level has not been well assessed. Another major issue is the relationship between liver fibrosis and insulin resistance. While this association was well demonstrated in non-alcoholic fatty liver disease, it remains controversial in chronic hepatitis C. The aim of this study was to analyze the association between insulin resistance, and HCV genotypes, viral replication level and liver fibrosis stage in a large prospective cohort of patients with chronic hepatitis C. Patients and Methods: 600 consecutive patients [chronic hepatitis C (n=500); chronic hepatitis B (n=100)] were evaluated on the day of liver biopsy. Insulin resistance (Homeostasis Model) and all components of the metabolic syndrome were assessed. Independent factors associated with insulin resistance (HOMA-IR >3) and significant fibrosis (META VIR F2-F4) were analyzed. Parameters of insulin resistance were compared between matched chronic hepatitis B and chronic hepatitis C patients. Results: The characteristics of chronic hepatitis C patients were: male gender (57%), mean age 47±10 years, mean BMI 24.8±4 kg/m2, metabolic syndrome (12%), diabetes mellitus (7.6%) and insulin resistance (35.6%). With multivariate analysis, insulin resistance was associated in non-diabetic patients with the metabolic syndrome, genotypes 1 and 4, significant fibrosis and severe steatosis. Insulin resistance was diagnosed in 15% of 145 patients without metabolic disorders or significant fibrosis, and associated with genotypes 1 and 4, high serum HCV RNA level and moderate-severe liver necroinflammation. Insulin resistance was less frequent in chronic hepatitis B than in matched chronic hepatitis C patients (5% vs. 35%; p<0.001). With multivariate analysis, significant fibrosis was associated in chronic hepatitis C patients with: male gender, age>40 years, insulin resistance, moderate-severe liver necroinflammation, and severe steatosis. Interestingly, HOMA-IR increased significantly and progressively with the fibrosis stages, whereas the C-peptide/insulin ratio was not different. Conclusion: Insulin resistance is a specific feature of chronic hepatitis C, especially with genotypes 1 or 4. Insulin resistance is significantly associated with serum HCV RNA level and fibrosis stage. Therefore, insulin resistance should be systematically assessed and its management could have a major impact on the outcome of chronic hepatitis C patients.

The influence of adipose tissue and its cytokines on the regulation of metabolic and immunological processes is an area of considerable research. We hypothesize that adiponectin plays an important role in regulating the immune response in chronic HCV. The aims of the study are to: 1) Determine the relationship between serum adiponectin levels and the HCV specific immune responses; 2) Examine the direct effect of adiponectin on the peripheral immune response in chronic HCV; 3) Elucidate the molecular pathways whereby adiponectin mediates its regulatory effects on the immune response in chronic HCV. Methods: The serum concentration of adiponectin from 26 HCV infected patients was determined by a multiplex cytokine assay. T-cell specific immune response to HCV was determined by the IFN-γ ELISPOT and a Multiplex cytokine assay after stimulation of PBMCs from patients with pools of overlapping HCV peptides representing the entire HCV polyprotein. Assays were conducted in the presence of either HCV peptides, recombinant adiponectin or PBMCs treated with adiponectin and HCV peptides. Depletion of CD4 and CD8 cells from PBMCs was achieved by utilizing antibody bound microbeads. Activation of P38MAPK in response to adiponectin was determined by Western blotting. Results: There was a strong positive association between the concentration of serum adiponectin levels and the presence of an anti-HCV specific T cell response (p=0.005). Adiponectin serum levels were significantly decreased in HCV infected patients with increased BMI. Pre-treatment of PBMCs with recombinant adiponectin prior to HCV peptide stimulation significantly enhanced IFN-γ production (p=0.03). Further experiments confirmed T cells (CD4 and CD8 T cells) as the cellular source of the IFN-γ response to adiponectin. Cytokine assays showed that pre-treatment of PBMCs with adiponectin prior to HCV peptide stimulation resulted in increased expression of IFN-γ (p=0.03) while reducing the expression of HCV-induced IL-6 production (p=0.02). In addition, adiponectin treatment resulted in activation of the P38MAPK pathway. Selective inhibition of P38MAPK activity by SB203580 blocked the IFN-γ response by PBMCs to adiponectin. Conclusions: The data indicate that adiponectin plays a key role in regulating the immune response in patients with chronic HCV infection. Thus, low adiponectin levels in obese subjects with HCV infection may alter T cell function and shift the cytokine responses towards a pro-viral state. Further, the effect of adiponectin on the immune response appears to be in part mediated by the P38MAPK signaling pathway.

Functional polymorphisms in adrenergic receptors and in adiponectin and its receptors have been reported to be associated with various phenotypes of the metabolic syndrome such as diabetes and obesity and also impact on the course of chronic HCV infection. In this study, we aimed to evaluate in HCV-infected subjects whether liver injury and response to antiviral therapy are influenced by polymorphisms in genes for the adrenergic receptors (ADRs) [alpha 2A, beta 2, beta 3] and genes for adiponectin and its receptors (1 and 2). Methods: 26 single nucleotide polymorphisms (SNPs) were tested across 12 genes for an association with liver fibrosis and response to antiviral therapy. Examined genes included ADRB2-related allelic variants [Arg16Gly, Gln27Glu, Thr164Ile], ADRB3 (Trp64Arg), ADR-alpha2B (Glu del 301-101), adiponectin (G276T) and adiponectin receptors 1 and 2. Gene polymorphisms were determined by direct sequencing of the polymerase chain reaction products. Comparisons within each group were performed with the Chi-squared tests. Categorical variables were compared using Fisher’s exact test. Results: The majority of the cohort were Caucasian 67%, and 60% were male, the mean age was 38 ± 15 yr. A significant association was present between the ADRB2 Gln27Glu allele and the presence of advanced fibrosis (OR 12.3, p=0.04). Failure to respond to antiviral therapy was strongly detectable in subjects with the variant alleles ADRB2 Gln27Glu (OR 2, p=0.02) or ADRB3 Trp64Arg (OR 2.2, p=0.04). Subjects with adiponectin G276T showed a trend towards a poor response to antiviral therapy (p=0.06). Further, adiponectin G276T and ADRB3 polymorphisms synergistically influenced the response to antiviral therapy (OR 2, p=0.01). In multivariate analysis including age, BMI, gender and alcohol intake, the association between ADRB2 Gln27Glu and fibrosis as well as response to therapy was still evident (p=0.04, & 0.03 respectively). The ADRB2 Gln27Glu polymorphism was present in 30% of the examined cohort, was more frequent in males than females (p=0.04) and Caucasians than African Americans (p=0.02). A correlation was present between the ADRB2 Gln27Glu polymorphism and increased BMI (p=0.005). Conclusions: These novel findings confirm in HCV infected subjects, that polymorphisms for the adrenergic receptor genes (in particular ADRB2 Gln27Glu) are associated with increased hepatic fibrosis and poorer responses to antiviral therapy. Similarly, adiponectin polymorphisms effect responses to antiviral therapy.

INVESTIGATION OF RESIDUAL HEPATITIS C VIRUS (HCV) IN PRESUMED RECOVERED SUBJECTS

Kei Fujiwara, Richard Y. Wang, Robert D. Allison, Cathy Schechterly, Francesco M. Marincola, Harvey Alter; Department of Transfusion Medicine, Clinical Center, National Institutes of Health, Bethesda, MD

Background: Published studies have suggested that peripheral blood mononuclear cells (PBMCs) serve as a reservoir of residual HCV even in persons persistently HCV RNA negative in plasma. Aims: 1) To measure HCV RNA in PBMC and specific mononuclear cells of chronically infected and recovered subjects; 2) To determine if PBMC-associated HCV RNA is in a replicative form; 3) to determine if HCV might bind to PBMC without infecting them. Methods: 29 patients with chronic hepatitis C and 23 presumed recovered subjects (repeatedly anti-HCV+, HCV RNA-) were studied. Viral load was determined by Cobas Amplicor (Roche Diagnostics) and an in-house nested real-time detection PCR (n-RTD PCR). Negative strand HCV RNA was detected using strand-specific n-RTD PCR. Subsets of PBMC were separated on a magnetic cell separator. Results: 28/29 chronic carrier PBMC tested HCV RNA+. In 8 patients where PBMC subpopulations were tested, the viral load (log copies/106 cells) in the B cell subset (4.14 ± 0.71) was higher than in total PBMC (3.62 ± 0.71, p< 0.05), T cells (1.67 ± 0.88, p< 0.05), and non-B/T cells (2.48 ± 1.15, p< 0.05). HCV negative-strand (replicative intermediate) RNA was not detected in any of 25 PBMC samples, or 8 B, T, or non-B/T subsets. Further, healthy donor PBMC, when mixed in-vitro with HCV RNA+ plasma, incubated at RT for 2 hours and extensively washed, became HCV RNA+ and mimicked cells recovered from chronic carriers (total PBMC: 3.46 ± 0.14 log copies/106 cells; B cells 4.35 ± 0.07, p<0.001). Based on these findings in chronic carriers, residual HCV was sought in presumed recovered patients; no residual virus was detected in PBMC, the B cell subset, or in plasma of any of 23 presumed recovered patients. Conclusions: 1) HCV can be detected in PBMCs in patients with chronic hepatitis C and is recovered predominantly in B cell subpopulations; 2) HCV detected in PBMC does not contain negative strand RNA and is presumed non-replicative; 3) PBMC from normals can take up HCV viral particles in vitro when mixed with HCV+ plasma and then mimic cells recovered from HCV-infected patients suggesting that HCV binds to, but does not infect or replicate in PBMC; 4) Residual HCV was not detected in any of 23 recovered patients suggesting that PBMC do not generally serve as a reservoir of persistent HCV infection in patients otherwise presumed to have recovered.

UPREGULATION OF PROGRAMMED DEATH-1 (PD-1) ON HCV-SPECIFIC AND CMV-SPECIFIC CD8+ T CELLS IN CHRONIC HCV INFECTION ASSOCIATED WITH REVERSIBLE IMMUNE EXHAUSTION

Lucy Golden-Mason1,2, Brent Palmer3, Jared Klarquist1, John A. Mengshol1, Nicole Castelblanco3, Hugo R. Rosen1,2; 1Division of Gastroenterology & Hepatology, Hepatitis C Center & Department of Medicine, University of Colorado Health Sciences Center, Denver, CO; 2Integrated Program in Immunology, University of Colorado Health Sciences Center & National Jewish Hospital, Denver, CO; 3Division of Clinical Immunology, University of Colorado Health Sciences Center & National Jewish Hospital, Denver, CO

The inhibitory molecule programmed death-1 (PD-1) is up-regulated on exhausted virus-specific CD8+ T cells (CTLs) in mice with LCMV and humans with HIV; emerging data indicate a significant role for this immunoreceptor in HCV. Here, we examined PD-1 expression on peripheral and intrahepatic (IH) CTLs and assessed the effect of PD-1 blockade on the functional competence of HCV-specific CTLs. Methods: Four groups were studied: chronic HCV (n=31), including 13 patients from whom IH lymphocytes were studied directly ex vivo; HCV spontaneous resolvers (n=11); non-HCV liver disease (n=12); ten healthy subjects served as controls. Different pentamers were used to screen viral-specific CTLs. CD4+ T cell responses were assessed using overlapping peptides spanning the entire HCV polyprotein in an IFN-g ELISPOT. Results: HCV-specific CTLs displayed levels of PD-1 that were markedly elevated in patients with chronic HCV relative to resolved HCV infection (figure below). PD-1 MFI, which correlates directly with the number of molecules expressed on a per cell basis, was higher on HCV-specific CTLs within the IH compartment compared to peripheral blood. CD57+ level was greater in chronic than resolved infection on both PD-1 high and PD-1 low fractions. The effect of HCV on PD-1 expression extended to non-HCV-specific cells: CMV-specific CTLs exhibited higher PD-1 in patients with chronic HCV compared to non-HCV liver disease patients and normals (p=.007). Next, CFSE was used to monitor proliferation of HCV CTLs following in vitro blockade with monoclonal Abs specific to its ligands. Blockade with either anti-PDL-1 or anti-PDL-2 antibodies enhanced proliferation 2-fold whereas dual blockade of PD-1 and LFA-3 with Abs specific to its ligands enhanced proliferation 4-fold.

HEPATITIS C VIRUS-INDUCED REACTIVE OXYGEN SPECIES CAUSE IRON ACCUMULATION IN MICE BY REDUCING HEPcidIN TRANSCRIPTION

Sohji Nishina1, Keisuke Hino2, Masaaki Korenaga1, Antonello Pietrangelo3, Yoichi Mizukami3, Takakazu Furutani1, Michiari Okuda1, Isao Hidaka1, Kiwamu Okita4, Isao Sakaida1; 1Department of Gastroenterology and Hepatology, Yamaguchi University Graduate School of Medicine, Ube, Japan; 2Department of Basic Laboratory Sciences, Yamaguchi University Graduate School of Medicine, Ube, Japan; 3Department of Center for Gene Research, Yamaguchi University Graduate School of Medicine, Ube, Japan; 4Department of Gastroenterology and Hepatology, Shimonseski Kohsei Hospital, Shimosekai, Japan; 5Center for Hemoschromatosi, Department of Internal Medicine, University of Modena and Reggio Emilia, Modena, Italy

Background and Aims: Despite abundant clinical evidence, the mechanisms by which hepatic iron overload develops in patients with hepatitis C virus (HCV)-associated chronic liver diseases remain unknown. The aim of this study was to investigate how hepatic iron overload develops in the presence of hepatitis C virus (HCV) proteins. Methods: Male C57BL/6 transgenic mice expressing the HCV polyprotein and nontransgenic littermates were assessed for iron concentrations in the liver, spleen and serum, and iron regulatory molecules in vivo. Reporter gene assays were performed for primary mouse hepatocytes to study promoter activity of hepcidin. We also performed electrophoretic mobility shift assay using mouse nuclear extracts to examine DNA binding activity of transcriptional factors. Results: Transgenic mice had lower hepcidin expression in the liver accompanied by higher expression of ferroportin in the duodenum and spleen, which led to increased hepatic and serum iron concentrations, and a decreased splenic iron concentration. The expression level of divalent metal transporter 1 in the duodenum was not different between transgenic and nontransgenic mice. In response to hepatocellular iron excess, transferrin receptor 1 expression decreased and ferritin expression increased in the transgenic liver. Transgenic mice showed no inflammation in the liver, but preserved the ability to induce hepcidin in response to proinflammatory cytokines induced by lipopolysaccharide. Hepcidin promoter activity and the DNA binding activity of CCAAT/enhancer-binding protein alpha (C/EBPα) were down-regulated concomitantly with increased expression of C/EBPα homology protein (CHOP), an inhibitor of C/EBP DNA binding activity, and the abundance of reactive oxygen species (ROS) in transgenic mice at the ages of 8 and 14 months. The expression level of C/EBPα in the liver was not different between transgenic and nontransgenic mice. In response to hepatocellular iron excess, transferrin receptor 1 expression decreased and ferritin expression increased in the transgenic liver. Transgenic mice showed no inflammation in the liver, but preserved the ability to induce hepcidin in response to proinflammatory cytokines induced by lipopolysaccharide. Hepcidin promoter activity and the DNA binding activity of CCAAT/enhancer-binding protein alpha (C/EBPα) were down-regulated concomitantly with increased expression of C/EBPα homology protein (CHOP), an inhibitor of C/EBP DNA binding activity, and the abundance of reactive oxygen species (ROS) in transgenic mice at the ages of 8 and 14 months. The expression level of C/EBPα in the liver was not different between transgenic and nontransgenic mice. Conclusions: HCV-induced ROS down-regulate hepcidin transcription through inhibition of C/EBPα DNA binding activity by CHOP, which in turn leads to increased duodenal iron transport and macrophage iron release, causing hepatic iron accumulation. This finding provides a potential mechanistic pathway for HCV-induced iron accumulation in the liver, even though the present model is different to what is observed in patients with chronic hepatitis C with respect to a lack of inflammation.

NATURAL HCV CORE VARIANTS REDUCE CELL GROWTH INHIBITION AND FACILITATE INDUCTION OF EPITHELIAL TO MESENCHYMAL TRANSITION (EMT) MEDIATED BY TGF-BETA

Serena Battagia1, Soizic Nobilet1, Olivier Bregerie1, Michelle Gigou1, Pierre Charneau2, Christian Bréchot1, Marie F. Bourgeade1; 1CHB, INSERM, Villejuif, France; 2Virology, Institut Pasteur, Paris, France

The HCV core protein is a pleiotropic modulator of cell growth and viability which likely participates in HCV-related HCC. Although the precise mechanisms involved are still unclear, the TGF-β plays a major role in fibrosis and exerts a biphasic action during tumor progression, thereby acting as a tumor suppressor at early stages and as an enhancer of invasiveness at later stages. We have previously demonstrated that HCV core variants isolated from tumor and non-tumor nodules differentially bind Smad3, a transcriptional factor mediating the TGF-β specific signalling pathway but the biological relevance of this interaction remains to be established. We here present three major findings that shed light into the functional consequences of HCV core protein modulation of TGF-β signalling. First, the tumor-suppressive effects of TGF-β, in term of cell growth inhibition and apoptosis are highly reduced in Huh7 cell lines stably expressing these natural HCV core variants. Second, the same inhibitory effects on TGF-β cytostatic effects were obtained in both primary human hepatocytes expressing these HCV core variants after lentivirus transduction and primary hepatocytes isolated from transgenic mice expressing the same core sequences. Third, core variants increased the TGF-β-mediated EMT (epithelium to mesenchymal transition), a process involved in tumor spreading and invasiveness. These results define a new concept where HCV could participate to fibrosis by increasing TGF-β levels and later contribute to HCC development by emergence of new variants that are able to switch TGF-β responses from tumor suppression to tumor promotion functions.

A CIRRHOSIS RISK SCORE IDENTIFIES THOSE CHRONIC HEPATITIS C INFECTED PATIENTS PRESENTING WITH NO LIVER FIBROSIS THAT ARE AT HIGH RISK FOR FIBROSIS PROGRESSION

Bradford Young1, Martina Gerotto2, Moira Marcolongo2, Francesca Dal Pero2, Robert Lagier1, Charles Rowland1, Giada Sebastiani2, Alfredo Alberti2,3,1 Celeria, Alameda, CA; 2 Venetian Institute of Molecular Medicine, Padova, Italy; 3 Department of Clinical and Experimental Medicine, University of Padova, Padova, Italy

Background and Aims: Chronic hepatitis C (CHC) infection can promote liver fibrosis, yet the time course for fibrosis progression is highly variable and can be influenced by host factors including gender, age at infection, alcohol consumption and genetic variants. Recently, we described seven genetic variants that identify CHC patients at risk for developing cirrhosis and created a Cirrhosis Risk Score (CRS) that is calculated based on these seven SNPs and the patient’s gender. In this study, we asked whether the CRS could identify CHC patients at high risk for fibrosis progression. Methods: We examined Caucasian patients with CHC infection enrolled from the University of Padova, Italy. These patients received two liver biopsies spon-
ing an average interval of 80 months and had their biopsies scored according to the META VIR units (F0-F4) prior to receiving any treatment. For each patient, genomic DNA was isolated from whole blood and genotypes for the CRS genetic markers determined using a multiplex PCR and Oligonucleotide Ligation Assay based on the LumineX® 200TM System. Association of the proportion of F0 patients remaining at F0 at the second biopsy across low (0 to 0.5), intermediate (0.5 to 0.7) and high (0.7 to 1.0) CRS scores was assessed using the Armitage trend test. Results: Among 50 CHC patients with F0 at their first biopsy, 57% (9 of 16) with a low CRS remained at F0 at the second biopsy compared to 42% (8 of 19) with intermediate CRS and 20% (3 of 15) with a high CRS, trend test p value of 0.04. Since gender is a component of the CRS score, we also analyzed the data separately by gender although power was limited. Among females, we found no significant difference (p value = 0.73) in the proportion of subjects remaining at F0 at the second biopsy. However, in males, there remained a significant trend (p value = 0.02; age adjusted p value = 0.04) with 57% (4 of 7) of low CRS males remaining at F0 compared to 22% (2 of 9) with intermediate CRS and 14% (1 of 12) with high CRS. Conclusion: In this study, increasing CRS was associated with fibrosis progression in CHC infected patients presenting with no liver fibrosis. Previously, we described the ability of CRS to identify CHC patients at high risk for cirrhosis in patients enrolled from 5 US centers. This current study suggests that the CRS may identify CHC patients at high risk for fibrosis progression and the potential generalizability of the CRS to other non-US populations. Collectively, these studies suggest that the CRS genetic signature could potentially be a useful prognostic indicator of those patients with CHC infection most likely to develop fibrosis progression and/or cirrhosis.

460 EFFECTS OF HEME OXYGENASE-1 (HO-1) OVEREXPRESSION ON HEPATITIS C VIRUS (HCV) REPLICATION AND CELLULAR INJURY IN VITRO
Zhaowen Zhu1,2, Meleah Mathahs2,1, Feng Wen1,2, Kyle Brown2,1, Bruce A. Luxon1,2, Warren N. Schmidt1,2; 1Division of GI & Hepatology, Department of Internal Medicine, University of Iowa, Iowa City, IA; 2Research Services, Veterans Administration Medical Center, Iowa City, IA

Introduction. Oxidative injury to hepatocytes occurs as a consequence of HCV infection, replication, and viral protein expression. Modulation of host cell antioxidant enzymes is an attractive, yet unexplored strategy that potentially may minimize cellular injury, reduce viral replication and ultimately attenuate liver disease. We have previously described interactions of HCV viral proteins with HO-1, an important antioxidant enzyme that is induced in hepatocytes in response to oxidative stress. The focus of this work was to evaluate the effects of HO-1 overexpression on HCV replication and hepatocellular injury.

Methods. Full length (FL) or Non-structural (NS) replicons (I 389 NS3-3') were transfected with plasmid containing complete human HO-1 sequences or empty vector for control. Clonal cell lines overexpressing HO-1 (2.5 fold above basal values) or empty vector were isolated and quantified for HCV RNA synthesis, viral protein production and resistance to oxidative injury. Results. HO-1 overexpression markedly decreased HCV RNA synthesis in both FL and NS replicons (2- and 4-fold respectively) without affecting cellular growth or DNA synthesis. Both FL and NS replicons overexpressing HO-1 showed reduced prooxidant production as measured by dichlorofluorescein assay and increased resistance to peroxide toxicity. HO-1 overexpression also led to differences in levels of viral proteins with an increase in HCV core protein, but a decrease in NS5A levels in Huh7.5 FL replicon cells transfected with HO-1. Conversely, knock-down of HO-1 mRNA by siRNA in control FL or NS replicons with basal levels of HO-1 did not alter HCV replication but reduced expression of HCV core protein by greater than 50% with no change in NS5A level. Conclusions. Overexpression of HO-1 decreases HCV replication and protects from oxidative injury. Overexpression of HO-1 or knock-down of HO-1 mRNA leads to differential expression of HCV viral proteins which may, in part, mediate the observed changes in HCV replication and susceptibility to cellular injury. These findings suggest a potential role for HO-1 in antiviral therapy and protection against hepatocellular injury in hepatocytes infected with HCV.

461 COMPREHENSIVE GENE EXPRESSION ANALYSIS OF IRON METABOLISM-RELATED GENES IN PATIENTS WITH CHRONIC VIRAL HEPATITIS AND HEPATOCELLULAR CARCINOMA
Masao Honda, Teruyuki Ueda, Taro Yamashita, Ryuhei Nishino, Hajime Takatori, Shuichi Kaneko; Gastroenterology, Graduate School of Medical Science, Kanazawa University, Kanazawa, Japan

Objective: Abnormal iron metabolism generates oxidative stress, DNA damage and cellular injuries that accelerate the progression of various liver diseases. We have reported gene expression profiling of chronic hepatitis (CH)-B, CH-C and hepatocellular carcinoma (HCC) using a cDNA microarray and serial analysis of gene expression (SAGE) (Hepatology. 2006, 44, 1122). To elucidate the functional role of iron metabolism in these liver diseases, we examined iron metabolism-related gene expression and analyzed the patho-physiological roles of these genes in liver disease. Material and Methods: Liver tissue samples were obtained from 36 patients with CH-B, 34 patients with CH-C, 17 patients with HBV-related HCC (HCC-B), 17 patients with HCV-related HCC (HCC-C) and 10 patients with normal livers. Gene expression profiling was obtained from these samples using an in-house cDNA microarray comprising 9614 clones selected from 256,550 tags of hepatic SAGE libraries. Results: We selected and evaluated the expression of 47 iron metabolism-related genes. These genes included iron-binding proteins, iron transport proteins, mitochondrial electron transport enzymes and oxidative-related enzymes. The comparison of CH-C and normal liver showed that genes related to iron storage, such as transferring receptor, DMT-1, sideroflexin 1 and transferrin were upregulated in CH-C. These genes are involved in iron uptake, iron transport from endosome to cytosol, iron transport to mitochondria and iron storage. In contrast, hepcidin, an inhibitor of iron uptake from the intestine, was significantly downregulated in CH-C. Interestingly, when gene expression was compared between CH-C and CH-B, hepcidin was significantly downregulated in CH-C and ferroportin-1, which is repressed by hepcidin, was significantly upregulated in CH-C. Iron metabolism is thus more activated in CH-C than in normal liver or CH-B. Consistent with these findings, genes related to electron transport enzyme

AN ASSESSMENT OF THE ROLE OF ENDOPLASMIC RETICULUM (ER) STRESS IN THE PATHOGENESIS OF HCV  
Stuart McPherson1,3, Elizabeth E. Powell1,2, Helen D. Barrie1, Andrew D. Clouston2, Julie R. Jonsson3,  
1Hepatology, Princess Alexandra Hospital, Brisbane, QLD, Australia; 2Southern School of Medicine, University of Queensland, Brisbane, QLD, Australia; 3University of Newcastle, Newcastle-upon-Tyne, United Kingdom  
Background: Viruses are dependent on the endoplasmic reticulum (ER) to correctly fold and process viral proteins. If the ER becomes overloaded, unfolded or misfolded proteins accumulate causing ER stress, which triggers downstream intracellular pathways that globally attenuate the translation of mRNA, increase the production of molecular chaperones to aid protein folding, and promote cellular apoptosis. ER stress may also cause mitochondrial dysfunction, oxidative stress and cellular injury. A number of hepatitis C virus (HCV) proteins have been shown to induce ER stress in experimental models, however, it remains to be determined whether ER stress has a role in the pathogenesis of HCV-induced liver injury. Aims: To investigate the role of ER stress in the pathogenesis of HCV Methods: Liver biopsy samples from 123 patients with chronic HCV, 12 with chronic hepatitis B (HBV) and 14 HCV/HBV-negative subjects with histologically normal liver (NDL) were assessed. The mRNA expression of markers of ER stress (PERK, ATF6 and IRE1 pathways) were measured by real-time (RT)-PCR. Results: A comparison of the hepatic expression of ER stress markers between groups is shown in the Table. In comparison to NDL, subjects with HCV have significant upregulation of the PERK pathway and downregulation of the ATF6 pathway. Subjects with HBV have upregulation of the PERK and IRE1 pathway compared to NDL. There was significant upregulation of the PERK and IRE1 pathways in subjects with HBV compared with HCV. Among the patients with HCV, the expression of ER stress markers was higher in subjects with genotype 3 compared with genotype 1 (CHOP (p=0.02), GADD34 (p=0.01), EDEM (p=0.02), sXBP1 (p=0.02)). There were no relationships between the expression of ER stress markers and liver histology (inflammation, fibrosis or steatosis), BMI, HOMA score or alcohol intake in subjects with HCV. Conclusions: We observed differential expression of the hepatic ER stress pathways in subjects with HCV and HBV compared to NDL. In particular there was increased expression of CHOP which is known to increase the susceptibility to cell death.

PROTECTION BY HLA-B27 IN HCV INFECTION: ROLE OF VIROLOGICAL AND IMMUNOLOGICAL FACTORS  
Christoph Neumann-Haefelin1, Eva Dazert2, Susan McKiernan3, Dermot Kelleher3, Hubert E. Blum1, Ralf Bartenschlager2, Robert Thimme1, 1Department of Medicine II, University Hospital Freiburg, Freiburg, Germany; 2Department of Molecular Virology, University of Heidelberg, Heidelberg, Germany; 3St. James Hospital, Dublin, Ireland  
B27 is a highly protective HLA allele in HCV infection. Indeed, 80% of B27+ Irish women with accidental HCV genotype 1b infection resolved the infection spontaneously while only 20% developed chronic infection (McKiernan et al., Hepatology 2004). We recently linked this protective effect of HLA-B27 as well as viral evolution within the few B27+ individuals who developed chronic infection to a single, immunodominant HLA-B27 restricted CD8+ T cell epitope within NS5B (Neumann-Haefelin et al., Hepatology 2006). In order to further define the mechanisms of protection mediated by this epitope, we analyzed the virological and immunological characteristics in more detail. To determine the replication capacity of the variants observed in vivo, we cloned these into a subgenomic Con1 replicon harbouring a luciferase reporter gene. All variants were still able to replicate, however a significant reduction in viral replication was observed for most mutants indicating impaired fitness. Interestingly, some clustered mutations seem to represent compensatory rather than escape mutations that restore viral fitness partially. The epitope has an enormous binding affinity to HLA-B27 molecules and cross-reacts with peptides from clinically common microorganisms, indicating that heterologous immunity contributes to the dominant effect of this epitope. In conclusion, our results show that both, immunological factors (high binding affinity, cross-reactivity) as well as virological factors (high viral fitness cost) contribute to the protective effect of HLA-B27 observed in vivo. We hypothesize that viral escape within this epitope is constrained, giving the strong CD8+ T cell response enough time to clear the virus in most acutely infected patients before viral evolution can lead to the establishment of persistent infection.

464 IMPAIRED TLR/RIG-I-MEDIATED INNATE IMMUNITY IN MYELOID DENDRITIC CELLS IN HCV-INFECTED INDIVIDUALS
Masanori Miyazaki, Tatsuya Kanto, Naruyasu Kakita, Michiyao Inoue, Ichiyio Iose, Hideki Miyatake, Mitsuru Sakakibara, Takayuki Yakushijin, Naoki Hiramatsu, Tetsuo Takehara, Akinori Kasahara, Norio Hayashi; Osaka University Graduate School of Medicine, Suita, Japan

BACKGROUND and AIMS: Inhibition of innate immunity is one of the strategies of HCV escaping from immune surveillance system. HCV NS3/4A was reported to inhibit signaling pathways downstream of Toll-like receptor (TLR) 3 and RIG-I/MDA5 by cleavage of adaptor molecules TRIF or IPS-1, respectively. Dendritic cells (DCs) presumably sense HCV by TLR or RIG-I/MDA5 and produce type-I IFN and inflammatory cytokines, involving in the regulation of innate and adaptive immunity. Numerical and functional impairment of blood myeloid DC (MDC) in HCV infection was reported as a crucial mechanism leading to HCV persistence. However, little is known whether TLR or RIG-I system is impaired or not in MDC in HCV infection, as shown in HCV-replicating hepatocytes. We thus aimed to clarify this issue and its mechanism, in order to search for therapeutic targets contributing to immune restoration. METHODS: Thirty-nine patients with chronic hepatitis C (CH) and 52 healthy volunteers (HV) were enrolled. Blood MDCs were magnetically isolated from PBMCs. The expressions of TLR2, TLR3, TLR4, RIG-I and MDA5 in freshly isolated MDCs were quantified by real-time RT-PCR. For functional analyses, we stimulated MDCs with specific TLR agonists (TLR2: Pam3CSK4, TLR3/RIG-I: polyI:C, TLR4: LPS) and examined their cytokine induction by real-time PCR. To compare the signaling pathways downstream of TLR3/RIG-I in MDC between CH and HV, we stimulated MDCs with poly I:C and subjected them for PCR Array analysis. Then we compared the expression of adaptor molecules of TLR or RIG-I in MDC, such as MyD88, IPS-1, TRIF, and TRAF6. RESULTS: The relative expressions of TLR2, TLR3, TLR4 and RIG-I in MDCs from CH were significantly higher than those from HV (p<0.005, others: p<0.005), whereas TLR3 and MDA5 expressions did not differ between the groups. LPS or polyI:C-stimulated induction of IFN-α and TNF-α in MDC from CH were significantly lower than those from HV (p<0.005, p<0.01), suggesting that inhibitory mechanisms exist in the downstream of TLR3, TLR4 or RIG-I. PCR Array analysis demonstrated that some molecules categorized in TLR/RIG-I adaptors, MAPK and NF-κB pathways exhibited lesser degree of expression in MDC from CH. More precisely, the expression of TRIF and TRAF6 was lower in CH (P<0.05, P<0.001), whereas IPS-1 and Myd88 expression was higher in CH (P<0.05, P<0.005). CONCLUSIONS: In MDCs from HCV-infected patients, TLR3, TLR4 or RIG-I-mediated cytokine responses were impaired regardless of their enhanced expressions. Lower expression of TRIF and TRAF6 is one of the plausible mechanisms of such impairment, suggesting their potential role as therapeutic targets for immune modulation.

Disclosures: The following people have nothing to disclose: Masanori Miyazaki, Tatsuya Kanto, Naruyasu Kakita, Michiyao Inoue, Ichiyio Iose, Hideki Miyatake, Mitsuru Sakakibara, Takayuki Yakushijin, Naoki Hiramatsu, Tetsuo Takehara, Akinori Kasahara, Norio Hayashi

465 ERADICATION OF HCV BY INTERFERON TREATMENT LEADS TO IMPROVEMENTS IN WHOLE-BODY INSULIN SENSITIVITY
Yasunori Kawaguchi, Toshihiko Mizuta, Yuichiro Eguchi, Tsutomu Yasutake, Keisuke Ario, Hirokazu Takahashi, Shinni Iwane, Iwata Ozaki; Internal Medicine, Saga Medical School, Saga, Japan

Aim: It is well known that HCV infection causes insulin resistance (IR) and hepatic steatosis, following the occurrence of hepatoma, as shown in an HCV core transgenic mouse model. But little is known about the precise mechanism for IR in HCV-infected patients. We analyzed how eradication of HCV by interferon (IFN) therapy influences whole-body IR, consisting of hepatic IR and skeletal muscle IR, in patients with chronic hepatitis C Methods: In twenty HCV-infected patients with sustained virologic response (SVR) and sixteen with non-SVR, who were undergoing IFN treatment, we assessed the HOMA-IR value as an index of hepatic IR, the ISI composite, an index of whole-body insulin sensitivity, which was calculated as 10000/√FPG × FIRI × mean BS (0-120) × mean IRI (0-120) from a 75 g oral glucose tolerance test, and the HOMA-β and insulinogenic index values for the evaluation of insulin secretion from the pancreas. Indices were determined at the start and 6 months after IFN treatment. Results: In the SVR group, ISI composite values after 6 months treatment were significantly higher than at the start of therapy (p=.022), but there were no significant changes in HOMA-IR values. The insulinogenic index at 6 months was lower than at the start of treatment (p=.047), but there were no significant changes in HOMA-β values. In the non-SVR group, there were no significant changes in the ISI composite, HOMA-IR, HOMA-β or insulinogenic index between the start of treatment and at 6 months. Furthermore, there were no significant changes in body weight between the start and after 6 months treatment in both groups. Conclusions: Eradication of HCV by IFN therapy could lead to improvements in insulin sensitivity in patients with chronic hepatitis C, not only HCV-infected liver but also whole-body (primarily muscle) insulin sensitivity. These results indicate that HCV infection might cause systemic insulin resistance, probably via cytokines or other humoral factors.

(75g OGGT in SVR cases)

466 INTRAHEPATIC ANGIOPOIETIN-2 PROTEIN EXPRESSION MODULATION BY HEPATITIS C VIRUS: MAPK, PI3K AND ACTIVE OXYGEN SPECIES (ROS) IMPLICATION

Paloma Sanz-Cameno, Samuel Martín-Vilchez, Yolanda Rodríguez-Munoz, Maria Jesús Borque, Jose A. Moreno-Montenegro, Pedro L. Majano, Francisca Molina-Jimenez, Manuel Lopez-Cabrera, Ricardo Moreno-Otero.

Chronic hepatic disease related to hepatitis C virus (HCV) is characterized by intrahepatic inflammatory infiltrates, fibrosis and angiogenesis, and it is associated with cirrhosis and hepatocellular carcinoma in a substantial proportion of infected individuals. During these events there is a vascular homeostasis imbalance, in which the Angiopoietin/Tie2 system plays a significant role. Recently, we have observed elevated expression of Angiopoietin2[Tie2] in both, chronic hepatitis B (CHB) patients, which is mediated by HBx viral transactivator in CHB (Sanz-Cameno et al., 2006), as well as in chronic hepatitis C (41st Annual Meeting of the EASL, 2006). The AIM of this work was to identify the HCV protein/s that could mediate the Ang2 induced expression and to study its modulation by diverse cellular signalising pathways: MAPK, PI3K and ROS. METHODS: Ang2 expression was evaluated by western blot in hepatic cell lines harbouring genomic (I389/Core-3') or subgenomic (I377/NS3-3') HCV replicons (Bartenschlager, 2002) and in the parental cells Huh7. All these cell lines were subjected to different treatments, PD98059, LY294002 or Ebselen at 25 µM for 48 hours in order to inhibit or modulate several cellular signalling pathways: MAPK, PI3K and ROS, respectively. RESULTS: There was a significant Ang2 up-regulation in cells containing HCV complete genome compared with parental or non-structural proteins expressing cells. The MAPK inhibitor and the antioxidant, Ebselen, reflected a differential influence in Ang2 isoforms expression (64 and 50 KDa), with a significant induction of inflammatory and tumoral related one (50 KDa), meanwhile the PI3K inhibition diminished the expression of the 64 KDa form. CONCLUSIONS: The prominent Ang2 expression in cells containing HCV complete genome indicates that its modulation is mostly mediated by structural viral proteins. Additionally, the differential Ang2 isoforms regulation by diverse cellular signalling routes could account for an important point of vascular quiescence control in response of tissular microenvironment and could contribute to the clarification of the molecular pathogenetic mechanisms involved in the onset and progression of this and others chronic inflammatory diseases.

Disclosures: The following people have nothing to disclose: Paloma Sanz-Cameno, Samuel Martín-Vilchez, Yolanda Rodríguez-Munoz, Maria Jesús Borque, Jose A. Moreno-Montenegro, Pedro L. Majano, Francisca Molina-Jimenez, Manuel Lopez-Cabrera, Ricardo Moreno-Otero.

467 LACK OF FUNCTIONAL RESTORATION BY PD1/PD-L1 BLOCKADE IN INTRAHEPATIC HCV-SPECIFIC CD8 T CELLS FROM CHRONICALLY HCV-INFECTED PATIENTS

Nobuhiro Nakamoto, David Kaplan, Yun Li, Jennifer Colecloough, Abraham Shaked, Mary Kaminski, David A Price, E. John Wherry, Gordon Freeman, Kyong-Mi Chang.1 University of Pennsylvania, Philadelphia, PA; 2Philadelphia VA Medical Center, Philadelphia, PA; 3The Wistar Institute, Philadelphia, PA; 4Medical Oncology, Dana-Farber Cancer Institute, Boston, MA; 5Weatherall Institute of Molecular Medicine, University of Oxford, Oxford, United Kingdom

Programmed Death 1 (PD1) is negative immune costimulatory molecule. Increased PD1 expression in antigen-specific CD8 T cells during chronic viral infections is associated with functional impairment that may be reversed by inhibiting the interaction between PD1 and its ligand (PD-L1). While the role of PD-L1 blockade has been explored in peripheral HCV-specific CD8 T cells, we asked if HCV-specific CD8 T cells in the liver share similar responsiveness to PD-L1 blockade. Methods: The frequency, phenotype and antiviral effector function of CD8 T cells specific for HLA-A2-restricted HCV and control influenza or EBV epitopes were examined in peripheral blood of patients with acute, chronic and resolved HCV infection by FACS using class I tetramers directly ex-vivo and following in-vitro stimulation. Virus-specific CD8 T cells in blood and liver were examined concurrently in HCV-infected patients undergoing liver transplantation. In a subset, antiviral effector functions in peripheral blood and liver were compared before and after antigenic stimulation with and without PD-L1 blockade by anti-PD-L1. Results: PD1 was highly expressed ex-vivo in circulating CD8 T cells specific for HCV (but not Flu) from patients with acute and chronic HCV infection but not in those with resolved infection. The level of PD1 expression ex-vivo in virus-specific CD8 T cells correlated negatively with their effector function (e.g. perforin, granzyme B, IFNg and CD107α expression) following antigenic stimulation in-vitro. HCV-specific CD8 T cells were more highly PD1-positive in the liver than blood (84% vs. 28%, p<0.0001). Furthermore, intrahepatic HCV-specific CD8 T-cells showed markedly reduced capacity for antiviral effector function compared with peripheral HCV-specific CD8 T cells. These compartmental differences were HCV-specific since Flu-specific CD8 T cells from the same patients showed similar PD1 expression between liver and blood (Median 17% vs. 19%, p=0.44) with highly efficient effector function. Finally, in-vitro PD-L1 blockade improved in-vitro expansion and effector function of HCV-specific CD8 T cells from peripheral blood, but not the liver. Conclusion: While these findings confirm the association between virus-specific CD8 T cell dysfunction and PD1 expression in HCV persistence, we also show that PD-L1 blockade promotes functional restoration of HCV-specific CD8 T cells from peripheral blood but not the highly PD1-positive HCV-specific CD8 T cells from the liver. These results suggest a profound and potentially irreversible impairment in intrahepatic HCV-specific CD8 T cells with pathogenetic and therapeutic relevance.

CRYOGBLOBULINEMIA IN CHRONIC HEPATITIS C A NEW MARKER OF ADVANCED FIBROSIS AND SEVERE STEATOSIS

Rami Moucari1,2, Pierre Bedossa3, Michel Vidaud4, Anna-Carolina Cardoso5, Marie-Pierre Ripault1, Nathalie Boyer1, Michelé Martinot-Peignoux6, Marie-Hélène Nicolas-Chanoine6, Dominique Vallal1,2, Patrick Marcellin1,2, Tarik Asselah1,2; 1Hepatology, Beaujon Hospital, Clichy, France; 3Pathology, Beaujon Hospital, Clichy, France; 4Biochemistry, Beaujon Hospital, Clichy, France; 6Microbiology, Beaujon Hospital, Clichy, France

Background and Aim Hepatitis C virus infection is associated with a spectrum of extrahepatic manifestations, mainly mixed Cryoglobulinemia. The positive association between cryoglobulin and severity of liver disease in chronic hepatitis C (CHC) remains a controversial issue. The aim of this prospective study was to assess the association of asymptomatic Cryoglobulinemia with steatosis and liver fibrosis stage in a large cohort of patients with CHC. Patients and Methods 400 consecutive patients with CHC and no signs of vasculitis were evaluated on the day of liver biopsy. Insulin resistance was assessed using the homeostasis model and defined as HOMA-IR >3. Cryoglobulins were detected by precipitation at 4°C in sera adequately collected and centrifuged at 37°C. Serum HCV RNA was quantified (bDNA, Bayer) and genotype determined for all patients. Liver histology was assessed using the METAVIR score. Results The baseline characteristics of patients were: male gender (58%), mean age (48±10 years), mean BMI (25±4 kg/m2). 35% of patients had insulin resistance. Genotype distribution was: 1 (55%), 2 (9%), 3 (14%) and 4 (20%). Mean serum HCV RNA level was 1.05±1.1 106 IU/ml, > 600000 IU/ml in 46% of patients. Cryoglobulins were detected in the serum of 53% of patients. Liver necroinflammation was significant (METAVIR A2-A3) in 27%, and fibrosis significant (METAVIR F2-F4) in 58% of patients. Steatosis was present in 52% of patients, moderate-severe (>30% of hepatocytes) in 31% of patients. At univariate analyses, the presence of cryoglobulin was associated with serum HCV RNA level < 600,000 IU/ml, significant necroinflammation, significant fibrosis, and moderate-severe steatosis. Patients with compared to those without cryoglobulin had similar age and duration of disease. At multivariate analysis, the presence of cryoglobulin was associated with serum HCV RNA level < 600000 IU/ml (p=0.01, OR=1.7), significant fibrosis (p=0.001, OR=2.5), and moderate-severe steatosis (p=0.002, OR=2.2). At multivariate analysis, significant fibrosis was associated with male gender (p=0.001, OR=2.2), age > 45 years old (p=0.006, OR=2.0), insulin resistance (p=0.008, OR=2.0), Cryoglobulinemia (p=0.001, OR=2.3), significant necroinflammation (p=0.001, OR=3.36) and moderate-severe steatosis (p=0.004, OR=2.2). Conclusion In this prospective study including 400 consecutive patients with CHC, asymptomatic cryoglobulinemia was detected in 53%. Cryoglobulinemia was an independent factor associated with more severe liver disease (fibrosis and steatosis). Further studies are ongoing to investigate the relationship between cryoglobulinemia and HCV RNA level, steatosis and fibrosis.

Chung; Gastrointestinal Unit, Department of Medicine, Massachusetts General Hospital, Harvard Medical School, Boston, MA

Background/Aims: Due to their shared routes of transmission, HIV/HCV coinfection is prevalent in the U.S. HIV increases HCV RNA levels, TGF-β1 expression, hepatic fibrosis progression, HCV persistence, decreases response to interferon-based anti-HCV therapy. However, the mechanism by which HIV and TGF-β1 contribute to HCV pathogenesis has not been well studied. We sought to explore whether inactivated HIV and gp120 increase HCV through TGF-β1 regulation by using HCV replicon and infectious JFH1 models. Methods: Inactivated HIV and recombinant HIV proteins (gp120, Gag, Tat, Pol, Rev) were incubated for 48 h in OR6 replicon (Huh7 cell stably harboring a genotype 1b full-length HCV RNA and co-expresses Renilla luciferase) or infectious HCV JFH1 cells. HCV replication was monitored by measuring Renilla luciferase unit (RLU) in OR6 cells and by measuring HCV core in JFH1 cells. To test the effect of HIV and gp120 on TGF-β1 expression in hepatocytes, we performed the assay in serum-free medium, which has undetectable levels of TGF-β1. TGF-β1 levels were measured using a human TGF-β1 ELISA. Recombinant TGF-β1 and neutralizing antibody to TGF-β1 were introduced to assess the effect of TGF-β1 on HCV replication. Neutralizing antibodies to the CXCR4 and CCR5 receptors were added to the HCV-infected cells to verify that gp120 and inactivated HIV were signaling through these receptors. Results: We found a greater than 2-fold increase in HCV replication levels from baseline in the presence of gp120 (45305± 3375 vs 20997± 1428 RLU in OR6 cells, 2014± 101.07 vs 1043± 66.9 pg/ml HCV core in JFH1 cells). In contrast, there were no changes in HCV RNA or core protein in the presence of any of the other HIV proteins. The increased HCV levels were specifically abrogated by preincubation with neutralizing antibody to CCR5 or CXCR4. HIV gp120 protein significantly increased TGF-β1 expression in serum-free medium (3721± 266.1 vs 1814.4± 114.3 pg/ml in OR6 cells, 2996± 203.8 vs 1593.2± 105.2 pg/ml in JFH1 cells.). Recombinant TGF-β1 (4 ng/ml) enhances HCV replication in OR6 cells (41151± 259.2 vs 21427± 1466.1 RLU) in serum free medium. Neutralizing antibody to TGF-β1 blocked this effect (p< 0.003 for all comparisons). Conclusions: Our data indicate that inactivated HIV and gp120 have a proximal effect on HCV replication that is dependent on co-receptor engagement. We speculate that HIV and gp120 promote HCV replication through upregulating TGF-β1 in HCV-infected hepatocytes. These results implicate an effect of circulating HIV on innate antiviral immunity to HCV, and suggest a novel mechanism by which HIV enhances HCV replication and hepatic fibrosis progression.

470 INCREASED IRF-1 AND IFN-α GENE EXPRESSION IN CHRONIC HEPATITIS C G-300A IRF-1 PROMOTER POLYMORPHISM A ALLELE CARRIERS

Parwez Aideriy, Giuliano Ramadori, Sabine Mihm; Gastroenterology, Georg-August-Universität, Göttingen, Germany

Interferon regulatory factor-1 (IRF-1) is a type I and type II interferon (IFN) inducible transcription factor which is involved in the regulation of the IFN response. Recently, we were able to report on an association of the G-300A IRF-1 promoter polymorphism genotype and the outcome of an hepatitis C virus (HCV) infection. We now analyzed IRF-1 and IFN-α transcript expression with regard to G-300A IRF-1 genotype in peripheral blood mononuclear cells (PBMC) from healthy individuals (n=11) and from chronic hepatitis C patients (n=17) ex vivo and after overnight incubation. Both, basal IRF-1 and IFN-α mRNA levels were found to be significantly higher in chronic hepatitis C patients than in healthy volunteers. Whereas IRF-1 transcript expression was not observed to be significantly different with regard to promoter genotype distribution in ex vivo isolated PBMC, an overnight incubation in the presence of autologous HCV containing sera revealed an increase of IRF-1 transcripts preferentially in hepatitis C A allele carriers, whereas such an increase was not observed for patients homozygous for the wildtype allele G nor for healthy individuals. Moreover, IFN-α transcript expression in freshly isolated PBMC from hepatitis C A allele carriers was found to be 5-fold higher compared to homozygous G patients. Our findings support the assumption that the genetic background in the IRF-1 promoter may be related to type I IFN response in hepatitis C infection. Allele specific transcript quantification (ASTQ) studies are running to evaluate the functional impact of the two alleles.

471 IMPAIRMENT OF CHEMOKINE RECEPTOR CXCR4-EXPRESSING IN HCV INFECTION AS POTENTIAL IMMUNE ESCAPE MECHANISM

Kerstin Herzer1, Christoph C. Schimanski1, Regina Boger1, Sandra Weyer1, Stefan Biesterfeld2, Gerd G. Otto3, Stephan Kanzler1, Peter R. Galle1; 1Dept I of Medicine, Johannes Gutenberg University, Mainz, Germany; 2Department of Pathology, Johannes Gutenberg University, Mainz, Germany; 3Department of Transplantation and Hepatobiliarypancreatic Surgery, Johannes Gutenberg University, Mainz, Germany

The Hepatitis C Virus (HCV) causes chronic infection in about 85% of patients. Thus, the virus is able to combat the immune system very efficiently. The mechanisms of immune evasion and the role of the early immune response in chronic infection caused by HCV are still unclear. In order to address this issue, we studied the expression of diverse surface molecules on liver cells in HCV infected versus non-infected liver tissue and noticed a considerable difference in surface expression of the chemokine receptor CXCR4. While ‘healthy’ cells express CXCR4 on their surface, HCV infected cells show a rather perinuclear stain for CXCR4 in immunohistochemistry. Using HCV replicon cells, we could confirm these findings in vitro employing immunofluorescence staining of Huh7-replicon-cells, which display a cytoplasmatic localisation of CXCR4, versus ‘native’ Huh7 hepatoma cells, with CXCR4 expression on the cell surface. Interestingly, upon HCV core transfection of Huh7 cells, the receptor showed the same perinuclear localisation as in replicon-containing cells or HCV infected liver cells. Moreover, CXCR4 colocalises with HCV core in perinuclear compartments. In addition, HCV infected cells and HCV core transfected cell lines show diminished CXCR4 mRNA expression compared to uninfected liver tissue and untransfected cell lines. The mechanism of receptor internalisation is matter of ongoing investigations. Previous results demonstrate that HCV-infection causes induction of the CXCR4-ligand SDF-1a. So far, our data suggest the following sequence of events: HCV causes induction of SDF-1a secretion which is followed by internalisation of CXCR4 via ligand binding. Inside the cell CXCR4 accumulates in the cytoplasm/ perinuclear compartments, most likely in complex with HCV core. In addition, CXCR4-expression is directly impaired on the transcriptional level by HCV core. Considering that CXCR4 was initially described to regulate the homing of lymphocytes in inflammatory tissues and, thus, the established role of CXCR4 and its ligand for attraction of immune cells to sites of inflammation, the downregulation of CXCR4 by HCV may be a newly identified strategy by HCV to efficiently hide from immune recognition.

472 CONTROLLING B-CELL ACTIVATING FACTOR (BAFF/BLYS) LEVELS IN CHRONIC HEPATITIS C VIRUS INFECTION

Gerond Lake-Bakaar, Peter Tsang; Medicine, Weill Cornell University Medical Center, New York, NY

B-cell activating factor (BAFF) is predominantly expressed in myeloid cells including macrophages and dendritic cells and is primarily responsible for B cell maturation and survival. The factors that determine BAFF levels in man are unclear. Possible feedback mechanisms might would allow control of B cell numbers. Induction by direct hepatitis C virus (HCV) activation of macrophages through TLR dependent or independent pathways could begin to explain the lymphoproliferative nature of chronic HCV infection. We measured Human BAFF in serum using a solid phase ELISA (Quantikine, R&D Systems, MN) designed to eliminate interference by biological factors, including cryoglobulins. We compared BAFF levels in patients with HCV-related mixed cryoglobulinemia HCV-MC (n=11) with a similar group of patients with HCV-MC, eight weeks after treatment with rituximab (n=3) to deplete the mature B cell pool. We also measured BAFF levels at short intervals immediately after an initial dose of pegylated interferon and ribavirin and correlated these with HCV RNA levels using bDNA technology (Bioreference Labs, Elmwood Park, NJ) in a single interferon naive patient with HCV-MC. BAFF levels in HCV-MC patients after rituximab therapy were significantly higher, 998±1734 pg/ml than the control group of HCV-MC patients that had not received rituximab, 2927±3464, p<0.0009. Both BAFF and HCV RNA levels rose after an initial decline. The changes in HCV RNA after interferon correlated extremely closely with BAFF, r = 0.93, p=0.006 (fig 1). These data suggest an important role for BAFF in the control of the mature B cell pool in man. The very close relationship between HCV RNA and BAFF raises the interesting possibility that the cytokine might be induced by direct viral activation and could begin to explain the lymphoproliferative effects of this virus.
INVolvEMENT OF REGULATORY T CELL DYNAMICS IN THE ACHIEVEMENT OF BIOCHEMICAL RESPONSE IN 48-WEEK PEG-INFNα2b AND RIBAVIRIN COMBINATION THERAPY FOR CHRONIC HEPATITIS C PATIENTS

Ichiyo Itose1, Tatsuya Kanto1, Michiyo Inoue1, Naruyasu Kakita1, Masanori Miyazaki1, Hideki Miyatake2, Mitsuru Sakakibara2, Takayuki Yakushijin1, Naoki Hiramatsu1, Tetsuo Takehara1, Akinori Kasahara2, Norio Hayashi1; 1gastroenterology and hepatology, Osaka university graduate school of medicine, Osaka, Japan; 2General medicine, Osaka university graduate school of medicine, Suita, Japan

Aim: In Peg-INFNa and ribavirin combination therapy for chronic hepatitis C, the therapy might be discontinued in patients who fail to become negative HCVRNA by week 24 of the therapy, since the probability of SVR in them is extremely low. It is reported that the progression of fibrosis is slow and the incidence of hepatocellular carcinoma is low in patients who achieved biochemical response (BR), even if they failed to eradicate HCV. Therefore, in order to prevent hepatocarcinogenesis in patients who fail to eradicate HCV, it is clinically important to continue the therapy in patients who would achieve BR. Regulatory T cells (Treg) are capable of suppressing antigen-specific and non-specific T cell responses, which is reported to be increased in chronic hepatitis C. We reported that Treg function is enhanced in patients with persistently normal ALT levels (PNALT) than in patients with active hepatitis, suggesting that Tregs possess minor roles in virological response. In parallel with such increase of Treg, plasma TGF-β level in BR patients was higher than those in non-BR, suggesting its possible role in Treg induction. Conclusion: Increase of Tregs may be involved in biochemical response in PEG-INFNα and ribavirin combination therapy, being independent of virological response.

474 ADIPONECTIN: A NEW INDEPENDENT PREDICTOR OF LIVER STEATOSIS AND RESPONSE TO IFN-A TREATMENT IN CHRONIC HEPATITIS C?

Theodoros A. Zografos1, Christos Liaskos1, Eirini I. Rigopoulos1, Elias Togosidis1, Kostantinos Makaritsis1, Anastasios Germinis2, George N. Dalekos1; 1Dept. of Medicine, Academic Liver Unit and Research Lab of Internal Medicine, University of Thessaly, Medical School, Larissa, Greece; 2Laboratory of Immunology and Histo-combatibility, University of Thessaly, Medical School, Larissa, Greece

Background/Aims: Adiponectin is an insulin-sensitizing adipokine with anti-inflammatory properties. In the past year, 3 research groups have investigated serum adiponectin in chronic hepatitis C (CHC) with respect to the patients’ histological and biochemical characteristics. However, the relationship between IFN-a therapy and serum adiponectin has not been investigated in detail. We conducted a study in order to: compare serum adiponectin levels between CHC and chronic hepatitis B (CHB) patients; investigate for associations between adiponectin and histological or viral characteristics of CHC; investigate adiponectin alterations during IFN-a treatment and to assess the relationship between adiponectin and response rates to treatment. Methods: Adiponectin concentrations were determined from serial samples (before, the middle, the end of treatment and 6 months after end of treatment) from 83 CHC and 59 CHB patients. 43 donors served as healthy controls. Patients treated with IFN-a (4.5 MU/tiw) for 12 months in CHB and IFN-a (3 MU/tiw) plus ribavirin for 6-12 months according to HCV-genotype in CHC. Results: After adjustment for body mass index (BMI) and gender, CHC patients infected with HCV-genotype 3 had significantly lower adiponectin levels at baseline compared to those patients with non-3 HCV-genotypes (p<0.05). Lower serum adiponectin at baseline identified as an independent predictor of liver steatosis (HCV-genotype 3; p=0.02 and HCV-genotype 1; p=0.025) and for no virologic response at the end of treatment (OR 0.76; 95% CI: 0.66-0.87; p<0.001). At the end of IFN-a, HCV-genotype 3 patients had significantly higher serum adiponectin compared with their levels before the initiation of treatment (p<0.05). Conclusions: This study suggests that HCV-genotype 3 may directly affect adiponectin. This is further supported by the significant increase of adiponectin in HCV-genotype 3 patients at the end of treatment compared to their pretreatment levels. The direct implication of IFN-a seems unlikely, as similar increase of adiponectin was not observed in CHB and CHC patients infected with non-3 HCV-genotypes. Serum adiponectin at baseline appears to be an independent predictor of liver steatosis and for the achievement of end of treatment virologic response irrespective of the HCV-genotype. We believe that further efforts should be done in an attempt to corroborate our findings regarding SVR.
and to evaluate the possible usefulness of a potential increase of serum adiponectin using novel molecules or treatments leading to an increase of adiponectin (e.g. thiazolidinediones) before the initiation of antiviral treatment in CHC patients.

475 ABERRATIONS OF CELL CYCLE MACHINERY IN CHRONIC HEPATITIS C INFECTION
Saira Sarfraz, Saeed S. Hamid, Anwar Siddiqui, Syed Ali, Syed MW Jafri, Anwar Siddiqui; Medicine, Aga Khan University, Karachi, Pakistan

Introduction: Increasing scientific evidence suggests that Hepatitis C Virus (HCV) manipulates the cell cycle machinery during the course of HCV-associated pathogenesis. Considering that the cell cycle proteins play a fundamental role in the regulation of cell growth, HCV-associated disruption in their function contributes to disease progression and, subsequently, hepatocellular carcinoma. Objective: To identify cell cycle disruptions during the course of chronic HCV disease. Methods: Liver biopsy samples classified on histological basis as early (Stage 1-2) or advanced (Stage 3-4) fibrosis were used to extract RNA. Pooled RNA samples from normal liver (NL), HCV-early fibrosis (EF) and HCV-advanced fibrosis (AF) groups were analyzed by RT-PCR cell cycle array (Superarray). Additionally, protein expressions of differentially expressed cell cycle genes (TP53, CDKN1B and CDKN2B) were studied in same groups by immunohistochemistry. Results: PCR array analysis of cell cycle genes showed more than two fold change in 36% of the transcripts in EF as compared to normal liver sample. 10% of these were significantly differentially expressed including positive regulators of cell cycle [Mcm-2, cyclin E1] and G1, G2/M phase checkpoint genes [CDKN1B, GADD45A and KNTC1]. In EF versus AF comparison 23% showed more than 2-fold change, 50% of which were significantly differentially expressed including G1 inhibitor CDKN2B and tumor suppressor p53. Evaluation of protein expression shows decreased immunopositivity for p53 in AF as compared to EF, however, in case of p15 and p27 mRNA and protein levels are concordant. Conclusion: Based on the observations in the expression pattern in EF, it can be suggested that the up-regulation of cell cycle activators along with G1, G2 and M checkpoint regulators are seen as an early event in HCV-associated liver injury, however, in AF a different set of inhibitors was found up-regulated and tumor suppressor p53 is down-regulated that might predisposes cells to malignant transformation.

479 HUMAN MONOCLONAL ANTIBODIES RECOGNIZING A CONSERVED HCV E1 DOMAIN EFFECTIVELY NEUTRALIZE HCV IN THE CELL CULTURE (HCVCC) SYSTEM

Ann Union1, Erik Depla1, Jean-Christophe Meunier2, Vera Goossens1, Suzanne U. Emerson2, Sofie Priem1, Robert H. Purcell2, Geert Maertens1, Therapeutics, Innogenetics NV, Zwijnaarde, Belgium; 2Laboratory of Infectious Diseases, NIAID, Bethesda, MD

Background: Until recently, neutralizing antibodies for HCV have been shown to be directed against the E2 envelope protein. In this study we explored the properties of an E1 epitope region recognized by three different human monoclonal antibodies (humAbs) with strong neutralizing capacity against HCV pseudoparticles. Methods: Epitope mapping of neutralizing and non-neutralizing antibodies directed against E1 was initially performed with overlapping peptides. Detailed analysis of the neutralizable epitope region was done by alanine scan, analysis of natural variants, and affinity measurements. For the neutralization assays, the HCVcc genotype 2a (JFH1) system was used. Results: Neutralizing humAbs against E1 were mapped to an extremely well-conserved E1 domain (amino acid 313-326), which was bound with high affinity (≈10^{-10} M). Several non-neutralizing anti-E1 humAbs also recognized this domain, but detailed epitope mapping revealed recognition patterns that were different for non-neutralizing and neutralizing antibodies. The alanine scan revealed a remarkable flexibility of the neutralizing antibodies in recognition of variant peptides. This was confirmed by investigating reactivity with natural variants representing 94% of known E1 sequences, and is in line with the previously observed broad cross-genotype neutralization in the HCVpp system (Meunier et al., Hepatology 2006,44, suppl 1, 344A). Since the HCVcc system is expected to mimic HCV more closely than the pseudoparticle system, two anti-E1 humAbs were further tested for their neutralizing capacity against HCVcc. Both humAbs could effectively neutralize genotype 2a infectious HCV in vitro. The different properties of the neutralizing humAbs allowed selection of one antibody for development of a passive immunotherapy candidate for application in HCV-related liver transplantation. Conclusion: The E1 protein contains a neutralizable domain consisting of several epitopes, which resides in the most conserved region of the entire HCV envelope. Several humAbs were identified that recognize this domain and which display unique properties with respect to cross-genotype recognition and neutralization.

CELL CULTURE-PRODUCED HEPATITIS C VIRUS IMPAIRS PLASMACYTOID DENDRITIC CELL MATURATION AND FUNCTION VIA DIRECT INTERACTION, BUT NOT INFECTION

Masaoki Shina, Barbara Rehermann: Immunology Section, Liver Diseases Branch, NIDDK, National Institutes of Health, Bethesda, MD

Previous studies suggested a functional impairment of dendritic cells (DCs) in patients with chronic hepatitis C. To investigate whether this effect was mediated by a direct interaction of HCV with DCs we studied the effects of cell culture-derived, infectious HCV (HCVcc) on ex vivo isolated plasmacytoid and myeloid DCs and on in vitro generated monocyte-derived DCs of healthy blood donors. HCVcc inhibited maturation and TLR9-mediated IFN-α production by plasmacytoid DC. This inhibitory effect did not require HCV infection of plasmacytoid DCs, because it was also observed in response to UV-inactivated, non-infectious HCVcc, and it was not abrogated by neutralizing antibodies. Infection of plasmacytoid DCs with influenza A virus restored maturation and TLR9-mediated IFN-α production. In contrast to its effect on plasmacytoid DCs, HCVcc inhibited neither TLR3- and TLR4-mediated maturation nor IL-12, IL-6, IL-10, IFN-γ and TNF-α production by myeloid DCs and monocyte-derived DCs. Likewise, HCVcc did not alter the capacity of myeloid DCs and monocyte-derived DCs to induce CD4 T cell proliferation. While phagocytosis of apoptotic hepatoma cells by monocyte-derived DCs resulted in DC maturation, this effect was independent of whether the phagocytosed hepatoma cells were infected with HCV or not. In conclusion, HCVcc inhibited maturation and IFN-α production of plasmacytoid DCs, but not myeloid and monocyte-derived DCs via a direct interaction that did not require infection. The response of plasmacytoid DCs to influenza A virus infection was not impaired, consistent with the observation that HCV-infected patients are not impaired in their immune response to influenza A virus.

HEPATITIS C P7 PROTEIN ALTERS THE PROTON CONDUCTANCE OF INTRACELLULAR MEMBRANE VESICLES

Ann L. Wozniak1, Stephen Griffin2, David Rowlands2, Mark Harris2, Steven A. Weinman1; 1Neuroscience & Cell Biology, University of TX-Medical Branch, Galveston, TX; 2Institute of Molecular and Cellular Biology, University of Leeds, Leeds, United Kingdom

The hepatitis C virus (HCV) p7 protein functions as a virus-encoded ion channel, but its role in the virus life cycle is not known. A similar viroporin, the m2 protein of influenza virus, provides a proton conductance that prevents acidification during viral particle exocytosis and an analogous function has been proposed for HCV p7. The AIM of this study was to determine whether p7 mediates proton movement and pH changes in intracellular vesicles. METHODS: Flag-tagged HCV p7 and a channel defective mutant (p7KR) were expressed in 293T cells. Subcellular distribution was examined by immunofluorescent confocal microscopy and membrane biotinylation. Intracellular vesicles were isolated by density gradient centrifugation. Proton movement in isolated vesicle fractions was assessed using the fluorescent indicators acridine orange (AO), which quenches in acidic compartments, and the pH sensitive fluorophore, carboxyfluorescein. RESULTS: When expressed in 293T cells, p7 displayed a diffuse intracellular distribution that overlapped with ER. Plasma membrane localization could not be detected by cell surface biotinylation. To assess proton movement, isolated vesicles were added to a pH 7.4 AO solution and pH changes were measured. When vesicles had been pre-equilibrated at pH 7.4, addition resulted in a rapid fluorescence increase as AO associated with the lipid membrane. There were no subsequent fluorescence changes. The situation differed when vesicles were pre-equilibrated at pH 5.5. In this case, both mock transfected and, mutant p7KR transfected vesicles behaved as before causing a rapid initial increase and no subsequent change. However, the wild-type p7 containing vesicles caused a transient decrease in fluorescence compared to control which persisted for approx. 90 sec. This fluorescence quenching event thus required the presence of both p7 and a transversable pH gradient. To confirm that this change reflected proton movement across the vesicle membrane, we performed preliminary experiments after incorporating the pH indicator, carboxyfluorescein, into vesicles. Vesicles were treated with the K ionophore, valinomycin, and exposed to an inwardly directed K gradient to create an electrochemically positive vesicle interior. When the vesicles contained p7, this maneuver alkalized the vesicle interior. In mock transfected vesicles, the inward K gradient did not alter intravesicular pH. CONCLUSIONS: The HCV p7 protein allowed transvesicular proton fluxes markedly greater than those seen in vesicles from either mock transfected or p7KR mutant transfected cells. This indicates that p7 could serve as a pH equilibrating agent in the HCV lifecycle.

INTERFERON (IFN) SENSITIVITY OF NATURAL RECOMBINANT RF1-2K/1B HCV STRAIN IN CHIMERIC UPA/SCID MICE

Fuat Kurbanov1, Yasuhito Tanaka1, Isao Maruyama2, Takashi Shimada2, Masashi Mizokami1; 1Department of Clinical Molecular Informative Medicine, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan; 2PhoenixBio Co., Ltd, Higashi-Hiroshima, Japan

Background: Transplanted with human liver, urokinase-type plasminogen activator-transgenic SCID mice (chimeric mice) became recently available for studying in vivo replication of the hepatitis C virus (HCV), and its sensitivity for antiviral drugs. HCV genotype is an important determinant of the virological response to antiviral therapies. A series of recent reports described natural inter-genotypic recombinants isolated from HCV-infected individuals. Aim: To assess usefulness of the chimeric mice in maintaining replication of the natural recombinant HCV RF1 RF1_2k/1b (RF1) strain, and to test the effect of the recombinant on the interferon sensitivity of the virus. Methods: A cohort of chimeric mice was infected with human sera obtained from RF1 HCV-carrier. Two cohorts used as control were; [1b-SVR] infected by a stored “base-line” serum from HCV-1b-infected patient, who had sustained virological response, and [1b-NR] infected by an “in-treatment” serum from another 1b-infected patient who had null response to Peg-IFN & Ribavirin treatment. The mice were treated by 3 intraperitoneal injections of pegylated interferon alpha-2a using two different dose-regimens; 3 and 30 mg/kg. Results: Mean HCV titer in the
1b-NR and RF1 groups reached plateau at 7.6 and 7.0 log copies/ml, respectively by the day 14 after infection, whereas titer of the 1b-SVR rose to 8.5 log until day 21 and then reached plateau at 8.0 log. At day 35 after infection, the interferon was administrated in dose of 3 mg/kg three times (day 0, 2, 5). Relative trends were seen when HCV titer at Day 0 was taken as 100% and titers at consecutive Day 2, 5 and 7 were calculated respectively; by the day 7, HCV-RNA levels of 1b-SVR and RF1 were 22-23%, whereas in 1b-NR it remained unchanged. Restoration of the baseline levels for 1b-SVR and RF1 observed on day 9 and 12 after injection, respectively. After confirmed stabilization of the HCV titers, second course was launched with dose of 30 mg/kg (day 0, 2, 5). This resulted in significant reduction of the viral titers at log scale; compared to the baseline (day 0 of the second course), more than 2.0 log copies/ml reduction was observed by the day 7 in HCV titer of the 1b-SVR (2.3) and RF1-infected mice (2.7) that was lower than in 1b-NR (1.4 log, p<0.04). Interestingly, sequencing of the previously reported interferon sensitivity determinant region revealed wild-type in 1b-NR, mutant in 1b-SVR and intermediate in RF1. Conclusion: Chimeric mice model is useful for a natural recombinant HCV replication. The HCV-2k/1b is sensitive to the Peg-IFN, suggesting that the variant is useful for a natural recombinant HCV replication. The HCV-2k/1b is sensitive to the Peg-IFN, suggesting that the variant is useful for a natural recombinant HCV replication.

**483 PRODUCTION OF INFECTIONOUS GENOTYPE 1B HEPATITIS C VIRUS IN HUMAN HEPATOMA CELLS**

Carlos Coito, Smitha Kota, David Willoughby, Timothy Tellinghuisen, Donny Strosberg

Chronic infection with Hepatitis C virus (HCV) afflicts over 170 million people world-wide. The only effective treatment, pegylated interferon combined with ribavirin, displays considerable differences in efficacy. Notably, strains of genotypes 2 and 3 are cleared in up to 80% of infected patients, while strains of genotype 1 are cleared in only about 40% of patients. To gain a better understanding of these genotype-specific differences, considerable efforts have gone into the development of an in vitro mammalian monolayer cell culture system to assess mechanisms of action of treatment regimens on infectious HCV. Infectious HCV cell culture systems have been described for genotypes 2a, (ref.1-3), and more recently genotype 1a (4), but an infectious cell culture system, combined with previous 2a systems, should significantly improve our understanding of how HCV genotype relates to susceptibility to anti-HCV therapy.

**484 THE CHOLESTEROL AND SPHINGOLIPIDS OF HEPATITIS C VIRUS PARTICLES PLAY CRITICAL ROLES IN THE VIRAL INFECTIVITY**

Hideki Aizaki, Masagi Fukasawa, Hideki Tani, Yoshitomo Matsura, Kentaro Hanada, Michael M. Lai, Tatsuo Miyamura, Takaji Wakita, Tetsuro Suzuki, Virolology II, National Institute of Infectious Diseases, Tokyo, Japan; Biochemistry and Cell Biology, National Institute of Infectious Diseases, Tokyo, Japan; Research Institute for Microbial Diseases, Osaka University, Osaka, Japan; Molecular Microbiology and Immunology, University of Southern California, Los Angeles, CA

Background and aims: It is known that enveloped viruses are highly dependent on viral lipids for infection of the host cells. Although association of lipids with HCV particles has been suggested, its role in the viral assembly and infection is poorly characterized. The aim of this study is to assess the requirement for lipids within the viral envelopes in HCV infection. Methods: Infectious HCV particles (HCVpp) derived from JFH-1 are used for lipid composition analysis, cholesterol-depletion assay, sphingomyelin-hydrolysis assay, inhibition analysis of sphingolipid biosynthesis, and viral binding assay. Results: Lipid composition analysis of HCVpp and cellular membranes demonstrated that the cholesterol to phospholipids molar ratio, which is known as a major parameter of membrane viscosity, is significantly higher in HCVpp compared to that in total cellular membrane fraction, suggesting that HCV virions are enriched with cholesterol through the course of their assembly and maturation. Upon depletion of cholesterol from HCVpp with methyl-beta-cyclodextrin (B-CD), infectivity was almost completely abolished. Replenishment by adding exogenous cholesterol restored infectivity to that of untreated control. Sphingomyelinase (SMase)-mediated hydrolysis of viral surface sphingomyelin also reduced infectivity. Furthermore, we found that inhibitors for serine palmitoyltransferase (Myriocin) or for ceramide trafficking from ER to Golgi ((1R, 3R)-N-(3-hydroxy-1-hydroxymethyl-3-phenylpropyl) dodecanamide) suppress HCVpp production but not RNA replication of JFH-1 replicon. These data suggested that cholesterol and sphingomyelin are important for viral particle formation and/or secretion. Sphingolipids and cholesterol are known to be major components of lipid rafts. The insolubility in nonionic detergents suggested that subpopulations of HCV structural proteins are associated with lipid rafts in HCV-infected cells, and that transmembrane domains of envelope proteins are important for this association. B-CD- or SMase-treatment of HCVpp strongly inhibits the viral binding to cells. Conclusions: We suggest that cholesterol and sphingomyelin associated with HCV virions play critical roles in the early step of the infection. These studies provide important insights into the mechanism of assembly and budding of HCV and also suggest novel potential inhibitors targeting HCV particles.

485 NEUTRALIZING HOST RESPONSES IN HEPATITIS C VIRUS INFECTION TARGET VIRAL ENTRY AT POST-BIND-
I NG STEPS AND MEMBRANE FUSION

Anita Haberstroh1,2, Eva K. Schnober1,2, Patric Carolla1,2, Heidi Barth1, Mirjam B. Zeisel2,3, Hubert E. Blum1, Marleane Dreux4,5, George Koutsoudakis6, Ralf Bartenschlager4, Arvind Patel7, Catherine Schuster2,3, Françoise Stoll-Keller2,3, Eric Depla8, Michel Doffoel8,9, Thomas F. delberg, Germany; 7MRC Virology Unit, University of Glasgow, Glasgow, United Kingdom; 8Innogenetics NV, Ghent, Belgium; 9Service d’Hépatogastroentérologie, Hôpitaux Universitaires de Strasbourg, Strasbourg, France

Hepatitis C virus (HCV) is a leading cause of chronic hepatitis worldwide. Viral attachment and entry - representing the first encounter of the virus with the host cell - are major targets of adaptive host cell defences. The mechanisms of antibody-mediated neutralization by host neutralizing responses in HCV infection are only poorly understood. Retroviral HCV pseudotypes (HCVpp) have been successfully used for the study of viral entry and antibody-mediated neutralization. In this study, we used this model system to study the mechanism of antibody-mediated neutralization by monoclonal anti-envelope antibodies and polyclonal anti-HCV immunoglobulin purified from HCV-infected patients. Using a panel of monoclonal anti-E1 and anti-E2 antibodies, we show that anti-envelope antibodies neutralize HCV entry during various steps of HCV entry including binding and post binding events. Interestingly, we observed that host neutralizing responses in the majority of HCV-infected individuals target HCV entry during an entry step occurring post binding of virus to the target cell membrane. Using a kinetic assay based on HCVpp entry, we demonstrate that purified antiviral immunoglobulins derived from defined HCV infected individuals appear to inhibit HCV infection during an entry step closely linked to CD81. Using a recently developed HCVpp-based membrane fusion assay, we identified one individual with neutralizing immunoglobulins able to inhibit HCV fusion. This inhibition could occur through steric or allosteric blocking of the HCV E1E2 glycoproteins and could prevent conformational rearrangements required to promote fusion with their target membrane. Our results indicate that host neutralizing responses in HCV-infected humans target HCV entry at a post binding step most likely related to HCV-CD81, SR-B1 or claudin-1 interaction or membrane fusion. These findings may have important implications not only for the understanding of the pathogenesis of HCV infection but also for the design of novel immunotherapeutic and preventive vaccine approaches.

486 HEPATITIS C VIRUS NSSA BINDING TO NUCLEOSOME ASSEMBLY PROTEIN 1 (NAP 1) ACCELERATED HCV REPLICATION

Run-Xuan Shao1,2, Naoya Kato1, Motoyuki Otsuka1, Naoyuki Yamada3, Jin-Hai Chang1, Ryosuke Muroyama1, Takao Kawabe1, Masao Omata1; 1Gastroenterology, School of Medicine, University of Tokyo, Tokyo, Japan; 2Gastrointestinal Unit, Massachusetts General Hospital, Boston, MA; 3Institute of Life Sciences, Ajinomoto Co., Inc, Tokyo, Japan

Background & Aims: Hepatitis C virus (HCV) non-structural protein, NSSA, was reported to counteract host interferon-induced antiviral response. Recently, it was suggested that NSSA binds with various host factors, and plays an important role in HCV replication as well as modulates host intracellular signaling pathways. The aim of this study is to determine host NSSA binding protein and its effect on HCV replication. Methods: A HuH7 cell line stably expressing FLAG-tagged HCV NSSA was generated. Then, FLAG-tagged NSSA and its binding proteins were co-immunoprecipitated using anti-FLAG antibody. FLAG-tagged NSSA binding proteins were sequenced using 2D nano LC-MS/MS system. Binding of NSSA and target protein was determined using confocal fluorescence microscopy. Then, the target gene was knocked down by RNA interference technique in HuH7 cells. The effect of knocking down target gene on HCV replication was observed using a recently developed genotype 2a full-length HCV (JFH1) replication and infection system. Results: Nucleosome assembly protein 1 (Nap1) was identified as an NSSA binding protein. Nap1 is a histone chaperone and a chromatin-assembly factor having additional roles in transcriptional regulation, apoptosis, histone shuffling, and cell-cycle regulation. NSSA and Nap1 co-localized mainly in the cytoplasm. Replication of JFH1 was significantly reduced in Nap1 knocked-down HuH7 cells. Conclusions: HCV NSSA binds with Nap1, and this is crucial for HCV replication. Nap1 could be a target for anti-HCV drug development.

**HEPATITIS C RESOLUTION CORRELATES WITH PATTERNED KIR RECEPTOR EXPRESSION ON KILLER LYMPHOCYTES**

James C. Ryan, Alexander Mento, Mandeep Lehl, Michael Kim, Daniel Tracy, Sally George, Alan P. Kennedy, Teresa L. Wright, Sue Currie

**Background:** Inhibitory killer immunoglobulin receptors (KIR) on lymphocytes bind to HLA class I ligands and downmodulate immune defense against infection. Antibodies to KIR can block inhibitory effects and they may augment antiviral responses to HCV. Genes for weakly inhibitory KIR-ligand pairs are associated with HCV resolution, while strongly inhibitory KIR-ligand pairs are associated with viral persistence. Reported effects of KIR genes on HCV are modest, perhaps due to confounders that cannot be controlled by genotyping alone. Individuals with similar KIR-HLA genotypes exhibit great variability in KIR expression among their lymphocyte subsets. Also, individual allelic polymorphisms of a single KIR gene may affect receptor expression and function. Aim: To correlate KIR expression patterns on lymphocytes with HCV resolution. Methods: Flow cytometric analyses of KIR were performed on natural killer (NK) and T cell subsets from injection drug users (IDU) with chronic or resolved HCV. NK (CD56+/CD3-) cells and CD3+ T cells were stained with antibodies directed against KIR2DL3, KIR2DL1, KIR3DL1/3DS1, and KIR3DL2. The percentage of NK cells and T cells staining for individual and multiple KIR receptors was quantified. Phenotypic factors associated with HCV resolution were analyzed using Student’s t-Tests, univariate and logistic regression analyses. Results: Among 46 patients, 18 were HCV resolvers and 28 were chronically infected. The percentage of NK cells expressing the weakly inhibitory KIR2DL3 was higher in resolvers than in chronic patients (p=0.06). Conversely, there was a trend toward a greater percentage of NK cells expressing the strong inhibitor KIR2DL1 in chronically infected HCV patients compared with resolvers. The ratio of KIR2DL3/KIR2DL1+ NK cells was greater than unity in 16 of 18 (89%) resolvers, compared with only 14 of 28 (50%) chronically infected patients (p=0.06). NK cell staining with an antibody reactive against both KIR3DL1 and KIR3DS1 was highly variable, with a correlation toward higher levels in chronic patients (p=0.07). T cell expression of KIR was low, but ranged up to 5% in some chronic patients. Linear regression analyses show that the expression of KIR2DL3 and the KIR2DL3/KIR2DL1 >1 were independently associated with resolution (R=0.43, p=0.055). Conclusion: These preliminary data support the hypothesis that NK cell KIR phenotypes for KIR2DL3 and KIR2DL1 play a primary role in the regulation of HCV immunity. Further phenotypic and correlating genotypic analyses will further elucidate the contribution of KIR to HCV immunity.

INTERACTIONS OF CXCL-8 WITH INNATE ANTIVIRAL DEFENSES DURING HCV INFECTION

Jessica Wagoner1, Anne M. Werthermeier2, Hugo R. Rosen2, Stephen J. Polyak1
1Laboratory Medicine, University of Washington, Seattle, WA; 2Gastroenterology, University of Colorado Health Sciences Center, Denver, CO; 3Vaccine and Gene Therapy Institute, Beaverton, OR

Background: The alpha chemokine, CXCL-8 (interleukin 8) has been previously shown to be induced by HCV infection and inhibit the antiviral actions of IFN alpha. In the current study, we investigated induction of CXCL-8 by HCV, the effects of CXCL-8 on HCV replication, and whether CXCL-8 blocks IFN signaling. Methods: Genomic or subgenomic replicon cell lines, or direct JFH-1 infection of Huh7 and Huh7.5.1 cells, were used to study the effects of CXCL-8 on HCV replication. Human dendritic cells (DC) were exposed to apoptotic cells expressing HCV proteins and tested for changes in gene and protein expression, and IFN signaling. Results: HCV dsRNA induction of the RIG-I pathway-activated CXCL-8 transcription via recruitment of IFR-3 to the CXCL-8 promoter. The half-life of CXCL-8 mRNA increased in 3 of 4 HCV replicon cell lines, particularly after treatment with TNF-alpha. CXCL-8 protein levels correlated positively with HCV RNA levels in 4 replication lines (R = 0.41, P = 0.0013). In contrast, CXCL-8 mRNA levels correlated inversely with CXCL-8 protein and HCV RNA levels in all cells. HCV RNA synthesis in BB7 replicon cells was inhibited by CXCL-8 silencing. Huh7 and replicon cells expressed CXCR1 but not CXCR2, yet CXCL-8 did not inhibit IFN alpha signaling in these cells, even when both receptors were over-expressed. In contrast, when exposed to NSSA intracellularly, DCs expressed CXCL8, which was associated with inhibition of basal and IFN-induced Stat1 and Stat2 phosphorylation. Conclusions: The data indicate that: 1) HCV infection triggers dsRNA signaling pathways that induce CXCL-8 via transcriptional activation and mRNA stabilization, 2) CXCL-8 protein levels are positively associated with HCV replication, 3) CXCL-8 does not block IFN signaling in Huh7 cells, and 4) DCs exposed to NSSA increase CXCL8 expression which is associated with blockade of IFN signaling. The results suggest that HCV protein-induced CXCL-8 can block the IFN-alpha pathway at multiple levels, depending on the cell type and the manner by which the HCV proteins are encountered by the cell.

The HCV core gene is a complex genetic element whose full coding and regulatory functions remain unknown. 293T cells transfected with in vitro transcribed RNA containing HCV core gene sequences were analyzed by Western blot. A unique monoclonal antibody directed against core amino acids 104-110 detected a p9 protein designated “mini-core”. Mini-core had not been detected previously because it contains only the C-terminal portion of core and does not react with the more widely used anti-core antibodies that recognize the N-terminal portion. While mini-core is produced from both 1a and 1b expression constructs that extend from the 5’UTR through 2/3 of E1; genotype 1b constructs produce more. Cellular stress (Na arsenite) increases the amount of mini-core. Mini-core is also expressed from a full length1a/2a (H77/JFH) replication-competent virus in Huh7.5 cells. Investigations into mini-core production revealed that the core-encoding region may contain a novel IRES that is able to drive mini-core expression. Deletion

GENOMIC ANALYSIS OF HCV BREAKTHROUGHS OCCURRING DURING THE HALT-C TRIAL LEAD-IN TREATMENT PHASE

Hejun Yuan1, Mamta K. Jain1, Michael Gale2, William M. Lee3
1Internal Medicine, UTSW Medical Center at Dallas, Dallas, TX; 2Microbiology, UTSW Medical Center at Dallas, Dallas, TX

Background: The various hepatitis C virus (HCV) genotypes have different rates of clearance following interferon (IFN) and ribavirin (RBV), suggesting that the virus itself determines therapy response. In the HALT-C study lead-in phase, patients received 48 weeks of therapy if virus was undetectable at wk 20. Viral breakthrough (BT) was observed when HCV RNA reappeared at wk 36 or 48. We analyzed NSSA sequence changes over time in BT patients since this protein has been considered important to IFN resistance. Methods: Of 1,045 patients, 43 patients had breakthrough but, of these, only 12 patients had taken full dose (>80%) of peg-IFN and RBV. The entire NSSA region was amplified with RT-PCR and the amplification products sequenced from sera from baseline (BL), wk12 and at the time of BT (either wk36 or 48) from the 12 BT patients. Sera from BL, wk12 and wk24 from 2 matched non-responders (NR) for each BT patient were also sequenced. The number of synonymous and non-synonymous substitutions, total number of amino acid (aa) substitution and error rate were calculated by comparing BL to wk12 and BT time points. For NR patients we compared BL to wk12 and wk24. Results: BT HCV genotypes were 1a in 6 patients, 1b in 4 and 3a in 2; thus far, we have analyzed all 1a time points only. The 1a BT patients [median(range): 4(2-5) vs. 1(0-5), P=0.01], but BT patients and NR patients had comparable number of synonymous substitutions [median(range): 22(3-38) vs. 4(3-31), P=0.09]. At the protein level, BT patients also demonstrated significantly higher numbers of aa substitutions compared with NR patients [median(range): 3.5(2-5) vs 1(0-5), P=0.03]. When the later BT time point sequences (or wk24 sequences from NR patients) were analyzed, both groups had comparable median number of synonymous substitutions and non-synonymous substitutions and total number of aa substitution (P=NS). The error rates of nucleotide (nt) and aa at the time of breakthrough are 2.8X10-2 nt/site/ys and 1.5X10-2 aa/site/ys respectively in BT patients and 1.72X10-2 nt/site/ys and 9.7X10-3 aa/site/ys at wk24 in NR patients (both P=NS). Conclusions: The higher number of non-synonymous and aa substitutions at wk12 compared with NR patients [median(range): 4(2-5) vs 1(0-5).150, P=0.01], but BT patients and NR patients had comparable number of synonymous substitutions [median(range): 22(3-38) vs. 4(3-31), P=0.09]. The following people have nothing to disclose: Hejun Yuan, Mamta K. Jain, Michael Gale, William M. Lee
mutagenesis mapped this second IRES to the region between codons 56 and 154. Transfected DNA lacking the first 55 codons of the core gene not only retains the ability to express mini-core, but is greatly enhanced for mini-core production, as expected if core and mini-core compete for translational initiation. Constructs with codons 1-154 fused to a 3XFLAG-tag express (truncated) mini-core, whereas constructs with codons 1-125 do not. RNA transcripts lacking both a 5’ cap and the conventional HCV IRES express both mature core and mini-core, providing further evidence that a novel IRES activity is embedded within the core gene. (NIH DAO16156, DK066939 and ALF Scholar’s Award).

492 DEVELOPMENT OF JFH1-BASED INTERGENOTYPIC CELL CULTURE SYSTEMS OF HEPATITIS C VIRUS GENO-TYPES 1-5 AND THEIR USE IN STUDIES OF VIRAL ENTRY AND NEUTRALIZATION

Judith M. Gottwein1, Troels Scheel1, Tanja Bertelsen Jensen1, Jannick Prente1, Maria L. Knudsen2, Jesper Eugen-Olsen3, Jens Bukh1,2, 1Department of Infectious Diseases and Clinical Research Unit, Copenhagen University Hospital, Hvidovre, Denmark; 2Laboratory of Infectious Diseases, National Institutes of Health, Bethesda, MD

Recently the first full hepatitis C virus (HCV) life cycle culture systems were developed for the genotype 2a strain JFH1, as well as for the intragenotypic recombinant J6/JFH in which Core through NS2 of JFH1 were replaced by the corresponding genes from the genotype 2a strain J6CF. It has been reported that efficient growth of JFH1 in the hepatoma cell line Huh7.5 depends on adaptive mutations. However, in the present study we found that J6/JFH could be cultured efficiently without the need for adaptive mutations. We aimed at establishing cell culture systems for the different major genotypes of HCV. Utilizing the unique replication characteristics of JFH1 we developed a panel of intergenotypic recombinant HCV cDNA clones by insertion of the structural genes (Core, E1, E2), p7, and NS2 of genotype 1a, 1b, 1b, 2a, 3a, 4a, and 5a prototype isolates, respectively, into the JFH1 backbone. After transfection of RNA transcripts into Huh7.5 cells, viral spread occurred after an eclipse phase for all recombinants, except 2b/JFH1, which spread immediately. However, after serial passage the released intergenotypic viruses showed growth kinetics, genome titers and infectivity titers comparable to the intragenotypic recombinant J6/JFH control virus. The HCV RNA and infectivity titers in culture supernatant peaked at approximately 7 log10 IU/mL and 5 log10 50% tissue culture infectious doses (TCID50) per mL, respectively. By sequence analysis of the complete open reading frame of recovered viral genomes, we identified putative adaptive mutations for the intergenotypic recombinants and analyzed their role by testing them singly and in combination in reverse genetic studies. Thus, we identified adaptive mutations in p7 and NS3 for 1a/JFH1 and 3a/JFH1, in NS2 and NS3 for 1b/JFH1, and in NS2 for 4a/JFH1 and 5a/JFH1 recombinants that promoted efficient growth in Huh7.5 cells. Others have found that JFH1 infection depends on the putative co-receptor CD81. In initial studies we have demonstrated anti-CD81 dependent inhibition of 3a/JFH1, 4a/JFH1 and 5a/JFH1 infection in Huh7.5 cells. Thus, CD81 appears to be important for entry of all genotype viruses. Furthermore, we have demonstrated homologues serum neutralization of 100 TCID50 of 4a/JFH1 (100% neutralization) and 5a/JFH1 (>98% neutralization) viruses. The 4a/JFH1 and 5a/JFH1 viruses were furthermore cross-neutralized using genotype 1a serum. In summary, we developed intergenotypic recombinant cell culture systems for 5 of the 6 major HCV genotypes, which will be an important research tool for genotype specific functional studies of Core, E1, E2, p7 and NS2, and for related therapeutics.

493 PLAQUE-FORMING ASSAYS FOR HEPATITIS C VIRUS AND ISOLATION OF HCV-JFH1 MUTANTS WITH ENHANCED CYTOPATHOGENICITY AND REPLICATION CAPACITY

Naoya Sakamoto1,2, Yuko Sekine-Osajima1, Kako Mishima1, Mina Nakagawa1,2, Megumi Tasaka1, Yuki Nishimura-Sakurai1, Yasuhiro Itsui1, Takaji Wakita2, Mamoru Watanabe1; 1Dept. of Gastroenterology and Hepatology, Tokyo Medical and Dental Univ., Tokyo, Japan; 2Dept. for Hepatitis Control, Tokyo Medical and Dental Univ., Tokyo, Japan; 3Department of Virology II, National Institute of Infectious Diseases, Tokyo, Japan

Background and Aim: The mechanisms of hepatitis C virus-induced liver damage are not understood completely. HCV-JFH1 culture in-vitro (Wakita, Nature Medicine 2005) results in massive cell death, which suggests the involvement of HCV-induced cytopathic effects. Therefore, we investigated the mechanisms and viral nucleotide sequences involved in this effect using HCV-JFH1 cell culture and a newly developed cytopathic plaque-forming assay. Method: In-vitro synthesized HCV-JFH1 RNA was transfected into Huh-7.5.1 cells (Zhong, PNAS 2005) and the virus-containing culture supernatant was inoculated serially onto naive cells. Virus replication was measured by HCV core antigen assay and real-time RT-PCR. Viral cytopathogenicity was measured using the plaque-forming assay. Results: The HCV plaque-forming assay showed the appearance of cytopathic plaques, depending on the titer of the inocula. In the virus-infected cells, the ER stress markers, GRP 78 and phosphorylated eIF2-alpha, were overexpressed. Cells in the plaques were strongly positive for the apoptosis marker, annexin V. Isolated virus subclones from individual cytopathic plaques had acquired substantially greater replication efficiency and cytopathogenicity than the parental virus strain. The cytopathic JFH1 subclone, Pl #1, had 9 amino acid substitutions, of which 5 were clustered in the C terminal of NS5B region. The 3 amino acid substitutions of NS5B region were redundantly appeared in the 4 plaque-isolated clones and in all three Pl #1-derived subclones. Conclusion: HCV infection and replication showed cytopathic effects that were characterized by ER-stress-induced apoptotic cell death. HCV nucleotide sequences in certain regions might determine the viral replication and cytopathogenicity.

494 ANTI-MALARIAL DRUG CHLOROQUINE SUPPRESSES THE REPLICATION OF HCV REPLICON VIA PKR-INDEPENDENT MECHANISMS

Tomokazu Mizui1, Shunhei Yamashina1, Yoshiyuki Takei2, Kenichi Ikejima1, Tsuneo Kitamura1, Takashi Ueno2, Eiki Kominami2, Sumio Watanabe1, 1Gastroenterology, Juntendo University, Tokyo, Japan; 2Biochemistry, Juntendo University, Tokyo, Japan.

Background: It has been reported that autophagy plays a pivotal role in the replication of some RNA viruses. We previously reported that chloroquine treatment, which inhibits lysosomal and autophagic acidification, prevents replication of HCV replicon. However, it is unclear whether continuous chloroquine treatment keeps an antiviral effect. The mechanisms by which chloroquine inhibits the replication of HCV replicon has not been characterized. Here, we confirmed an antiviral effect of continuous chloroquine treatment and determined if the treatment of chloroquine activates interferon signaling and blunts autophagic protein degradation.

Methods: Huh-7 cells transfected with HCV replicon expressing firefly luciferase (Huh7/Rep-Feo) were used for this study. Cells were cultured with chloroquine (10^{-5} M) and/or IFNα (100 U/ml) for 7 days, then continued to incubate without drugs for another 21 days. Replication levels of HCV replicon were determined by luciferase assay at 7th and 21th day from cessation of drugs. Expression of phospho-PKR (p-PKR) and microtubule-associated protein-1 light chain 3 (LC3) were detected by western blot analysis. Alteration of autophagic proteolysis was evaluated by protein degradation assay. The number of autolysosome in cytoplasm was counted by using transmission electron microscopy.

Results: Luciferase activity was undetectable in cells treated with IFNα for 7 days; however, it reappeared when cells were subsequently cultured without IFNα for 21 days. In sharp contrast, co-incubation with IFNα and chloroquine for 7 days suppressed HCV replication for the extensive period up to 21 days even in the absence of these drugs. On the other hand, P-PKR was detected in cells treated with IFNα for 48 hours, but it was not observed in cells treated with chloroquine. Marked accumulation of autolysosome was observed in cytoplasm after 18 hours chloroquine treatment. Chloroquine treatment induced the expression of LC3-II to 3-fold over control after 4 hours. Moreover, chloroquine treatment for 4 hours significantly decreased degradation of leucine to about 76% of control value.

Conclusions: These findings indicate that chloroquine treatment possesses a powerful antiviral effect to prevent re-propagation of HCV replicon in combination with IFNα through the unique mechanism independent on interferon signaling pathway. It was hypothesized that suppression of autophagic protein degradation contributes to antiviral effect of chloroquine. The efficacy of chloroquine against HCV replication might provide a new therapeutic option for the patients with chronic hepatitis C.

495 CROSS-LINKING OF CD81 WITH HCV E2 REGULATES MIGRATION OF NATURAL KILLER (NK) CELLS IN A ROCK-DEPENDENT FASHION

Jacob Nattermann, Benjamin Krämer, Ludger Leifeld, Hans Dieter Nischalke, Tilman Sauerbruch, Ulrich Spengler; Internal Medicine I, University of Bonn, Bonn, Germany.

Background: Natural killer (NK) cells are crucial for the establishment of an efficient antiviral immune response but are also suggested to contribute to the HCV-induced hepatic injury. Previous data demonstrated that cytotoxic functions of NK cells is affected by interactions of the HCV E2 protein with CD81, a member of the tetraspanin family. Tetraspanins are organized in a cell-surface network containing several different tetraspanins which interact specifically with each other and their associated proteins (including integrins), called the tetraspanin web. Based on in vitro studies CD81 has been proposed to be part of the cellular receptor mechanism for HCV entry via binding of the HCV envelope protein E2. In addition, tetraspanins are involved in many cellular responses such as cell adhesion, activation, differentiation, and migration. In the present study we analyzed the effects of HCV E2/CD81 interactions on the migratory capacity of NK cells. Methods: NK cells were immunomagnetically isolated and stimulated with anti-CD81 or immobilized HCV E2 protein. NK migration towards RANTES (CCL5) was analyzed using a nitrocellulose filter micro chamber system. Surface expression of adhesion molecules were analyzed by flowcytometry and laser scanning microscopy. Activation of the proteins Ezrin, Moesin and Radizin (ERM), which are involved in lymphocyte migration, was studied by Western blot. Results: We found that cross-linking of CD81 by HCV E2 dramatically enhanced migration of NK cells towards the inflammatory chemokine CCL5. This effect could be blocked by pre-incubating NK cells with anti-CD81 mAb. HCV E2/CD81 interactions did not affect expression of chemokine receptors CCR1, CCR3 or CCR5. However, HCV E2-induced NK migration was associated with down regulation of surface expression of the adhesion molecules CD29, CD49d, and CD54 which are critically involved in cell migration. Western blot analysis confirmed that cross-linking of CD81 induced a ERM phosphorylation which could be blocked by pre-incubation with the ROCK-inhibitor Y27632. Conclusion: We found that cross-linking of CD81 by HCV E2 dramatically enhances the migratory responses of NK cells to CCL5 in a Rock-dependent fashion. As chronic hepatitis C is associated with enhanced intrahepatic expression of CCL5 this mechanism might be facilitate NK cell migration towards the liver potentially contributing to NK cell-mediated liver damage.

Hepatitis C virus (HCV) is a major cause of chronic hepatitis worldwide. Scavenger receptor class B type I (SR-BI) has been shown to bind HCV envelope glycoprotein E2, participate in entry of HCV pseudotype particles and modulate HCV infection. We have previously demonstrated that anti-SR-BI antibodies directed against epitopes of the human SR-BI extracellular loop and down-regulation of SR-BI expression by SR-BI-specific siRNAs markedly inhibited HCVcc infection. These data suggest that SR-BI plays an important role in productive HCV infection of human hepatoma cells. In this study, we mapped the HCV entry step targeted by SR-BI and addressed whether SR-BI and CD81 are involved in the same HCV entry pathways. Kinetic studies demonstrated that anti-SR-BI antibodies were able to inhibit HCVcc infection when added both during and after binding of the virus to the target cell. These data indicate that SR-BI is involved in an entry step occurring after HCV binding. Kinetic studies using anti-SR-BI and CD81 antibodies in side-by-side experiments demonstrated that SR-BI is required for an entry step occurring at a similar time point as CD81-HCV interaction. Both anti-SR-BI and anti-CD81 antibodies were able to inhibit HCV infection when added up to 60 min post binding and lost its ability to inhibit HCV infection when added 80 min post binding. In conclusion, our data suggest that SR-BI (i) represents a key host factor for HCV entry, (ii) is implicated in the same HCV entry pathway as CD81 and (iii) targets an entry step closely linked to HCV-CD81 interaction.

EVIDENCE FOR HIV AND HCV REPLICATION IN THE PERITONEAL MACROPHAGE
John J. Garber1, Arielle L. Klepper2, Julio A. Gutierrez2, Theresa L. Chang3, Aprille Rapista1, Viktoriya Khaitova, Douglas T. Dieterich1, Thomas D. Schiano4, Andrea D. Branch2; 1Division of Infectious Diseases, Mount Sinai Medical Center, New York, NY; 2Division of Liver Diseases, Mount Sinai Medical Center, New York, NY; 3Recanati/Miller Transplantation Institute, Mount Sinai Medical Center, New York, NY

Background: HCV replication has been reported in extra-hepatic cells, including white blood cells. Peritoneal macrophage are related to circulating monocytes, but have unique properties. To determine whether they harbor HCV and to measure their susceptibility to HIV, we isolated macrophage from the ascitic fluid (AF) of cirrhotic HCV patients and controls and maintained these powerful immunomodulatory cells in culture.

Methods: AF was collected from cirrhotic patients with HCV (n=9), HCV/HIV (n=4), alcoholic liver disease (n=5), and HBV (n=1), with IRB approval. Ascitic mononuclear cells (AMCs) were isolated from ~5 liters of AF by Ficoll-Histopaque density gradient centrifugation and plated in RPMI 1640 with 10% fetal calf serum. Non-adherent cells were removed after 12 hours. Adherent AMCs were cultured without cytokine supplementation for up to 3 months. Cells were stained with anti-CD68 (KP1), anti-CCR5, and produced >50 ng/ml of p24 at 12 days after HIV exposure. HIV infection appeared to increase the level HCV RNA at 14 days after infection. Conclusions: The majority of adherent cells in AF are CD68-CCR5-positive, phagocytic peritoneal macrophage. When isolated from HCV patients, these cells contain HCV RNA and viral proteins which persist for up to 4 weeks in culture. Peritoneal macrophage support HIV replication and HCV RNA is increased following HIV infection. These cells may represent a valuable cell culture system capable of supporting the replication of clinical isolates of HCV and exploring interactions between HIV and HCV. (NIH DA016156/DK066939)

ESTABLISHMENT OF INFECTIOUS GENOTYPE 1B HEPATITIS C VIRUS CLONE TO HUMAN HEPATOCYTE CHIMERIC MOUSE
Takashi Kimura1, Michio Imamura2, Kiyomi Toyota1, Nobuhiko Hiraga1, Chiemi Naguchi, Masataka Tsuge1, Shoichi Takahashi2, Keiko Arakaki2, Kazuaki Chayama1; 1Department of Medicine and Molecular science, Graduate school of Biomedical Science, Hiroshima University, Hiroshima, Japan; 2Internal Medicine, Hiroshima Prefectural University Hospital, Hiroshima, Japan

Background/Aims: Interferon (IFN) is the only useful drug to eradicate the hepatitis C virus (HCV). The therapeutic effects of IFN vary according to the HCV genotype; genotype 1b is the most resistant. However, the underlying mechanism of the vari- able IFN resistance among genotypes is yet to be solved. In this study, we attempted to establish a genotype 1b molecular clone which replicates in human hepatocyte chimeric mice. Methods: A full length HCV genome, HCVK19, was cloned from a serum
sample from a patient who developed severe acute hepatitis. Each of the chimeric mice was inoculated intrahepatically with 30 μg of in vitro-transcribed HCV RNA. Sera obtained from infected mice were subjected to passage experiments. HCV infected mice were treated with 1000 IU/g/day of IFN-alpha.

Results: The intrahepatic injection of transcribed HCV-KT9 RNA to chimeric mice resulted in measurable viremia at 2 weeks post-infection, which persisted for more than 6 weeks. Passage experiments indicated that the sera of these mice contained infectious HCV. Interestingly, a similar clone HCVKT1, a shorter poly(U/UC) tract version of KT9, showed poorer infectivity and replication ability. These results confirm the importance of poly(U/UC) tract length in the experimentally-induced viremia (HCV-KT1 clone has 86-nucleotide tract compared with HCV-KT9, which has a 115-nucleotide tract) and are consistent with a previous study that reported the high replication ability of HCV replicon with a long poly(U/UC) tract. A two-week IFN-treatment showed only 1.25 log reduction in HCV levels. These results are consistent with our previous study that showed a similar poor reduction of HCV RNA in mice infected with genotype 1a clone, and differ from our results in mice infected with HCV genotype 2a, which became negative for HCV RNA following daily treatment with 1000 IU/g of IFN for two weeks. These results are in agreement with our clinical experience that genotype 1 is more resistant to IFN therapy than genotype 2.

Conclusions: The established genotype 1b clone using human hepatocyte chimeric mice seems useful for the study of HCV virology, particularly the mechanism underlying the variable resistance of HCV genotypes against IFN therapy.

HCV-specific T cell responses are essential for viral resistance of HCV genotypes against IFN therapy. In virology, particularly the mechanism underlying the variable resistance of HCV type 1 is more resistant to IFN therapy than genotype 2. Consistent with our previous study that showed a similar poor reduction of HCV RNA in mice infected with genotype 1a clone, and differ from our results in mice infected with HCV genotype 2a, which became negative for HCV RNA following daily treatment with 1000 IU/g of IFN for two weeks. These results are in agreement with our clinical experience that genotype 1 is more resistant to IFN therapy than genotype 2. Conclusions: The established genotype 1b clone using human hepatocyte chimeric mice seems useful for the study of HCV virology, particularly the mechanism underlying the variable resistance of HCV genotypes against IFN therapy.

HYPERPROLACTINEMIA ASSOCIATED WITH CHRONIC HEPATITIS C AND INDUCTION OF PROLACTIN EXPRESSION IN HUMAN PERIPHERAL BLOOD MONONUCLEAR CELLS STIMULATED BY HEPATITIS C VIRUS

Rika Ishii, Takafumi Saito, Shao Li, Kazuo Okumoto, Jun-itsu Ito, Kazuhiko Sugahara, Koji Saito, Hitoshi Togashi, Sumio Kawata; 1Department of Gastroenterology, Yamagata University Faculty of Medicine, Yamagata, Japan; 2Department of Public Health, Yamagata University Faculty of Medicine, Yamagata, Japan

Background: Prolactin (PRL) is a pituitary hormone associated with lactation and reproduction. It is also known as an immunoregulatory hormone secreted from lymphocytes, and noted to have influence on cell immunity in infectious disease. PRL stimulates the production of IFN-γ and increases the effect of IL-2 in lymphocytes. Elevation of serum PRL levels has been reported in patients with HIV or in those with some infectious diseases, and hyperprolactinemia has been demonstrated in 20% of HIV-infected men. Thus PRL influences cell immunity in infectious disads, however, PRL induction in relation to HCV infection has not been elucidated. Methods: We examined serum PRL levels and frequency of hyperprolactinemia in both 232 subjects of our HCV cohort study and 31 male patients of the hospital, who were chronically infected with HCV. Serum PRL levels in healthy individuals without HCV infection were used as controls. Furthermore, serum PRL levels were compared in 20 male patients before and after anti-viral therapy using interferon. We measured expression of PRL mRNA level in PBMCs in 12 male patients and 6 healthy controls, and also investigated PRL mRNA of PBMCs collected from 5 healthy men that stimulated by HCV produced by Huh7.5 cells in vitro. The levels of serum PRL and PRL mRNA in PBMCs were measured by chemiluminescence immunoassay and real-time PCR, respectively. Results: Serum PRL levels were significantly higher in the HCV-infected subjects than in the controls (p<0.01). They were significantly higher in HCV-infected male subjects than in the controls (p<0.001), however, the difference was not significant between HCV-infected female subjects and controls. Frequency of hyperprolactinemia was significantly higher in HCV-infected male subjects than in the controls (p<0.05). Serum PRL levels were significantly higher in male patients than in the controls (p<0.01). Frequency of hyperprolactinemia was significantly higher in male patients than in the controls (p<0.05). Serum PRL levels decreased significantly after anti-viral therapy using interferon in 10 patients with sustained virological response to therapy (p<0.05), but no changes were found in 10 patients
501 ANTIVIRAL EFFECTS OF INTERFERON-INDUCED PROTEINS, GBP-1, IFI-6-16 AND IFI-27 AND THEIR INTERACTIONS WITH HEPATITIS C VIRUS NONSTRUCTURAL PROTEINS

Yasuhiro Itsui1, Naoya Sakamoto1,2, Mina Nakagawa1,2, Yuko Sekine-Osajima1, Yuki Nishimura-Sakurai1, Megumi Tasaka1, Mamoru Watanabe1, 1Department of Gastroenterology and Hepatology, Tokyo Medical and Dental University, Tokyo, Japan; 2Department of Hepatitis Control, Tokyo Medical and Dental University, Tokyo, Japan

Backgrounds: Interferons (IFNs) and the interferon-stimulated genes (ISGs) play a central role in antivirus responses against HCV infection. We have previously reported that ISGs including GBP-1, IFI-6-16 and IFI-27 directly and specifically inhibited HCV subgenomic replication (Itsui, JVH 2006). In the present study, we screened effects of ISGs against HCV cell culture and their direct mechanisms of antiviral actions. Materials and methods: The ISGs that were examined in this study were 18 genes, which expression levels were highly induced by the IFN-alpha treatment. Plasmids expressing individual ISG were constructed and were transfected into Huh7 cells that express selectable chimeric reporter protein of neomycin phosphotransferase and firefly luciferase (Huh7/Rep-Feo, Tanabe, J Infect Dis 2004). After transfection, replication level of HCV replicon was analyzed by luciferase assay. Plasmids expressing siRNA against GBP-1, IFI-6-16 and IFI-27 were transfected into Huh7/Rep-Feo. HCV-JFH1 cell culture system was used, and the replication levels were quantified by core protein detection in the culture medium. Plasmids expressing HCV-Nonstructural protein (NS3, NS4A, NS4B, NS5A and NS5B) and plasmids expressing ISG were cotransfected into HEK 293-T cells. Immunoprecipitation assays and mammalian two-hybrid assay were performed to analyze interaction of ISG with HCV proteins. Results: HCV subgenomic and genomic replication were significantly suppressed by overexpression of PKR (48.7±17.13%), MxA (46.8±5.60%), IRF9 (44.8±4.44%), GBP-1 (36.3±7.49%), IFI-6-16 (37.4±19.2%), IFI-27 (28.4±12.24%), 250AS (25.6±4.10%) and IRF1 (8.64±1.13%). The siRNA-knock down of GBP-1, IFI-6-16, and IFI-27 caused increase of HCV replication. The protein interaction assays showed that GBP-1 directly bound thumb epitope of HCV-NS5B- RNA-dependent RNA polymerase (RdRp). Conclusion: GBP-1, IFI-6-16 and IFI-27 negatively regulated HCV infection and replication. GBP-1 showed interaction with NS5B, suggesting direct effects on RdRp. Search for ISGs that regulate HCV replication may help elucidating the cellular defense mechanisms against HCV infection.

502 HCV-RELATED PROTEINS INDUCE PROINFLAMMATORY CYTOKINE PRODUCTION BY THE HUMAN KUPFFER CELL VIA THE MYD88-DEPENDENT SIGNALING CASCADE

Hiroshi Kono, Kenichi Ishii, Naohiro Hosomura, Nobuyuki Tanaka, Masanori Matsuda, Hideki Fuji; First Department of Surgery, University of Yamanashi, Chuo, Japan

Previously, it was reported from this laboratory that oxidative stress and the number of the activated Kupffer cell increased in patients infected with hepatitis C virus (HCV); however the exact mechanism of activation of the Kupffer cells is still unclear. Accordingly, the specific purpose of this study was whether HCV-related proteins could activate the Kupffer cell isolated from human liver tissues. Kupffer cells were isolated from non-cancerous surgical specimen by collagenase digestion and differential centrifugation using Nycodenz. After 24 hours incubation, Kupffer cells were co-cultured with HCV-related proteins (Core, NS3, NS4, and NS5) for 24 hours, and production of cytokine (TNF-α, IL-1β and IL-10) was determined by ELISA. Furthermore, DCF-probed Kupffer cells were cultured with HCV-related proteins, and production of free radical (H2O2) was assessed using the fluorescence microplate reader for 24 hours. The Kupffer cells produced proinflammatory cytokines, TNF-α and IL-1β by stimulation of all HCV-related proteins studied in a dose dependent manner and values were as same as production by the Kupffer cells stimulated with LPS (10 µg/ml). On the other hand, production of anti-inflammatory cytokine IL-10 was minimal. Production of TNF-α was greatest by stimulation of NS3 protein. Importantly, this production was significantly blunted by 40% by a neutralization antibody of the Toll-like receptor (TLR) 4 or a homodimerization inhibitory peptide of the myeloid differentiation factor (MyD) 88. Since production of interferon β did not detected by stimulation of NS3 proteins, HCV-related proteins activated the Kupffer cell predominantly via the MyD88-dependent signaling cascades. On the other hand, cytoklasatin B, which is an inhibitor of phagocytosis, did not affect production of TNF-α by the Kupffer cells. Free radical production was not detected in Kupffer cells stimulated with core proteins. Although free radical production was detected in Kupffer cells incubated with NS3, NS4 and NS5 proteins, the greatest production was observed by stimulation of NS5 protein. This production was not affected by an antagonist of TLR4. Thus, HCV-related proteins may cause prolonged activation of the Kupffer cells, leading to accumulation of inflammatory cytokines and oxidant stress in the liver in patients infected with HCV.

503 FULL-LENGTH SEQUENCE ANALYSIS OF HCV GENOTYPE-3A REVEALS NOVEL REGIONS OF HYPERVERSUS-ABILITY

Isla Humphreys1, Larry Park2, Katja Paffender1, Silvana Gautieri2, Paul Klenerman1, Eleanor Barnes1, 1Peter Medawar building, Nuffield department of medicine, Oxford, United Kingdom; 2Royal Perth Hospital, Centre for Clinical Immunology and Biomedical statistics, Perth, WA, Australia

Background: Patients with HCV genotype-3a are very commonly encountered in the UK as this genotype dominates in UK intravenous drug users and is highly prevalent in some immigrant populations. Surprisingly only 4 full length genotype-3a
sequences have been published to date. This makes both peptide design for T-cell assays and primer design for assessment of viral evolution problematic. The NIH have recently produced a peptide set for T cell analysis based on a single genotype-3a strain. The relevance of this single strain is currently unclear. Aim: To obtain near full-length (aa 1-2929) genotype-3a sequence from 23 patients in our local Oxford cohort. Methods: Viral RNA was concentrated from patients’ plasma by high-speed centrifugation for 1 hour then extracted using Qia-gen vRNA Extraction Kit. RNA was converted to cDNA using RT-PCR One-step reaction to produce two first round products at 4kb and 7kb in length. Ten second round primer pairs were used to generate 700-1500bp overlapping PCR products. These products were sequenced using 17 additional primers to build a sequence for each patient. Results: Amino acids 1-2929 were successfully obtained in 18 of 23 patients. In genotype-3a, regions of polymorphism are completely distinct as compared to other genotypes. The hypervariable region at the N-terminal of E2 was observed, as previously described. However we report 2 novel regions of hypervariability in E2, one of these is contained within the 15-nucleotide genotype-3a insertion. Conclusion: Full-length sequence analysis of genotype-3a infection has enabled us to generate a consensus sequence essential for peptide design and has revealed novel areas of hypervariability and polymorphism.

LOSS OF AUTOPHAGY PREVENTS APOPTOTIC CELL DEATH DURING ISCHEMIA-REPERFUSION IN THE MOUSE LIVER
Shunhei Yamashina1, Yoshiyuki Takei2, Tomokazu Mizui1, Kenichi Ikejima1, Masaaki Komatsu, Takashi Ueno2, Eiki Kominami3, Sumio Watanabe4; 1Dept of Biochemistry, Juntendo University, Tokyo, Japan; 2Dept of Gastroenterology, Mie University, Tsu-City, Japan; 3Dept of Biochemistry, Juntendo University, Tokyo, Japan

Background: The underlying mechanism by which apoptosis is activated during the early phase of reperfusion after liver ischemia remains poorly understood. In cerebral and cardiac ischemia, autophagy has been recognized as a protective response against nutrition deprivation and cellular damage. On the other hand, it has been suggested that autophagy can be activated by pro-death stimuli culminating in a programmed cell death. Here, we investigate if autophagy is directly linked to apoptosis in hepatic ischemia-reperfusion injury. Methods: Hepatic ischemia-reperfusion injury was induced in female C57BL/6 mice (wild type) and conditional Atg7-knockout mice, which have autophagy-deficient liver as described (J Cell Biol. 2005; 169, 425-34). Serum ALT value was measured to evaluate liver damage. The number of autophagosomes in cytoplasm was counted by using transmission electron microscopy. Moreover, expression of microtubule-associated protein-1 light chain 3 (LC3), cathepsin B and D were detected by Western blot analysis. TUNEL stain and immunofluorescent analysis of cytochrome c on the liver section were performed. Results: Serum ALT level at 2 hours post-reperfusion was elevated to about 50-fold as basal level in wild type mice, however, this elevation of ALT was blunted in mutant mice to about 60%. On the other hand, 2 hours after ischemia-reperfusion, the number of autophagosomes was increased to about 4-fold relative to basal level in wild type mice. Moreover, after ischemia-reperfusion, LC3-II expression gradually increased and reached a maximum at 2 hours after reperfusion and the elevated level was sustained up to 6 hours in wild type mice. The formation of autophagosome was not detected in Atg7 knockout mice liver during ischemia-reperfusion. Furthermore, deletion of Atg7 completely abolished apoptotic cell death in hepatocytes, whereas TUNEL-positive hepatocytes were induced by ischemia-reperfusion in wild type mice. Additionally, increases in the expression of both cathepsin B and D in the liver and the distribution of cytochrome c into cytosol of hepatocytes were observed after ischemia-reperfusion in the wild type mice, but not in the mutant mice. Conclusion: Autophagosome formation induced in hepatocytes during ischemia-reperfusion was correlated with the liver injury. Interestingly, loss of autophagy completely abolished apoptosis of hepatocytes due to ischemia-reperfusion. These results provide a direct evidence that autophagy is essential for induction of apoptosis in liver during ischemia-reperfusion.

GP130, THE SIGNAL-TRANSDUCING IL-6 RECEPTOR SUBUNIT, IS A SUBSTRATE OF CASPASES
Dirk Graf, Katrin Haslow, Ivo Münts, Johannes Bode, Dieter Häussinger; Clinic of Gastroenterology and Hepatology, Düsseldorf, Germany

Interleukin-6 (IL-6) is involved in acute phase reaction, liver regeneration, proliferation and anti-apoptosis. In this study we analysed the effects of bile acids and CD95 ligand on gp130 expression in rat hepatocytes, perfused rat liver and HepG2 cells, which were stably transfected with the sodium-taurocholate-cotransporting peptide (NTCP). Preincubation of rat hepatocytes with CD95 ligand or bile acids inhibited IL-6-induced tyrosine-phosphorylation of signal transducer and activator of transcription 3 (STAT-3) by down-regulation of gp130. CD95 ligand had no effect on gp130 mRNA levels or gp80 protein expression, but strongly decreased protein expression of the signal-transducing IL-6 receptor subunit gp130. Inhibition of proteasomal or lysosomal proteolysis by specific inhibitors did not prevent the CD95-induced gp130 loss. However, inhibition of caspase 3 (Z-DEVD-FMK) or 8 (Z-IETD-FMK) was able to recover CD95 ligand-induced inhibition of STAT3-phosphorylation on tyrosine 705 and gp130 down-regulation. The intracytoplasmic tail of gp130 contains an overlapping DXD motif at position 800-806 of its amino acid sequence, which might be an preferred cleavage motif of caspase 3. For confirming this hypothesis, we transfected NTCP-HepG2 cells with a chimeric receptor consisting of the extracellular domain of the erythropoietin (EPO) receptor and the intracytoplasmic domain of gp130. We mutated the potential cleavage motif by exchanging the aspartate at position 803 to glutamate. In vitro studies showed that addition of recombinant active caspase 3 to lysates of NTCP-HepG2 cells, which were cotransfected with EPO/gp130 wild type receptor, leads to down-regulation of this chimeric receptor, while a cleavage product simultaneously occurs with a molecular weight of nearly 18 kD. However, lysates of NTCP-HepG2 cells, which were transfected with an mutated EPO/gp130 (803E) as indicated above, showed no degradation in response to active caspase 3 in vitro. Cleavage resistance of gp130 in response to the hydrophobic bile acid glycochenodeoxycholate (GDC) was also obtained in NTCP-HepG2 cells, which were transfected with the mutated EPO/gp130 (803E). This down-regulation of gp130 may aggravate the hepatotoxicity in cholestatic liver disease by
blocking the known hepatoprotective effects, mediated by gp130 activation in response to IL-6.

506 ENDOTOXIN INDUCES ER STRESS IN RAT PRIMARY HEPATOCYTES VIA STELLATE CELLS: ROLE OF JNK MAPK ACTIVATION

SeonHee Oh1, Noor Mohamed Jameel1, Donna B. Stolz2, Chandrashekar R. Gandhi1; 1Surgery, University of Pittsburgh, Pittsburgh, PA; 2Cell Biology, University of Pittsburgh, Pittsburgh, PA

Background and Aims: Endotoxin-stimulated hepatic stellate cells (HSCs) were found to stimulate nitric oxide synthesis, inhibit DNA synthesis and cause apoptosis of hepatocytes. However, mechanisms of the effects of LPS-stimulated HSCs on hepatocytes are not known. We investigated signaling mechanisms of the actions of LPS-stimulated culture-activated HSCs on hepatocytes. Methods: HSCs isolated from the rat liver were activated in primary culture and stimulated with gram-negative bacterial lipopolysaccharide (LPS) for 24 hours. The conditioned medium was transferred to rat hepatocytes in primary culture. For control, hepatocytes were incubated without or with LPS and medium conditioned by HSCs without LPS. Morphological characteristics and signaling pathways were determined at various time points. Results: LPS-conditioned HSC medium (LPS-HSCm) caused cytosolic vacuolization and ER dilation as evidenced phase-contrast and electron microscopy. The effects were maximal at 6 hours of incubation. Medium conditioned by HSCs in the absence of LPS also elicited similar responses but the magnitude was much lower. The effects of LPS-HSCm were associated with the activation of ER stress molecules ATF6, PERK and eIF2α as well as CHOP. Although LPS-HSCm also caused activation of p38, ERK- and JNK-mitogen-activated protein kinases (MAPK) in hepatocytes, blockade of only JNK-MAPK ameliorated the ER stress [and apoptosis] caused by LPS-HSCm. These effects of LPS-HSCm on hepatocytes were comparable to the established ER stress inducers thapsigargin and tunicamycin. Conclusions: The results demonstrate for the first time that LPS-stimulated HSCs release mediators that cause ER stress in hepatocytes and this effect, which is related both to survival and apoptotic death, may be an important mechanism of hepatocyte survival/death in hepatic pathophysiology.

507 ARSENIC AT SUBHEPATOXIC DOSES SYNERGISTI-
CALLY ENHANCES LIPOPOLYSACCHARIDE-INDUCED LIVER INJURY IN MICE

Gavin E. Arteel1,2, Heather L. Miller1, Theresa S. Chen1, Luping Guo1, Thomas J. Schlief1, Juliane I. Beier1, J. Phillip Kaiser1, J. Christopher States1; 1Dept of Pharmacology/Toxicology, University of Louisville, School of Medicine, Louisville, KY; 2James Graham Brown Cancer Center, University of Louisville, Louisville, KY

Background. The risk of developing chronic liver disease (e.g., NAFLD) depends on many factors, both environmental and genetic. Exposure to arsenic via drinking water is a serious health concern in the US. Whereas studies have identified arsenic alone as an independent risk factor for liver disease, concentrations of arsenic required to damage this organ are generally higher than found in the US water supply. The purpose of the current study was to test the hypothesis that arsenic (at subhepatotoxic doses) may also sensitize the liver to a second hepatotoxin. To test this hypothesis, the effect of chronic exposure to arsenic on liver damage caused by acute lipopolysaccharide (LPS) was determined in mice. Methods. Male C57Bl/6 mice (4-6 weeks) were exposed to arsenic (49 ppm as sodium arsenite in drinking water). After 7 months of exposure, animals were injected with LPS (10 mg/kg i.p.) and sacrificed 24 h later. Results. Arsenic alone caused no overt hepatotoxicity, as determined by plasma enzymes and histology. Whereas LPS significantly increased hepatic lipids, arsenic had no effect on these parameters, neither in the presence nor absence of LPS. In contrast, arsenic exposure dramatically enhanced liver damage caused by LPS, increasing the number and size of necroinflammatory foci. This effect of arsenic was coupled with increases in indices of oxidative stress (4-HNE adducts, depletion of GSH and methionine pools). The number of apoptotic (TUNEL) hepatocytes were similar in the LPS and arsenic/LPS groups. In contrast, arsenic preexposure blunted the increase in proliferating (PCNA) hepatocytes caused by LPS; this change in the balance between cell death and proliferation was coupled with a robust loss of liver weight in the arsenic/LPS compared to the LPS alone group. The impairment of proliferation after LPS caused by arsenic was also coupled with alterations in the expression of key mediators of cell cycle progression (p27, p21, CDK6 and Cyclin D1). Conclusions. Taken together, these results suggest that arsenic, at doses that are not overtly hepatotoxic per se, synergistically enhances LPS-induced liver injury. These results further suggest that arsenic levels in the drinking water may be a risk modifier for the development of chronic liver diseases.

508 METFORMIN PROTECTS RAT HEPATOCYTES AGAINST APOPTOSIS VIA THE PI3-KINASE/AKT SURVIVAL PATHWAY, BUT HAS NO EFFECT ON NF-κB SIGNALING

Titia E. Vrenken, Laura Conde de la Rosa, Manon Buist-Homan, Klaas Nico Faber, Han Moshage; Gastroenterology and Hepatology, University Medical Center Groningen, Groningen, Netherlands

Background. Metformin improves glucose tolerance in Diabetes Mellitus type 2. Additionally, metformin ameliorates liver damage in patients with non-alcoholic-fatty-liver disease (NAFLD). The mechanism of this hepatoprotective effect has not been elucidated yet. Previously we have shown that metformin protects hepatocytes against bile acid-induced apoptosis. The mechanism is still unknown. Furthermore, the effects of metformin in acute liver injury have not been examined yet. Previous research indicated that the PI3-kinase/Akt survival pathway and the transcription factor NF-κB are key regulators of the balance between survival and death in hepatocytes. Aim of this study was to elucidate the mechanism of the anti-apoptotic properties of metformin and to investigate the effect of metformin in an in vitro model of acute liver failure. Methods Primary rat hepatocytes were exposed to the bile acid glycochenodeoxycholic acid (GCDCa, 50 µM, 4 hrs), or 16 hrs to TNFα (20 ng/ml) with or without actinomycin D (200 ng/ml) or 16 hrs to a cytokine mixture (CM, containing mTNFα, hIL-1β, rIFNγ and LPS). Metformin (1 mM) was added simultaneously with the apoptotic stimuli. The PI3-kinase/Akt signaling pathway was blocked using LY294002 (50 µM). The mRNA
expression of the NF-κB-regulated gene iNOS, and the anti-apoptotic gene bcl-xl were determined by qPCR. Caspase-3-like activity was measured in cell lysates with a fluorometric assay. Necrotic cell death was determined using the Sytox Green nuclear staining. Results Metformin reduced GCDCA-induced caspase-3 activity by 84%, without increasing necrosis. In contrast, metformin did not inhibit TNF/ActD-induced apoptosis. Inhibition of PI3-kinase completely abolished the protection of metformin against GCDCA-induced apoptosis. Metformin increased Bcl-xl mRNA expression, while co-treatment with GCDCA even further increased Bcl-xl mRNA levels. Metformin did not inhibit CM-induced iNOS expression, and did not sensitize hepatocytes to TNF-induced apoptosis, indicating that metformin does not affect TNF-induced NF-κB-activation. Conclusion Metformin protects hepatocytes against bile acid-induced apoptosis, without switching cell death to necrosis. The protective effect of metformin is dependent on the PI3-kinase/Akt pathway, and may be partly mediated via induction of the anti-apoptotic protein Bcl-xl. Metformin does not protect against TNF/ActD-induced hepatocyte apoptosis, an in vitro model of acute liver failure. Metformin has no effect on NF-κB signaling and does not sensitize hepatocytes to TNF-induced apoptosis. Our results suggest metformin may be used in cholestatic liver disorders accompanied by inflammation.

509 ZINC SUPPLEMENTATION STIMULATES HEPATIC REGENERATION BY PRESERVING HEPATOCYTE NUCLEAR FACTOR-4α IN MICE SUBJECTED TO A LONG-TERM ETHANOL ADMINISTRATION

Xinqin Kang, Zhenyuan Song, Craig J. McClain, Y. James Kang, Zhanxiang Zhou; University of Louisville, Louisville, KY

Alcoholic liver disease is associated with sustained liver damage and impaired regeneration response. Our previous studies demonstrated that dietary zinc supplementation normalizes hepatic zinc level in association with inhibition of alcoholic liver injury. This study was undertaken to examine whether or not dietary zinc supplementation can improve liver regeneration in mice subjected to long-term ethanol exposure. 129SVE mice were paired-fed an ethanol-containing liquid diet for 6 months, and the effects of zinc supplementation on ethanol-induced liver injury and regeneration were analyzed. Zinc supplementation prevented ethanol-induced decrease in hepatic zinc concentration and liver injury as measured by serum alanine transferase activity and histopathological changes. Zinc supplementation also enhanced liver regeneration as indicated by increased number of PCNA-positive and BrdU-labeled hepatocytes in the ethanol-exposed mice. Real time RT-PCR demonstrated that zinc supplementation not only prevented ethanol-reduced suppression of gene expression of IGFBP1 and MT, but also upregulated HGF and cyclin D1. To determine the mechanism for zinc regulation of gene expression, hepatocyte nuclear factor-4α (HNF-4α), a zinc finger transcription factor, was evaluated. Zinc supplementation up-regulated the mRNA level of HNF-4α and preserved the protein level of HNF-4α. The link between zinc and HNF-4α in cell proliferation was examined in HepG2 cell cultures. Zinc deprivation by TPEN retarded cell growth in association with dysfunctions of HNF-4α. Gene silencing for HNF-4α retarded cell growth death in association with remarkable decrease in the protein levels of IGF-I, IGFBP1, MT and cyclin D1. HNF-4α siRNA transfection also attenuated zinc-induced expression of IGF-I, MT and cyclin D1. In conclusion, zinc supplementation stimulates liver regeneration through preservation of HNF-4α, through which gene involved in the regeneration were upregulated. (Supported in part by the National Institutes of Health grants and the Veterans Administration, Louisville)

510 QUALIFICATION OF FOUR SERUM BIOMARKERS OF HEPATOTOXICITY BY THE PREDICTIVE SAFETY TESTING CONSORTIUM (PSTC)

Shelli J. Schomaker1, Holly Jordan2, Frances Clemo3, Kyle Kolaja4, Patrick Wier2, William Mattes2; 1Drug Safety Research and Development, Pfizer Inc., Groton, CT; 2Safety Assessment, GlaxoSmithKline, King of Prussia, PA; 3Safety Assessment, GlaxoSmithKline, Research Triangle Park, NC; 4Toxicology, Roche, Palo Alto, CA; 5Toxicology, Critical Path Institute, Rockville, MD

The Predictive Safety Testing Consortium (PSTC), a collaboration among 16 pharmaceutical companies with FDA participation, has the goal of qualifying preclinical and clinical safety biomarkers for regulatory acceptance. This consortium, administered by the C-Path Institute, is formally endorsed by the FDA as a “Critical Path Initiative” activity. Several working groups have been formed to advance safety biomarkers for hepatic, renal, and vascular injury as well as carcinogenicity. Member companies use the consortium mechanism to bring forward putative safety biomarkers that have been derived from the literature or discovered in their internal laboratories that have significant supporting data and biological rationale. Cross-validation studies are planned to collaboratively qualify biomarkers for preclinical and ultimately clinical use. Specifically, this has involved the exchange of assay protocols and archived serum samples from internal studies. This poster will focus on the advances the Hepatotoxicity Working Group has made towards the qualification of four serum biomarkers of hepatotoxicity: glutamate dehydrogenase, paraoxonase, purine nucleoside phosphorylase, and malate dehydrogenase. The overall value of this PSTC effort extends beyond sharing of costs and intellectual resources as it will also enable a more rapid safety biomarker qualification and direct engagement of FDA on qualification and acceptance criteria for safety biomarkers.

511 OXIDATIVE STRESS MODULATES THE EXPRESSION OF KRÜPPEL-LIKE FACTOR-6 AND ITS SPLICE-VARIANTS

Raquel Urtasun, Francisco Javier Cubero, Steven Yea, Scott L. Friedman, Natalie Nieto; Medicine/Liver Diseases, Mount Sinai School of Medicine, New York, NY

Induction of ROS is one of the central mechanisms by which ethanol is hepatotoxic. Krüppel-like factor 6 (KLF6) is a transcription factor and a tumor-suppressor gene suggested to be mutated in several carcinomas. KLF6 is an immediate early responsive gene to cellular stress and injury, but the impact of ROS on its expression is unknown. Aim: To investigate the contribution of two different sources of ROS, cytochrome P450 2E1 (CYP2E1) and NADPH oxidoreductase (NQO1), on the modulation of KLF6 expression, alternative splicing to KLF6-full expression, and the effect on two downstream targets TNFRα and TGFβ. Results: 1) In a culture model of endogenous ROS production, CYP2E1-expressing HepG2 cells showed higher levels of KLF6-full mRNA and protein and its spliced variants compared to controls. Co-incubation with
arachidonic acid, arachidonic acid plus iron (inducers of lipid peroxidation-derived reactions), β-naphthoflavone (a CYP2E1 inducer), and H$_2$O$_2$, further enhanced KLF$_{6\text{full}}$ and its spliced forms. These effects were prevented by vitamin E, which blocks lipid peroxidation, and by CYP2E1 inhibitors. In primary hepatocytes isolated from rats fed the alcohol-containing Lieber-DeCarli diet for 4 months there was elevated lipid peroxidation-end products, H$_2$O$_2$, and CYP2E1, associated with a 2-fold increase in KLF$_{6\text{full}}$mRNA compared to hepatocytes isolated from rats fed a control diet. These results validated the role of alcohol and CYP2E1-derived ROS in the induction of KLF$_{6\text{full}}$ and the spliced variants. 2) Two powerful pro-oxidants such as menadione and paraquat which undergo two electron reduction via NQO1 induced KLF$_{6\text{full}}$ and its isoforms. Menadione also increased KLF$_{6\text{full}}$ in a colon cancer cell line. Addition of antioxidants such as catalase, SOD, glutathione ethyl ester, and vitamin E, and of dicumarol, a NQO1 inhibitor, all suppressed both the basal effect by CYP2E1 expression as well as the increase in KLF$_{6\text{full}}$mRNA by menadione and paraquat. Moreover GSH depletion by L-buthionine sulfoximine enhanced 2-fold the effect of menadione and paraquat suggesting that KLF$_{6\text{full}}$ expression may be also thiol-sensitive. 3) The CYP2E1-expressing cells and controls were transfected with siRNA for KLF$_{6\text{full}}$ and KLF$_{6\text{V1}}$. While levels of H$_2$O$_2$ and O$_2^-$ remained similar to those of the non-transfected cells, inhibition of KLF$_{6\text{V1}}$ caused an increase in both TNFα and TGFB mostly in the CYP2E1 cells. Conclusion: These results indicate that several sources of endogenous ROS increase KLF$_{6\text{full}}$ expression and its spliced variants, and that KLF$_{6\text{V1}}$ may play a key role in modulating the expression of critical cytokines involved in the development of liver disease.

A PROTEOMIC APPROACH TO NUCLEOSIDE ANALOGUE ASSOCIATED MITOCHONDRIAL TOXICITY

Matthias Banasch, Sven Liffers, Wolfgang E. Meyer, Heimut E. Meyer, Kai Stühler

Department of Internal Medicine 1, St. Josef Hospital, University of Bochum, Bochum, Germany; Medical Proteome Center, University of Bochum, Bochum, Germany

Introduction: Treatment with nucleoside inhibitors of reverse transcriptase (NRTI) may contribute to mitochondrial toxicity in chronic HIV-infection. Recent research has primarily focussed on mitochondrial DNA (mtDNA) encoded enzymes which are known to be affected by NRTI-associated inhibition of mtDNA replication. This approach ignores the majority of mitochondrial proteins which may be essential for manifestation of mitochondrial toxicity. Because of their limited protein content mitochondria are excellent candidates for proteomic analyses. We used this technique for examination of mitochondrial protein expression in an established in vitro model of NRTI-related hepatic mitochondrial toxicity. Methods: Human hepatocytes (HepG2) were exposed to steady state peak plasma levels of AZT and ddC for 14 days. Mitochondria were isolated by differential ultracentrifugation. Proteome analysis was performed by using a recently introduced DIGE (fluorescence 2-D difference gel electrophoresis) system. Differentially expressed proteins were subsequently identified by MALDI-PMF/PFF-MS analysis. Results: In preliminary image analysis we identified 18 differentially regulated mitochondrial proteins in NRTI exposed cells (t-test<0.05, expression change>1.5). Besides expected enzymes of the respiratory chain complex we identified several new proteins involved in cellular oxidative damage protection (e.g. peroxiredoxin-3, heat-shock protein 10) which were regulated in NRTI-exposed hepatocytes. Surprisingly protein expression pattern of AZT and ddC exposed cells showed distinct differences (only 3 identical proteins). Conclusion: Proteomic analysis may be useful for identification of yet unknown proteins beyond pol-γ-hypothesis and respiratory chain trail which are involved in manifestation of mitochondrial and cellular damage in NRTI-exposed cells and tissues. We identified several proteins which may play a crucial role in hepatocellular adaptation to NRTI-exposure. The distinctly different mitochondrial protein expression pattern in AZT- and ddC-exposed cells may explain the lower toxic potency of AZT. Future research may demonstrate the in vivo transferability of these in vitro results and will define the functional relevance of the identified proteins.
514 SUPPRESSIVE EFFECTS OF RETINOIDS ON IRON-INDUCED OXIDATIVE STRESS IN LIVER BY DOWNREGULATION OF HEMOJUVELIN

Hiroyuki Tsuchiya, Tomohiko Sakabe, Toshiko Hoshikawa, Goshi Shiota; Grad. Sch. Med., Tottori University, Yonago, Japan

[Background/Aim] We previously reported that dominant negative retinoic acid receptor alpha transgenic (RAR-E) mice exhibit steatohepatitis, possibly due to the abnormalities of lipid metabolism, leading to hepatocellular carcinoma (HCC). Recently, oxidative stress induced by hepatic iron overload has emerged as an important factor for the progression of HCV-related chronic hepatitis and non-alcoholic steatohepatitis (NASH). In the present study, we examined the effect of RA on the iron metabolism in vitro and in vivo. [Methods] In vitro studies, human hepatocellular carcinoma cell line HuH7 cells were treated with all-trans retinoic acid (ATRA). In in vivo studies, C57BL/6 mice were fed with retinoid-deficient, normal and retinoid-excessive diets for 1 month followed by intraperitoneal iron-dextrane administrations. The expression of iron metabolism-related genes was analysed by real-time RT-PCR. Promoter analyses were performed by chromatin immunoprecipitation (ChIP) assay. Non-heme iron concentrations and 59Fe-transferin uptake were determined by a colorimetric assay and a gamma counter, respectively. [Results] The overexpression of hemojuvelin (Hjv) gene and significantly higher iron contents were observed in RAR-E mice livers, compared to those in wild type mice. ATRA clearly inhibited HJV gene expression. ChIP assay demonstrated that RARalpha and RXRbeta2 were recruited to the 5'-region of HJV gene containing two RA response element half-sites. ATRA also significantly decreased the amount of iron in HuH7 cells. Furthermore, the iron-induced decrease in antioxidant activity and cytotoxicity were significantly prevented in the presence of ATRA. In accordance with in vitro observations, retinoid-excessive diet significantly decreased Hjv expression and iron contents in C57BL/6 mice, leading to decrease in iron-induced oxidative stress. [Conclusions] It was shown that retinoid has a protective effect on iron-related oxidative stress by regulating the HJV gene expression. Our findings suggest that the mechanism of hepatic carcinogenesis by loss of retinoid signals involves the abnormalities of iron metabolism as well as those of lipid metabolism.

515 HEPATOCYTE GROWTH FACTOR PROTECTS AGAINST OXIDATIVE INJURY INDUCED BY ETHANOL METABOLISM

Argelia Valdes-Arzate1, Luis E. Gómez-Quiroz1, Cynthia Licana1, Leticia Bucio1, Verónica Souza1, Elizabeth Hernandez2, David Kershenobich2, Dan L. Clemens3, Concepcion Gutiérrez-Ruiz1; 1Cien-ciencias de la Salud, Universidad Autónoma Metropolitana, Iztapalapa, México D.F., Mexico; 2Medicina Experimental, Facul-tad de Medicina, Universidad Nacional Autónoma de México, México D.F., Mexico; 3Liver Study Unit, Research Service, The Omaha Veterans Affairs (VA) Medical Center, Omaha, NE

Introduction: Hepatocyte growth factor and its receptor c-met, are involved in many cellular responses such as morphogenesis, mitogenesis, motility and apoptosis protection, however the effect against oxidative injury induced by ethanol (EtOH) metabolism is not well understood. Objective: The aim of the present work was to address the mechanism of HGF-induced protection against EtOH-generated oxidative stress damage in EtOH metabolizing cells. Material and Methods: VL-17A cells, HepG2 cells transfected with cytochrome P450 2E1 and alcohol dehydrogenase genes, were pretreated with 50 ng/ml HGF for 12 hr and then treated with 100 mM EtOH for 0 – 48 hr. Lipid peroxidation was determined by Buege and Aust method, protein oxidation was analyzed by Oxylab kit. Antioxidants enzymes and actin were determined by Western blot and cell proliferation was analyzed by BrdU DNA incorporation. Results: EtOH induced cellular damage and oxidative stress judge by a decrease in cell viability (28%) and cell proliferation (55%), elevation in lipid (4.7-fold) and protein oxidation, and reactive oxygen species production, effects that were prevented by HGF pretreatment. In order to explore if protection is dependent of an elevation of the antioxidant systems, we performed a Western blot analysis of catalase and superoxide dismutase1 (SOD1). We found that HGF induced the expression of both catalase (2.7-fold) and SOD1 (2.0-fold) in a time dependent manner. HGF/c-met can activate many signal transduction pathway which can promote survival. In order to explore the signaling pathway that regulates HGF-induced oxidative stress protection, VL-17A cells were pretreated with the PI3K inhibitor wortmannin, AKT inhibitor II, and sul-fasalazine an inhibitor NF-κB. We found that HGF-induced oxidative stress protection was abrogated by all inhibitors. HGF-induced catalase and SOD1 expression were suppressed. In conclusion our data sustains that HGF protects cells from damage induced by EtOH metabolism by a mechanism driven by NF-κB and PI3K/Akt signaling pathway. This work was supported in part by CONACyT: 45921.

516 HEPATIC MITOCHONDRIAL α-TOCOPHEROL AND CAR-DIOLIPIN IN YOUNG RATS MAY AFFORD PROTECTION AGAINST BILE ACID-INDUCED MITOCHONDRIAL PATHWAYS OF CELL DEATH

Ronald J. Sokol1, Michael W. Devereaux1, Genevieve C. Sparagano2, Scott W. Leonard3, Maret G. Traber3, Eric Gumpricht1; 1Pediatrics, University of Colorado School of Medicine, Denver, CO; 2University of Colorado-Boulder, Boulder, CO; 3Oregon State University, Corvallis, OR

Retention of bile acids in cholestatic disorders causes liver injury by mechanisms involving mitochondrial (mito) pathways of cell death. Although the human neonate is particularly susceptible to cholestatic injury compared to adults, liver mitos from young rats were surprisingly resistant to bile acid-induced mito permeability transition (MPT) and cytochrome c release (Hepatology 2005;42 [Suppl. 1]: 501A). Levels of MPT pore proteins, Bcl-2 proteins and antioxidant enzymes did not account for this resistance. Mito membrane function is also sensitive to lipid composition. Consequently, the objective of the current study was to determine whether mito alpha tocopherol (α-TH) or cardiolipin (CL) content played a role in this MPT resistance in young rats. [Methods] Mitos were isolated from pooled livers of 10 day-old or adult (9 wk-old) male Sprague-Dawley rats. MPT was assessed by mito swelling at 540nm during 5 minutes exposure to 100μM glycochenodeoxycholate (GCDC). α-TH concentrations in mitochondria were determined by HPLC with electrochemical detection. Mito CL (total and sub-
ALTER CELL FATE FOLLOWING OXIDATIVE STRESS DOES NOT ALTER CELL FATE
Jorge Allina, Bin Hu, Jingxiang Bai, Joseph Odin; Mount Sinai School of Medicine, New York, NY

Background: Mitochondrial oxidative damage is a common feature of liver diseases such as NAFLD. Though formation of mixed disulfides between oxidized glutathione and protein sulfhydryl groups, known as protein glycation, temporarily inactivates key mitochondrial enzymes, it also generates reduced glutathione, which can protect protein sulfhydryl groups from irreversible oxidation by reactive oxygen species. Thus modulation of mitochondrial protein glycation following oxidative stress may impact upon cell fate. Aim: The aim of this study was to determine whether several known antioxidants modulate mitochondrial protein glycation and are cytoprotective. Methods: HEK cells, which express little endogenous β2-microglobulin, were either transfected with a vector encoding β2-microglobulin or transduced with adenovirus encoding cathepsin (Ad·cat). In other experiments HEK cells were preincubated with estradiol. Following induction of oxidative stress by ultraviolet B irradiation, the percentage of HEK cells undergoing apoptosis following UV-B irradiation was determined.

COSUPPLEMENTATION WITH VITAMIN E AND COENZYME Q(10) REDUCES IRON-OVERLOADED INDUCED HEPATIC STEATOSIS IN TRANSGENIC MICE EXPRESSING THE HEPATITIS C VIRUS POLYPROTEIN
Masaaki Korenaga, Shoji Nishina, Keisuke Hino, Isao Sakaida; 1Department of Gastroenterology & Hepatology, Yamaguchi University graduate school of medicine, Ube, Japan; 2Basic Laboratory Sciences, Yamaguchi University graduate school of medicine, Ube, Japan

Background: It was well known that vitamins E and/or C might be useful to prevent the formation of oxidation products by dietary oxidized fats. Coenzyme Q is a redox compound acting as an antioxidant. Reduced coenzyme Q can prevent lipid oxidation chain reaction by itself or by reducing other antioxidants such as vitamins E and/or C. We reported that iron-overloaded in the hepatitis C virus (HCV) transgenic mice (TgM) developed HCC through mitochondrial injury and chromosomal damage due to accumulations of hepatic oxidative stress (Gastroenterology: 130: 2087–2096). The aim of this study was to investigate whether or not Cosupplementation with Vitamin E (alpha-tocopherol) and Coenzyme Q10 (Coq10) is able to prevent oxidative stress and hepatic steatosis caused by dietary iron-overloaded in HCV TgM. Methods: 3 months old female were divided into four groups. These were fed iron excess diet (carbonyl iron 225 mg/kg diet) with 100 or 500 mg alpha-tocopherol/20 mg Coq10 control II: 500 mg alpha-tocopherol/20 mg, IV: 500 mg alpha-tocopherol/20 mg Cosupplementation after 6 months, hepatic steatosis was evaluated from mice liver. ROS production was observed using the dehydroethidium (DHE) dye, which could detect superoxide anion in the liver. ALT, Serum iron and transferin-iron saturation were measurement. Finally, mitochondrial complex I activity and GSH were examined as mitochondria function. Results: Serum ALT levels (I: 218±71 II: 120±26 III: 57±11 IV: 70±21) and the ratio of liver weight to body weight (I: 4.7±0.2 II: 4.1±0.4 III: 4.1±0.2 IV: 3.8±0.2) were significantly lower in HCV TgM treated with Cosupplementation (III and IV) than in those in control (I). ROS production was attenuated in II, III and IV than in those in I. Although inhibition of hepatic oxidative stress, hepatic steatosis was suppressed only in IV. These data suggested that high dose Vitamin need to Coenzyme Q for the antioxidant effects. Mitochondrial complex I activity in IV 20% increased than in those species) was determined by electrospray-ionization mass spectrometry. Hepatic α-Th was enriched in vivo in the adult rat by a single subcutaneous (SQ) injection of emulsified α-Th. α-Th transfer protein (α-TTP) was analyzed from liver homogenate by immunoblot. Results: Mitos from young rats showed >60% resistance to GCDC-induced MPT compared with adults. Young rats also had elevated α-Th in hepatic mitochondria (0.25±0.09 vs 0.12±0.01 nmol/mg pro, p<0.005) and reduced expression of α-TTP compared to adult rats. SQ α-Th treatment raised α-Th content in adult rat mito to that of young rats and significantly reduced susceptibility (i.e., increased resistance) to MPT induction (p=0.0004). Young rat mito contained similar total CL as adult mito, however, the major class of CL, tetra-linoleoyl CL, was significantly lower in young rats (1.92±0.14 vs. 3.01±0.13 nmol/mg pro, p<0.001). Conclusions: Resistance to bile acid-induced MPT in mito from young rat liver was associated with elevated mito α-Th (possibly due to reduced expression of α-TTP), and altered CL composition, which in combination would decrease the susceptibility of membrane lipids to oxidation. Enhancement of α-Th levels in adult mito reproduced the MPT resistance that was present in young rat mito. We conclude that mito membrane lipid changes in the developing rat may permit the young rat liver to cope with physiologically and pathologically elevated hepatic bile acid concentrations without inducing mito pathways of cell death. This process may be exploited as a target for reducing cholestatic injury.

519 CORRELATION OF LIVER “COLLAGEN PROPORTIONATE AREA” BY COMPUTER ASSISTED IMAGE ANALYSIS AND HEPATIC VENOUS PRESSURE GRADIENT IN PATIENTS WITH RECURRENT HCV INFECTION AFTER LIVER TRANSPLANTATION
Vincenza Calvaruso1, Richard Standish2, Pinelopi Manousou1, Sergio Maimone1, David Patch1, James O’Beirne1, Elias Xirouchakis1, Alexandros Sigalas1, Alice Corbani1, Amar P. Dhillon2, Andrew K. Burroughs1; 1Liver Transplantation and Hepatobiliary Unit, Royal Free Hospital, London, United Kingdom

Objectives: To assess whether the measure of liver collagen proportionate area (CPA) by computer assisted digital image analysis (DIA) is associated with hepatic venous pressure gradient (HVPG) in patients with recurrent HCV infection after liver transplantation.

Methods: 53 consecutive liver biopsies of 41 patients transplanted for HCV cirrhosis who had HVPG measured contemporaneously at the time of transjugular liver biopsy. Median HVPG was 5.5 mmHg (range 1-24). There was a significant positive association between digital image analysis of the CPA and HVPG by linear regression analysis. Results: The following people have nothing to disclose: Vincenza Calvaruso, Richard Standish, Pinelopi Manousou, Sergio Maimone, David Patch, James O’Beirne, Elias Xirouchakis, Alexandros Sigalas, Alice Corbani, Amar P. Dhillon, Andrew K. Burroughs

520 EVALUATION OF WEEK 12 RESPONSE ON SVR IN HCV POST TRANSPLANT PATIENTS UNDERGOING PEG/RBV THERAPY
Reem H. Ghali1, Cheryl Levine1, Blaine Hollinger2, Rise Sribling3, Terry Box3, William R. Hutson3, Anthony B. Post4, Shobha N. Joshi3, Anisha Steephen1, Jeffrey Weinstein1, Alejandro Mejia1, Stephen Cheng1; 1Liver Institute at Methodist Dallas, Dallas, TX; 2Baylor College of Medicine, Houston, TX; 3University of Utah, Salt Lake City, UT; 4University Hospitals of Cleveland, Cleveland, OH; 5Tuane University, New Orleans, LA

Background: Current guidelines for treatment of chronic HCV utilize EVR to indicate which patients are likely to achieve an SVR. Reports show a 72% SVR rate in patients with an EVR. The purpose of this study was to evaluate the week 12 viral response on SVR rate in chronic HCV post liver transplant patients. Methods: This is a secondary analysis of a multi-center randomized clinical trial of post OLT patients with recurrent HCV treated with 2 dosages of PEG IFN alfa.2b plus ribavirin 800 mg/day. PEG IFN dosage began at 0.5 mcg/kg/wk and increased in the high dose group to 1.5 mcg/kg/wk over 6 weeks. Results: The total sample contained 59 patients (27 low dose and 32 on high dose treatment). There were 39 males and 20 females ranging from 37 to 67 years of age (mean 51.4 ± 6.0). Race distribution was White 45 (76%), Black 3 (5%), Hispanic 10 (17%) and other 1 (2%). At treatment week 12, 32 (54%) patients achieved undetectable HCV RNA, 4 (7%) patients had ≥ 2 log decrease with positive virus, and 23 (39%) patients had <2 log decrease (Table 1). There was no difference in the use of pegylated IFN alfa.2b across race groups. There was no difference in the use of pegylated IFN alfa.2b across gender groups. There was no significant difference in the use of pegylated IFN alfa.2b across genotype groups. There was no significant difference in the use of pegylated IFN alfa.2b across treatment groups. Number of Patients with Undetectable HCV RNA

**5 patients discontinued prior to week 48 with side effects

521 CHRONIC HEPATITIS E: A NEW ENTITY IN ORGAN TRANSPLANT PATIENTS

Nassim Kamar, Jean-Marie Péron, Leila Ouezzani, Jean-Michel Mansuy, Jannick Selves, Christophe Bureau, Joelle Guittard, Jacques Izopet, Dominique Durand, Jean-Pierre Vinel, Lionel Rostaing.

Introduction: Hepatitis E virus (HEV) is a RNA virus that causes acute hepatitis in developing countries, but also sporadic cases in industrialized countries (non travel associated or autochthonous hepatitis E). Non travel associated hepatitis E have a predilection for middle aged and elderly males, are caused by genotype 3 and can carry significant morbidity especially when seen in the context of chronic liver disease. We describe for the first time a chronic evolution in organ transplant patients.

Patients: We identified 13 cases of hepatitis E infection that occurred in 13 organ-transplant patients who presented with unexplained elevation of liver enzymes levels. There were 3 liver-transplant patients, 8 kidney-transplant patients and 2 kidney-pancreas transplant patients. The median time since transplantation was 57 (6-168) months. Six were asymptomatic while the 7 remaining patients presented with fatigue. Two patients had been in contact with animals and none had travelled abroad recently. At diagnosis, there was a significant increase in liver enzymes levels, from 23 (12.95) to 115 (37-436) IU/L for AST (p=0.0015), from 26 (10-102) to 245 (66-874) IU/L for ALT (p=0.0015), from 32 (8-1164) to 132 (40-3482) IU/L for gGT (p=0.0015), and from 105 (26-226) to 249 (107-822) for alkaline phosphate (p=0.0015). Cytomegalovirus and hepatitis C virus Abs, as well as HBs anti-hepatitis A virus were negative and remained negative until last follow-up. HEV serology was negative in all patients but one. HEV RNA was positive in the sera of all patients, and in the stool (n=3) when looked for. Nine patients underwent a liver biopsy at diagnosis which revealed signs of non specific modest inflammation. HEV RNA became negative within three months in 7 patients (group I), while it remained positive in the 6 other patients (group II), respectively 9, 12, 13, 15, 16, and 27 months after diagnosis. The time between the transplantation and the diagnosis was significantly shorter in patients who developed chronic hepatitis, i.e. 82 ± 17 months in group I vs. 31.6 ± 10 in group II (p=0.02). Two patients who had chronic hepatitis E infection underwent a second liver biopsy, respectively 12 and 18 months after diagnosis. Both biopsies revealed signs of chronic active hepatitis associated to liver fibrosis. Conclusion: HEV infection can progress to chronicity in organ-transplant patients. HEV must be looked for in transplant patients with even moderately elevated transaminases.

522 POST-LIVER TRANSPLANT SURVIVAL IN HEPATITIS C PATIENTS IS IMPROVING, NOT DECLINING

Jacqueline G. O’Leary, Lafaïne M. Grant, Henry Randall, Nicholas Onaca, Linda Jennings, Goran Klintmalm, Gary L. Davis.

Outcomes after orthotopic liver transplant (OLT) for chronic hepatitis C (HCV) have been reported to be worsening over the last 2 decades. We analyzed our center’s experience over 15 years to identify trends in post-OLT survival in patients with and without HCV. Methods: Patient and graft survival of adult primary OLT recipients from January 1991 to June 2006 at Baylor Regional Transplant Institute (n=2051) were evaluated by Kaplan-Meier analysis. Those with or without HCV were analyzed by era: 1:1991-1994 (n=509), 2:1995-1998 (n=459), 3:1999-2002 (n=532), and 4:2003-6/2006 (n=551). Differences in eras with disparate survivals were assessed by univariate and multivariate analysis. Results: Overall, patient and graft survival were significantly lower among HCV recipients than in others (p<0.0001). This difference was dependent on the era of transplantation with improvement in HCV patient (p=0.0015) and graft (p=0.0001) survival in sequential eras: 5-year patient survival of 61.5%, 62.6%, and 75.6% for eras 1, 2, and 3, respectively (era 4 not evaluable yet). The change is largely related to changes in listing criteria for hepatocellular carcinoma (HCC) beginning in era 3. Survival in those transplanted for HCC with HCV has improved dramatically over time (p<0.0001). In fact, there was no change in post-OLT patient survival over time (p=0.19) when those with HCC were excluded from the HCV cohort, while graft survival still improved in successive eras (p<0.007). There was no change in survival of non-HCV recipients between eras (p=0.14), although graft survival improved after 1994 and has remained stable since (p=0.02). The impact of potentially detrimental changes in recipient demographics over the eras including older patients, older donors, and a higher proportion with HCC have likely been ameliorated by positive trends including shorter cold ischemia time, fewer retransplants, greater use of tacrolimus and mycophenolate, and less steroid-resistant rejection. Conclusion: Post-transplant survival after OLT for chronic hepatitis C has improved significantly over the last 15 years despite demographic changes in patients and grafts that have been previously shown to impair survival. A major reason for this improvement is better selection of patients with concurrent hepatocellular carcinoma. No donor organs were obtained from executed prisoners or other institutionalized persons. The authors have no conflicts of interest.

523 INTRAHEPATIC COVALENTLY CLOSED CIRCULAR DNA (CCC DNA) DETECTION IN PATIENTS TRANSPLANTED FOR HBV-RELATED CIRRHOSIS: A TOOL TO JUDGE FOR HBIG PROPHYLAXIS WITHDRAWAL IN LOW-RISK TRANSPLANT RECIPIENTS?

Ilaria Lenci, Giuseppe Tisoni, Marco Ciotti, Daniele Di Paolo, Laura Tariciotti, Fabio Marcuccilli, Carlo F. Perno, Mario Angelico.

INTRODUCTION: The outcome of orthotopic liver transplantation (OLT) for HBV-related cirrhosis remains influenced by the presence of HBV-DNA in the liver of the recipient. The hepatitis B surface antigen (HBsAg) positive recipients, who have undergone a recent HBIG prophylaxis have low risk of developing a positive post-OLT HBsAg test in the absence of high HBV-DNA levels. However, the level of HBV-DNA in the liver as a parameter of liver activity is not always available and the HBsAg status of the donor is not known in most OLT recipients. We assessed the intrahepatic viral DNA in a cohort of OLT recipients before liver transplantation and the correlation with the post-OLT HBsAg status. METHODS: Between December 1999 and May 2005, 532 patients underwent OLT at our institution. HBV-DNA was measured before transplantation using the polymerase chain reaction (PCR) according to the parameters of the Centers for Disease Control and Prevention (CDC) laboratory guidelines for a detection level of 5.0 IU/mL. RESULTS: Of the 532 OLT recipients, HBV-DNA was detected in 111 patients (21%). Of these, 45 patients (40.5%) were HBsAg positive before transplantation (31 patients with a recent HBIG prophylaxis withdrawal and 14 patients with a prior HBIG prophylaxis). Post-OLT HBsAg seroconversion occurred in 41 (91%) of the 45 patients, 30 patients (67%) with recently withdrawn HBIG prophylaxis, and 11 patients (78.6%) with a prior HBIG prophylaxis. Conclusion: The detection of HBV-DNA in OLT recipients before transplantation can be used as a tool to judge for HBIG prophylaxis withdrawal in low-risk recipients.
524 HBV GENOTYPE C IS ASSOCIATED WITH HIGHER RATES OF HCC AND POST-LIVER TRANSPLANT (OLT) MORTALITY COMPARED TO GENOTYPES A, B AND D

Paul J. Gaglio1, Sundee Singh1, Bulent Degertekin2, Michael B. Ishtian3, Munira Hussain1, Robert P. Perrillo4, Anna S. Lok1, Study Group NIH HBV OLT5; 1University of Michigan, Ann Arbor, MI; 2Columbia University, New York, NY; 3Mayo Clinic, Rochester, MN; 4Baylor University, Dallas, TX

Background/Aims: HBV genotype, precore and core promoter mutations have been reported to be associated with activity of liver disease and hepatocellular carcinoma (HCC). We hypothesized that these factors might impact indication for OLT and post-OLT outcomes. Methods: 130 patients in the NIH HBV OLT Study with available sera and detectable HBV DNA were tested for HBV genotype and precore (G1896A) and core promoter variant (A1762T/G1764A) using line probe assay. HBV DNA was quantified using Amplicor assay. Post-OLT survival was estimated using Kaplan-Meier analysis. Results: 82% of patients were men, mean age was 51 years; 48% were white, 41% Asian, 8% African Americans and 3% others. Indication for transplant was cirrhosis (62%), HCC (29%) and acute liver failure (7%). 51% of the patients were HBcAg positive. The distribution of HBV genotypes was A (36.2%), C (33.1%), D (14.6%), B (11.5%), and others (4.6%). Genotype C and B were predominantly found among Asians, A and D among White, and all but one African American had genotype A. Pre-core and core promoter variants were detectable in 42% and 89% of patients, respectively. HCC was the indication for listing among 51% of patients with genotype C but only 21% of patients with genotypes A and D and 13% of patients with genotype B. Univariate analysis showed that gender, Asian race, HBV genotype C, and presence of core promoter mutation were associated with HCC at listing. Multivariate analysis identified genotype C as the only factor associated with HCC (p<0.001). 70 patients underwent OLT, and 9 died during a median follow-up of 24 months (range 0-60). Patients with genotype C had significantly poorer post-OLT survival compared to those with genotype non-C. The probability of post-OLT survival at 1 and 4 years were 83% and 66% vs 94% and 91%, respectively for patients with genotype C vs. non-C (p = 0.024). Survival was similar among patients with genotypes A, B and D. Although genotype C was predominantly found in Asians, post-OLT survival of Asians was not worse than non-Asians. Similarly, despite a strong association between genotype C and HCC, post-OLT survival of patients with HCC was not different compared to those with cirrhosis. Cox regression identified HBV genotype C as the only predictor of post-OLT survival (p=0.04). Neither HBV genotype nor the presence of pre-core or core promoter variant was associated with HCC or HBV recurrence. Conclusions: In this multi-racial population of patients listed for OLT for HBV, genotype C was associated with significantly higher rates of HCC and post-OLT mortality but there was no association with HCC or HBV recurrence.

525 EVALUATION OF THE INTRAHEPATIC EXPRESSION OF TWO INTERFERON-INDUCIBLE PROTEINS, MXA AND IFI16, DURING ACUTE REJECTION AND VIRAL REINFECTION OF LIVER ALLOGRAFTS

Carlo Smirne1, Cinzia Borgognola1, Carlo Fabris2, Barbara Azzimonti1, Cecilia Marconi1, Elena Miossa1, Michela Burlone1, Pierluigi Toniotto2, Rosalba Minisini1, Marisa Gariglio1, Mario Pirisi1; 1Department of Clinical and Experimental Medicine, University of Eastern Piedmont “Amedeo Avogadro”, Novara, Italy; 2DPMSC, University of Udine, Udine, Italy

Introduction. Character and strength of the adaptive immune response are influenced by signals from the innate immune response, including interferon alpha, that may be magnified by infection. In the transplantation setting, these processes may affect both infection control and allograft rejection. Our aim was to investigate the interplay between graft reinfection by hepatitis C virus (HCV), acute cellular rejection, and interferon-inducible protein expression (MxA and IFI16) among liver transplant recipients. Methods. Immunostaining for MxA and IFI16 expression was performed on formalin-fixed, paraffin embedded liver biopsy specimens, obtained from 28 patients (20 males, median age 52 years; 14 had been transplanted for HCV-related disease). The median interval between transplant operation and biopsy was 22 weeks. Eleven out of 28 biopsy specimens showed acute allograft rejection (Banff RA1 score 3-4: N=5; 5-6: N=5; ≥7: N=1). Leukocyte and macrophage infiltrates were characterized by CD45 and CD68 immunostaining, respectively. Results. The predominant MxA staining pattern was hepatocytic. IFI16 displayed a significant expression both in the hepatocellular and inflammatory compartments. MxA and IFI16 expression in hepatocytes were positively asso-

Les Lilly, Nigel Girgrah, George Therapondos; Toronto General Hospital, Toronto, ON, Canada

Introduction/Aim: Successful treatment of chronic hepatitis C virus (HCV) infection is defined by undetectable serum HCV RNA six months following cessation of antiviral therapy (sustained virological response; SVR). This response seems highly durable in immunocompetent HCV patients, with rates >96% reported after several years of follow-up. However, it is unclear whether an immunosuppressed patient population will enjoy the same long term success. We therefore examined our liver transplant patient population with SVR to assess the durability of their response. Patients: Over 150 patients in the liver transplant program at our institution have been treated for recurrent HCV; to date, 75 have achieved an SVR. Qualitative HCVRNA determinations were made q3m for one year from cessation of treatment, and annually thereafter, as well as during any rise in liver enzymes. Results: 39/75 patients (52%) were Genotype 1 (G1), and 24 (32%) were G2 or G3, the remainder were other genotypes or unknown. Two patients were transplanted for HCV/hepatitis B coinfection, and had undetectable HBV DNA prior to treating HCV. All patients who had undetectable HCV RNA 3m following treatment achieved an SVR. Follow-up from SVR ranged from 3m to 84m. Two patients died during the follow-up period, one 8m and the other 22m from end of treatment; both were HCV RNA negative 2m prior to death. Only one patient relapsed during the observation period. This patient had received an HCV positive graft, and become HCV RNA negative on combination therapy, remaining so for 18m after end of treatment. Retransplantation with combined liver/kidney then took place and, 3m later, serum HCV RNA became detectable. Conclusions: An SVR achieved in liver transplant patients appears to be as durable as that seen in a non-transplant population, with the only relapse in a patient who underwent retransplantation and had marked augmentation of immunosuppression. Further, HCV RNA determination 3m after end of treatment may suffice to define SVR in this difficult-to-treat population.

527 COMPARISON BETWEEN HEPATIC ELASTICITY MEASUREMENTS (FIBROSCAN®) AND LIVER BIOPSY IN PATIENTS TRANSPLANTED FOR HCV CIRRHOSIS

Flávio Feitosa1,2, Sylvie Radenne2, Tierry Bizollon2, Argemiro d’Oliveira1, Pierre Pradat2, Raymundo Parana1, Christian Trepo2

1Gastro-Hepatology, Hospital Prof Edgar Santos, Salvador, Brazil; 2Gastroenterologie et Hepatologie, Hospital de l’Hotel-Dieu, Lyon, France

Context and objectives: Liver biopsy is considered the gold standard to evaluate outcome post liver transplantation. Because of its non-invasiveness, hepatic elasticity measurement (Fibroscan®) has increasingly gained attention for the evaluation of fibrosis in transplanted patients. Our purpose was therefore to compare Fibroscan® values with those of liver biopsy in patients transplanted for HCV cirrhosis. Patients and methods: All consecutive patients transplanted for HCV cirrhosis who underwent a medical visit at Hôtel-Dieu Hospital between April and November 2006 and who had a recent liver biopsy or with indication for it were invited to participate in this study. 38 patients (27 men, mean age 58.3 years), between 44 and 75 years were included. We evaluated ALT values, viral load and genotype, treatment for chronic hepatitis, time between the biopsy and transplantation and between biopsy and Fibroscan® and possibility of any other hepatic comorbidity. The results of Fibroscan® were converted in Metavir Score values (using the values already validated for) and those were compared with the results of his biopsy. Results: 15 patients (39%) had fibrosis lower than F2 at liver biopsy and 3 (8%) were F4. For Fibroscan®, these results were 16 (42%) and 9 (24%), respectively. The mean duration between the transplantation and the biopsy was 76.8 months (3-172) and 3.2 months between the transplantation and the Fibroscan® (0.9). 17 patients (45%) had cleared HCV following therapy. At the time of transplantation, 8 patients (21%) presented already hepatocellular carcinoma on the explanted liver. The observed concordance between the methods was 0.71 (27 patients) and the expected concordance was 0.51. The sensibility of Fibroscan® was 0.76 (IC 0.58-0.94) and its specificity, 0.65 (IC 0.53-0.76) with predictive positive and negative values of 0.72 and 0.65, respectively. The prevalence and the corrected prevalence was 0.55 and 0.57. The positive likelihood ratio was calculated at 2.2 and the negative as 0.37. Intermethods reliability shows a kappa index at 0.41 (IC 0.09-0.73; statistical significance> 0.5). The comparison of all epidemiological and laboratory parameters between the two groups (concordants and non-concordants) did not show any statistically significant difference. Conclusions: Our data failed to show a close correlation between Fibroscan® and the liver biopsy in these patients. This discordance may be in part due to the high proportion of cases with mild fibrosis that all the more it emphasizes the need for specific validation of the Metavir Scores with Fibroscan® measurements in the context of transplantation which warrant further studies.

of Geneva, Geneva, Switzerland  
Background: Hepatitis B immune globulins (HBIG) in combina-  
tion with nucleos(t)ide analogues are used for the prevention of  
HBV graft re-infection after liver transplantation (LT). Several  
HBIG preparations with different biological activities are com-  
mercially available but associated costs for long-term treatment  
are very high. Thus, new strategies to lower post-LT costs are  
needed. Methods: In 1993 a blood center-based program for  
the production of hyperimmune anti-HBs plasma (HIP) was  
started in Geneva preparing fresh frozen plasma obtained by  
separation (separation-HIP) from HBV vaccinated donors with  
high titer anti-HBs (>20’000 IU/L). In 2000 the program was  
introduced at a regional Transfusion Center, far from the Trans-  
plant Center and the procedures were optimized by HIP pro-  
donation through plasma-apheresis (apheresis-HIP). Every  
apheresis procedure provided two preparations of 300cc  
leukocyte-deprived plasma (<106 WBC/ml). The plasma was  
frozen for four months and then tested again for the presence  
of viral markers. The total cost for production of one apheresis-HIP  
is 410$US. Both HIP formulations were produced according to  
the guidelines of the Swiss Red Cross Transfusion Service. The  
elimination kinetics of anti-HBs (antibody levels at time 0',  
directly after, 1h, 24h, 3d, 7d, 10d, 14d, 21d, 30d after trans-  
fusion) were assessed in 5 patients receiving apheresis-HIP and  
compared to commercial HBIG. Results: Since the introduction  
of HIP, 26 patients were treated with separation-HIP, and ten  
were switched to apheresis-HIP in 2000. Patients who were  
initially treated with commercial HBIG needed less frequent HBIG  
administrations after introduction of HIP: every 3-5 weeks with  
commercial HBIG vs 6-8 weeks with HIP. Mild transfusion reac-  
tions were observed occasionally with separation-HIP (n=5  
patients), and in this case patients were switched back to com-  
mercial HBIG. With apheresis HIP no side effects were  
observed ever since (10 patients over 7 years). The elimination  
kinetk of anti-HBs in apheresis-HIP were comparable to com-  
mercial formulations. The cost for commercial HBIG (7’500IU,  
4’050$US, median annual cost 48’600$US) was considerably  
higher compared to HIP (7’500IU, 410$US, median annual  
cost 4’100$US). Finally, with the introduction of HIP the median  
anti-HBs titer has risen with a less frequent need for HBIG  
administrations (from 100-200 to 200-300 IU/L). Conclusion:  
HIP is an effective, safe and economic treatment for the pre-  
vention of HBV recurrence after LT. It can be easily produced in  
any blood transfusion center and may be an attractive alterna-  
tive to commercial HBIG products, particularly in countries with  
limited resources.

529 CAUCASIAN AMERICAN HEPATITIS B LIVER TRANSPLANT PATIENTS HAVE HIGHER RATES OF WAITLIST MORTALITY AND HBV RECURRENTnCE THAN ASIAN AMERICANS  
Nathalie H. Bzowej2, Emmet B. Kefee3, Tram Tran4, Steven Han5,  
Sukru Emre6, Bulent Degertekin7, Anna S. Lok7, Study Group NIH  
HBV OLT7; 1University of Michigan, Ann Arbor, MI; 2California  
Pacific Medical Center, San Francisco, CA; 3Stanford University,  
Palo Alto, CA; 4Cedars Sinai Med Ctr, Los Angeles, CA; 5UCLA,  
Los Angeles, CA; 6Mt Sinai Med Ctr, New York, NY  
Background/Aims: Previous studies suggested that Asian Amer-  
icans (AS) had worse outcomes after liver transplantation (OLT)  
than Caucasian Americans (CA), related in part to more  
advanced disease at presentation. We compared the indica-  
tions for OLT, severity of liver disease at listing, and pre- and  
post-OLT outcomes between AS and CA. Methods: Data from the  
NIH HBV OLT study that includes 15 US centers were  
reviewed. Patients self declared to be AS or CA were included;  
those who had HCV, HDV or HIV coinfection or were listed for  
repeat OLT were excluded. Outcomes were analyzed by Kaplan-Meier analysis and predictors of outcome were ana-

yzed by Cox regression. Results: A total of 251 patients, 135  
AS and 116 CA, were included; 76% AS and 82% CA were  
men; mean age at listing was comparable, 53 vs. 54 yr. At list- 
ing, a higher percent of AS had HCC (47% vs. 16%,  
p<0.0001), while a lower percent had acute liver failure (3%  
vs. 9%, p=0.03). HBcAg status and HBV DNA levels were simil- 
ar, and MELD scores among the cirrhotics were comparable.  
A similar percent of AS and CA was receiving antiviral therapy  
at listing: 57% vs. 60%. Among the patients who had cirrhosis  
at listing, 8 (12%) of 67 AS and 14 (16%) of 87 CA had new  
diagnosis of HCC (NS). Probability of OLT at 1, 3 and 5 yr  
were comparable, being 48%, 58%, and 66% for AS and  
49%, 59% and 64% for CA. AS had lower waitlist mortality,  
with the probability of death at 1, 3 and 5 yr being 1%, 3%  
and 12% vs. 9%, 17% and 22% for CA (p=0.009). This dif-  
ference remained when the analysis was restricted to patients  
with cirrhosis and no HCC. Cox regression identified race  
(p=0.014) but not OLT indication as a predictor of waitlist mortal-  
ty. Of the 85 (49%) AS and 69 (41%) CA transplanted, 11  
(13%) AS and 8 (12%) CA died during a median follow up of  
30 mos (0-67). Probability of post-OLT survival at 1, 3 and 5 yr  
were 90%, 85% and 85% for AS and 93%, 88% and 88% for  
CA (NS). Cox regression identified HCC recurrence (p=0.001)  
but not race, OLT indication (HCC vs. non-HCC) or HBV recur- 
rence as predictors of post-OLT mortality. One (1%) AS and 1  
(16%) CA had HBV recurrence, and Cox regression identified  
race (p=0.017) as a predictor of HBV recurrence. Five (9%)  
of 54 AS and 4 (13%) of 30 CA with HCC at transplantation had  
HCC recurrence (NS). Conclusions: AS were significantly more  
likely to have HCC at listing than CA, but the rates of new HCC  
diagnosis after listing and HCC recurrence post-OLT were com-  
parable. AS and CA had similar post-OLT mortality as CA, but  
CA had significantly higher waitlist mortality and HBV recur- 
rence rates than AS. Further analyses are ongoing to explain  
these discrepant outcomes.

METABOLIC SYNDROME IS AN INDEPENDENT PREDICTOR OF FIBROSIS PROGRESSION IN PATIENTS WITH RECURRENT HEPATITIS C (HCV) AFTER LIVER TRANSPLANTATION (LT) USING SERIAL BIOPSY SPECIMENS

Ibrahim A. Hanouneh1, Charles M. Miller2, Arthur J. McCullough3, Rocio Lopez4, Federico Aucejo2, Ariel E. Feldstein5, Nizar N. Zein6; 1Internal Medicine, Cleveland Clinic, Cleveland, OH; 2General Surgery, Transplant Center, Cleveland Clinic, Cleveland, OH; 3Gastroenterology and Hepatology, Cleveland Clinic, Cleveland, OH; 4Biostatistics and Epidemiology, Cleveland Clinic, Cleveland, OH; 5Pediatric Gastroenterology and Cell Biology, Cleveland Clinic, Cleveland, OH

While hyperinsulinemia and its associated metabolic syndrome (MS) have been implicated in the progression of hepatic fibrosis in HCV patients, little is known about consequences of MS after LT. 

Aims: Assess the interaction between MS and fibrosis progression in patients with recurrent HCV after LT using serial liver biopsies. 

Methods: Using electronic pathology database, we identified all LT/HCV patients with at least two post-transplant liver biopsies (1998–2006). MS was defined using ATP III criteria at 1 year post LT. Ludwig-Batts scoring system was used to stage all biopsies (408 biopsies from 95 patients). The first biopsy that showed progression post LT was used for the time-to-progression analysis. Univariable and multivariable logistic regression analysis was performed to identify factors associated with fibrosis progression. 

Results: MS was present in 50% of patients. Median follow-up was 22 (Q25, Q75: 12.0, 31.2) months during which 71% of subjects had fibrosis progression. Overall median rate of fibrosis progression was 0.08 units per month (Q25, Q75: 0.0, 0.17). By univariate analysis, high HCV RNA at 4 months post-LT (p<0.001), diabetes (p=0.046), CMV infection (p=0.006) and MS (p=0.049) were associated with progression of fibrosis. In multivariate analysis, MS was not associated with fibrosis progression during the first year post-LT (OR=1.06, 95% CI: 0.49-2.26) but was independently associated with progression of fibrosis beyond 1 year after LT (OR=6.3, p=0.017). High viral load at 4 months postLT (OR=1.1, p=0.004), steroid therapy for acute rejection (OR=1.9, p=0.05), and CMV infection (OR=1.9, p=0.01) were independently associated with fibrosis progression. A Kaplan-Meier plot below outlines the association between MS and fibrosis progression. 

Conclusion: MS, a potentially modifiable factor, is common and appears to be strongly associated with long-term fibrosis progression in the setting of recurrent HCV after LT.

MULTICENTER RANDOMIZED TRIAL IN HCV-INFECTED PATIENTS TREATED WITH PEGINTERFERON ALFA-2A AND RIBAVIRIN FOLLOWED BY RIBAVIRIN ALONE AFTER LIVER TRANSPLANTATION: FINAL REPORT

Yvon Calmus1, Christophe Duvoux2, Georges-Philippe Pageaux3, Michel Messner4, Philippe Wali5, Lionel Rostaing6, Claire Vanlemmens7, Danièle Botta-Fridlund8, Sébastien Dharrany9, Jean Gugenheim10, François Durand11, Martine Neau-Cransac12, Olivier Boillat13, Olivier Chazouillères14, Isabelle Lonjon-Damanec15, Laurence Samelson15, Didier Samuel16, 1Hôpital Cochin, Paris, France; 2Hôpital Henri Mondor, Créteil, France; 3Hôpital Saint Eloi, Montpellier, France; 4Hôpital Pitié Salpêtrière, Paris, France; 5Hôpital Haute-pierre, Strasbourg, France; 6Hôpital Rangueil, Toulouse, France; 7Hôpital Minjoz, Besançon, France; 8Hôpital La Conception, Marseille, France; 9Hôpital Huriez, Lille, France; 10Hôpital L’Arche, Nice, France; 11Hôpital Beaujon, Clichy, France; 12Hôpital Pellegrin, Bordeaux, France; 13Hôpital Edouard Herriot, Lyon, France; 14Hôpital St Antoine, Paris, France; 15Roche, Neuilly sur Seine, France; 16Hôpital Paul Brousse, Villejuif, France

The aim of this randomized, double-blind study was to determine the effect of placebo or maintenance therapy with ribavirin (RBV) monotherapy, after a year of combination therapy with peginterferon-alfa 2a (PEG-IFNα-2a) and RBV, on continued eradication of HCV after liver transplantation (LT). 

Methods: The study enrolled 100 patients with recurrent HCV and a minimum of stage 1 fibrosis (METAVIR scoring) on a liver biopsy obtained 1–5 years after LT. At inclusion, the activity and fibrosis scores (METAVIR) were 1.67 ± 0.76 and 1.47 ± 0.70, respectively. PEG-IFNα-2a and RBV were initiated at 90 µg/wk and 600 mg/d, respectively, and increased to 180 µg/wk and 1000 mg/d or adjusted as a function of hematological tolerance. At week 52, combination therapy was discontinued and patients were randomized to RBV alone or placebo for a further 48 weeks (blinded). 75% of patients received tacrolimus and 25% cyclosporine. 

Growth factor use was permitted. Results: After one year of combined therapy, 63 patients were negative by PCR and randomized between RBV alone or placebo. At 78 weeks (6 months after combined therapy), a sustained virological response (SVR) was obtained in 40% of ITT patients (40/100). At 30 months (M30) (6 months after the end of the maintenance period), 47% of the patients randomized to RBV (16/34) and 55% of those randomized to placebo (16/29) had undetectable HCV-RNA (NS). At M30, the histological activity score was 1.52 ± 0.84 (vs 1.63 ± 0.74 at M12) in the RBV group and 1.72 ± 0.84 (vs 1.51 ± 0.88 at M12) in the placebo group (NS). At M30, the fibrosis score was 1.52 ± 0.84 (vs 1.63 ± 0.91 at M12) in the RBV group and 1.72 ± 0.84 (vs 1.51 ± 1.09 at M12) in the placebo group (NS). The fibrosis score marginally improved in the RBV group between M12 and M30 (-0.14 [CI : -0.5;-0.22]), whereas it worsened in the placebo group (+0.26 [CI : -0.02;+0.54]) (p=0.07). 

Conclusion: After 1 year’s combination therapy with peginterferon alfa-2a plus ribavirin, a SVR was achieved in 40% of patients following liver transplantation in ITT analysis. A main disadvantage of this study was the low SVR which can be attributed to low HCV-RNA at inclusion. The authors conclude that RBV plus placebo offers a good combination therapy for maintaining the cure of HCV after liver transplantation.

Disclosures:
532  
HEPATITIS C VIRUS (HCV) INFECTION IS A PROTECTIVE FACTOR FOR HEPATITIS B VIRUS REACTIVATION (HBVR) AFTER RECEIVING HEPATITIS B CORE POSITIVE (HBcAb+) DONORS FOR LIVER TRANSPLANTATION (LT)

Mauricio Orrego1, Ricardo Restrepo1, Barbara Aguilar2, Victor Araya3, Kenneth D. Rothstein4, Cosme Manzarbeitia5, David J. Reich5, Santiago Munoz1; 1Center For Liver Disease, Albert Einstein Medical Center, Philadelphia, PA; 2Surgery/Liver Transplantation Program, AEMC, Philadelphia, PA

HBVr occurs with a variable frequency after receiving an HBCAb+ liver donor. However, there is little data on clinical, serological and virological factors associated with HBVr after LT. Aim: To determine the incidence of HBVr in LT recipients and to identify clinical, serological and virological factors associated with HBVr. Methods: Retrospective analysis of our LT population from June 1995 to May 2007. Non-HBV infected recipients with complete laboratory data post LT were studied. HBVr was defined as a positive HBsAg or HBV DNA >20,000 IU/ml post LT. Fisher’s exact test was used for group comparisons. Results: 60 of 550 LT recipients (10.9%) received HBCAb+ donors. 42 of 60 patients met inclusion criteria. 6 of 42 (14%) LT recipients had HBVr. Laminiviremia prophylaxis was used post LT in 6% of the recipients. 74% of the recipients had HCV infection. Median time for HBVr was 20.7 (5.8 to 110) months. 75% were male. Mean age was 54.3 years. We identified three different groups for HBV (table1). Of the 26 patients in the MG, one (4%) patient had HBVr. In the UG, 4 of 12 (33%) patients developed HBVr. The UG had 8.7 (95%CI, 1.1 to 69) times the risk of HBVr compared to the MG after LT (p=0.03). The remaining 4 patients were vaccinated and one (25%) patient had HBVr. There was no difference in HBVr in the vaccinated group compared to the MG and the UG. To investigate HBVr by LT recipient diagnosis, we compared HCV infected recipients (74%) to non-HCV recipients (26%). Of the 31 HCV infected recipients, 2 (6.4%, 95% CI, 0% to 21%) developed HBVr. In contrast, 4 (36%, 95% CI, 10% to 69%) of the non-HCV recipients had HBVr. The non-HCV recipients had 5.6 (95% CI, 1.2 to 27) times the risk for HBVr in comparison with HCV infected recipients (p=0.03). Since both HCV infected recipients and MG recipients appeared to be protected against HBVr, we tested if the combination was also protective. 3 (60%) of the 5 recipients in the MG with non-HCV diagnosis had HBVr compared to 0 of 22 recipients in the MG with HCV infection (p=0.003). Conclusions. Serological and virological characteristics have important implications to allocate HBCAb+ livers. Recipients in the matched group with HCV infection appear to be protected from HBV reactivation after LT. UG and non-HCV recipients have higher risk of HBV reactivation and therefore, HBV antiviral prophylaxis should be strongly considered. HBVr in the vaccinated group may have been explained for low HBsAb titers in the recipient.

533  
HIGH PREVALENCE OF GLOMERULONEPHRITIS IN PATIENTS WITH END-STAGE HCV-INDUCED CIRRHOSIS

Brendan McGuire1, Bruce A. Julian1, Jan Novak2, Steve Bynon3, William J. Cook4, Stacy Eddleman1, Devin E. Eckhoff1; 1Medicine, University of Alabama, Birmingham, AL; 2Microbiology, University of Alabama, Birmingham, AL; 3Surgery, University of Alabama, Birmingham, AL; 4Pathology, University of Alabama, Birmingham, AL

Patients undergoing liver transplantation for cirrhosis due to hepatitis C virus (HCV) infection have a greater frequency of renal insufficiency after liver transplantation compared to patients without HCV. It is speculated that there is a greater prevalence of glomerulonephritis (GN) at the time of liver transplantation, but there are no data to support this postulate. The aims of this study were to determine the prevalence and type of renal pathology with HCV-induced and nonviral-induced cirrhosis and to correlate renal pathology with serum and urinary markers of renal disease. METHODS: Forty adult patients undergoing liver transplantation for cirrhosis (including 30 patients with HCV-induced cirrhosis previously reported) were evaluated prior to liver transplantation for renal dysfunction (serum creatinine), hematuria (dipstick > trace blood), and proteinuria (urinary protein/creatinine ratio >0.3). At the end of transplantation, a needle biopsy of the right kidney was done. RESULTS: The clinical data for the six patients with nonviral-induced cirrhosis included: mean age 55 yr (44-68), 5 men, and cause of liver disease was 2 non-alcoholic steatohepatitis, 2 alcohol, 1 primary sclerosing cholangitis and 1 cryoprecipitable. Hepatoma was present in 1 patient, diabetes in 3 and hypertension in 4. The mean calculated MELD score was 23. Preoperatively, 5 patients had one or more abnormal noninvasive study [3 elevated serum creatinine, 2 hematuria, and 2 proteinuria]; 1 patient had normal studies. Kidney biopsy showed 3 patients with IgA nephropathy (IgAN) and 3 without GN. The clinical data for the 34 patients with HCV-induced cirrhosis included: mean age 52 yr (41-73), 23 men, 13 hypertensive, 8 diabetic, and 2 had hepatorenal syndrome at engraftment requiring hemodialysis. Mean calculated MELD score was 24. Preoperatively, 19 patients had at least one abnormal noninvasive study (13 elevated serum creatinine, 12 hematuria, and 7 proteinuria); 15 patients had normal studies. Kidney biopsy showed 29 patients with an immune-complex GN (14 membranoproliferative GN, 9 IgAN, and 6 mesangial GN). No patient in either group had cryoglobulins by electronmicroscopy or serum measurement. At liver engraftment, histologically recognizable glomerular disease affected 29/34 (85%) of patients with end-stage HCV cirrhosis versus 3/6 (50%) of patients with nonviral-induced cirrhosis (p = 0.05). CONCLUSIONS: Patients with HCV-induced cirrhosis have a higher prevalence of immune-complex GN compared to patients with nonviral-induced cirrhosis at the time of engraftment. These findings may explain the decline in renal function that commonly occurs after liver engraftment for HCV.

Rapid Fibrosis in HCV-Patients After Liver Transplantation Is Associated with an Upregulation of Collagen Type I, MMP-9 and TIMP-1

Ulf Neumann1, Martin Ruehl2, Tarkan Dagdelen2, Friedmar Delissen2, Walburga Dieterich3, Maximilian Schmeding1, Martin Zeitz2, Peter Neuhaus1, Rajan Samusundaram2; 1Department of Surgery, Charité-Campus Virchow, Berlin, Germany; 2Gastroenterology/Hepatology, Charité-Campus B. Franklin, Berlin, Germany; 3Department of Gastroenterology, Friedrich-Alexander University, Erlangen-Nuernberg, Germany

Introduction/Aim: Only a subset of hepatitis C virus (HCV)-infected patients develop progressive hepatic fibrosis after liver transplantation (LT). Whereas non-transplanted chronic HCV-patients develop cirrhosis after 15-20 years LT-HCV-patients may develop cholestatic fibrosis with very high mortality during the first year (rapid progression, RP) or chronic progression with high or low ALT resulting in cirrhosis after 2-3 years or later (slow progression, SP). There are no reliable markers to identify high-risk recipients who will develop cirrhosis shortly after LT. Activation of hepatic stellate cells is an early step in hepatic fibrogenesis leading to the expression of a plethora of extracellular matrix genes and enzymes. The aim of this pilot study was to define a subset of ECM molecules allowing early discrimination between RP and SP. Methods: Samples from routine liver biopsies obtained 6, 12, 36 and 48 months post LT (11 HCV-LT patients) and 3 non-transplanted controls were stored in RNA later before mRNA was isolated, transcribed to cDNA and subjected to TaqMan real time quantitative PCR using primers and probes for matrix metalloproteinases and inhibitors (MMP-2, MMP-9, TIMP-1), growth factors (CTGF, TGF-beta, collagens (type I, VI-alpha3) transglutaminase-2 and GAPDH. Grading and staging of fibrosis was performed by histology and liver function tests were determined. Results: By histology six and five patients, respectively, were identified to have SP or RP. Biopsies from non-transplanted livers and livers with SP showed no difference in the expression of all 8 markers whereas 3 of the 8 markers (MMP-9, TIMP-1 and CI) showed a higher expression in the RP group compared to controls and SP. These changes were seen more pronounced in liver biopsies one year after LT. Conclusions: Three markers of hepatic stellate cell activation and extracellular matrix turnover were identified which discriminate between slow and rapid fibrosis progression in HCV patients after LT. Further studies are ongoing to confirm these results in large patient cohorts. The identification of patients with a rapid progression at an early timepoint after LT shall allow an early intervention either by modification of immunosuppression and/or addition of antifibrotic treatment.

Anti-HCV Immune Responses Modulate Recurrence of HCV Infection and Severity of Liver Histology After Liver Transplantation in HCV-Co-infected Patients

A. Samri1,2, Anne-Marie Roque-Afonso3,4, O. Beran4,5, C. Feray2,7, E. Dussaix8,9, Didier Samuel1,7, B. Autran4,5, Jean-Charles Duclos-Vallée1,6; 1Centre Hépato-Bilairne, AP-HP Hôpital Paul Brousse, Villejuif, France; 2Unité 543 Cell Immunology, Inserm, Paris F-75013, France; 3UMR-S 543, AP-HP Hôpital Pitié Salpêtrière, Paris F-75013, France; 4UMRS 543, Université Pierre et Marie Curie Paris VI, Paris F-75013, France; 5Département de Virologie, AP-HP Hôpital Paul Brousse, Villejuif F-94804, France; 6U 785, Inserm, Villejuif F-94804, France; 7UMR-S 785, Univ Paris-Sud, Villejuif F-94804, France; 8Département de Microbiologie, AP-HP Hôpital Paul Brousse, Villejuif F-94804, France

Background: Liver transplantation (LT) in HIV/HCV co-infected patients is successful. Hepatitis C reinfection is the major cause of recipient mortality. The aim of this work was to evaluate the immune responses against HCV before and after LT in HIV/HCV co-infected patients. Methods: 14 patients with HIV viral load (VL)<50 copies/mL and CD4 counts>200/mm3 receiving a graft for HCV-cirrhosis were included. Patients were monitored for HCV and HIV VL, liver histology and immune responses in pre- and post-transplantation course (2 years). T cell responses were evaluated in blood by IFN-γ-ELSpot assays using recombinant (r) proteins: core, NS3, and NS4 (HCV), HIV-1-p24 and CMV, PPD and candida, and 16 pools of HCV-peptides (core, NS3, and NS5) and 1 pool of HIV-1-p24-peptides. Results: Before LT and 2 years after, median CD4 counts and HIV-1VL were 276 and 238/mm3 and 5.73 and 6.40 log IU/mL. During the follow-up, T-cell responses against opportunistic antigens were detected in 13/14 patients with median frequency of 245 SFC/106 PBMC (range: 50 to 1677). 11/16 patients had responses against rHIV-1-p24 protein with a median frequency of 110 SFC/106 PBMC (range: 50 to 930). HCV-specific CD4 T cell responses were detected in 4 patients and directed against core in 3 patients (from 67 to 187 SFC/106 PBMC) and NS3 and NS4 in the fourth patient (87 and 50 SFC/106 PBMC). Ex vivo CD8 responses against HIV-1-p24 were observed in 7/11 patients with a median frequency of 195 SFC/106 PBMC (range: 60 to 875) whereas responses against HCV-epitopes were detected in 1 patient and directed against core and NS5 (153 and 220 SFC/106 PBMC respectively). In 3 patients without ex vivo CD8 response, in vitro HCV-peptide stimulation lead to generate responses directed against core in 1 patient (2340 SFC/106 PBMC) and NS3 in 3 patients (from 203, 280 and 1460 SFC/106 PBMC). Interestingly, 6/7 patients with anti-HCV responses had also anti-candida responses vs 1/7 patients without anti-HCV responses. The seven patients with anti-HCV responses had F0(n=3) or F1(n=2) or F2(n=2) (METAVIR) score at 2 years. 3/7 had undetectable HCV-VL. In patients with no anti-HCV response, the scores observed were: F1(n=1), F2(n=1), F3(n=2) and F4(n=3). Conclusions: Overall, higher levels of IFN-γ secretion to HCV and candida are associated with less severe fibrosis. Our results demonstrate that immune responses against HCV modulate recurrence of HCV infection and severity of liver histology after LT in HIV/HCV co-infected patients.

The following people have nothing to disclose: A. Samri, Anne-Marie Roque-Afonso, O. Beran, C. Feray, E. Dussaix, Didier Samuel, B. Autran, Jean-Charles Duclos-Vallée
Background: Severe hepatitis C (HCV) recurrence is the most important influencing factor of survival after liver transplantation (LT).Portal hypertension (PH) and fibrosis stage (FS) at 12th month after LT have been associated to severe recurrence and poor survival. Several serum biological markers have been proposed as predictors of fibrosis progression in non-transplanted HCV infected patients. Aims: To analyze the relationship between the early expression (3 mo) of a serum panel of biological markers related to progression of liver damage (TNF-alpha, IP-10, MCP-1, sCAM-1, sVCAM-1, VEGF, HGF, Ang2, MMP9, TIMP-1 and hyaluronic acid) and severity of HCV recurrence after LT. Patients and Methods: Thirty-seven consecutive LT recipients due to HCV (n=19) or alcoholic (n=18) cirrhosis were included. All patients received tacrolimus or cyclosporin based immunosuppression with steroids. In all cases rejection and technical complications were excluded at the time of evaluation. Serum samples were collected at 3 mo after LT. Severe HCV recurrence was defined as fibrosis stage ≥F1 (Metavir score) in the one-year protocol biopsy and/or the existence of a HVPG value ≥6mmHg. Values are expressed as median (IQR). Results: At one year, 12 out 19 patients had severe HCV recurrence. No liver fibrosis was found in the biopsies performed in non-HCV patients. Patients with severe HCV recurrence compared to non-severe HCV recurrence and to non-HCV alcoholic patients presented at 3 mo significantly higher level of IP10 [(820 (2409), 348 (280), 180 (240) pg/ml], sCAM-1 [2466 (839), 1266 (916), 1354 (1330) ng/ml] and hyaluronic acid [624 (246), 434 (351), 326 (207) pg/ml]. ROC curves were able to identify significant value to predict severe recurrence in HCV positive patients: IP10>=590: 0.74 (0.5-0.9); sCAM-1>1481: 0.89 (0.7-1); hyaluronic acid>461: 0.70 (0.5-0.9). Conclusions: Serum levels of IP10, sCAM-1 and hyaluronic acid measured early after LT are associated to severe HCV recurrence. Evaluation of these biomarkers may be useful for early identification of patients with bad prognosis in which a more aggressive therapeutic approach could be necessary.

537 HLA-DRW LOCUS DISPARITY IS ASSOCIATED WITH WORSE OUTCOME IN HCV TRANSPLANT RECIPIENTS

Alexandros Sigalas1, Pinelopi Manousou1, Elias Xirochakis1, Vincenzo Calvaruso1, Alice Corbani1, Graham Shirling2, Dimitrios N. Samokakis1, James O’Beirne1, David Patch1, Nancy Rolando1, Keith Rolles4, Brian Davidson4, Federica Grillo2, Amar P. Dhillon2, Andrew K. Burroughs1; 1Liver Transplantation and Hepatobiliary Unit, Royal Free Hospital, London, United Kingdom; 2Histopathology, Royal Free Hospital, London, United Kingdom; 3Antony Nolan Centre, Antony Nolan Trust, London, United Kingdom; 4Surgery, Royal Free Hospital, London, United Kingdom

Background & Aim: Host immune response may account for varying severity of Hepatitis C (HCV) recurrence after liver transplantation (LT). Data on HLA matching is conflicting, and could also influence survival, but this has not been evaluated. Our aim was to assess donor-recipient HLA disparity and severity of HCV recurrence, rejection, and survival at 3 months and long term after LT. Methods: Consecutive HCV cirrhotics, 229 transplants -17 retransplants; 180 males (78.6%). Mean age recipients 51.8(21-66); mean age donor 40.9(11-73). Median follow up was 52 months [range 1-216]. Hepatocellular carcinoma in 76 (31%); 74 had acute Hepatitis C (increased ALT>2x normal and consistent histology without features of cellular rejection, duct loss or other cause of liver injury). Overall 79(34%) died: 13 recurrent HCV cirrhosis, 5 chronic rejection, 37 other transplant related causes, 22 transplant unrelated cause, 2 sepsis. Serological typing for HLA class A and B, and microcytotoxicity assay for class II (DR and DQ) HLA disparity at each locus was performed and evaluated by multivariate analysis for recurrence and survival with respect to clinical data: donor and recipient age, donor and recipient gender, tacrolimus/cyclosporin monotherapy or any combination of immunosuppressive therapy, diabetes mellitus, HCV genotype, histological acute hepatitis C and occurrence and/or therapy of rejection episodes Results: HCV recurrence was evaluated histologically (Ishak scoring) from 1 year after LT (165 of 197 alive at 1st year); mean follow up 63.4 months -median 3 biopsies/patient (1-8). At last follow up 93 (37.7%) had fibrosis stage ≥3 and 72 (29.1%) had stage ≥4. Deaths occurred in 17% of fibrosis stage ≥3 and 26% stage ≥4. HLA locus disparity did not correlate with early deaths within 3 months, acute or chronic rejection, recurrent HCV or retransplantation. Severe fibrosis (≥4) stage was not associated with HLA disparity by Cox regression. However DRw locus disparity was significantly associated with patient survival (p=0.01). By Kaplan Meier analysis 75% survival if no mismatches, 62.5% with 1 mismatch, and 44.4% with 2 mismatches (x2=8.087, p=0.018). Conclusions: DRw locus mismatch does not associate with severity of HCV recurrence, but does correlate with survival after liver transplantation in HCV cirrhotic patients, independently of factors known to affect HCV recurrence.

PATIENTS WITH RECURRENT HEPATITIS C

Cristina Rigamonti1, Maria Francesca Donato1, Francesca Agnelli1,2, Mirella Fraqelli2, Giovanni Casazza2, Giorgio Rossi4, Massimo Colomba1; 1First Division of Gastroenterology, IRCCS Fondazione Ospedale Maggiore Policlinico, Mangiagalli e Regina Elena, Milan, Italy; 2Second Division of Gastroenterology, IRCCS Fondazione Ospedale Maggiore Policlinico, Mangiagalli e Regina Elena, Milan, Italy; 3Department of Statistic and Biometry, University of Milan, Milan, Italy; 4Liver Transplant Unit, IRCCS Fondazione Ospedale Maggiore Policlinico, Mangiagalli e Regina Elena, Milan, Italy

Background and aims: We previously demonstrated that TE reliably predicts severity of graft damage in LT patients. However, to what extent TE helps monitoring patients with recurrent hepatitis C under protocol liver biopsies (LB) needs to be assessed.

Methods: 34 patients (28 males, median age 57 years) with recurrent hepatitis C, who underwent sequential protocol LB and TE examinations twice, during a follow-up period of 18 months (first examinations at 6-96 months, median 6, from LT). Grading and staging were assessed according to Ishak score (grading 0-18; staging 0-6). TE examination was considered adequate if at least ten valid measurements for each patient were obtained with a >65% success rate. Changes in liver fibrosis and TE values were assessed as follows: worsening fibrosis (wF) or improvement fibrosis (iF) was defined as ≥1 point staging increase or decrease, respectively; worsening TE (wTE) or improvement (iTE) was defined as ≥30% increase or decrease of TE baseline value. Four groups were identified: wF/wTE=group 1; iF/iTE or stable F/stable TE=group 2; wF/stable TE=group 3; iF/wTE=group 4. Results: Median length of LB was 30 mm (range 15-60). At first examination median grading was 7 (range 1-11), staging 1 (0-5), TE 6.9 kPa (4.0-20.2). At second examination median grading 7 (range 1-13), staging 2 (1-6), TE 8.5 kPa (4.1-27.1). Changes in histological grading and staging positively correlated with changes in TE values (r=0.47, p=0.005 and r=0.68, p<0.0001, respectively). 11/34 (32%) patients were in group 1, 17/34 (50%) were in group 2, 3/34 (9%) were in group 3, and 3/34 (9%) were in group 4. In particular, in the group 3 staging worsened in one patient from 0 to 1, in the other two from 1 to 2; only one had grading decreased from 9 to 5. In the group 4: one with stable staging had grading increased from 8 to 13; the second developed de novo autoimmune hepatitis during follow-up, and the third had severe intrahepatic siderosis. Overall, sensitivity and specificity of TE in predicting wF were 79% and 85%, respectively. Conclusions: In patients with recurrent hepatitis C TE accurately predicted wF. TE could spare the need for protocol LB in patients with iT or stable TE.

Disclosures: The following people have nothing to disclose: Cristina Rigamonti, Maria Francesca Donato, Francesca Agnelli, Mirella Fraqelli, Giovanni Casazza, Giorgio Rossi, Massimo Colomba.
Background and Aim The recurrence of hepatitis C following liver transplantation (LT) is universal and it frequently leads to progressive fibrosis and cirrhosis with poor outcome. The aim was to evaluate the progression of fibrosis on protocol liver biopsies in patients transplanted for HCV cirrhosis. Materials and Methods A cohort of patients transplanted (1999-2005) for HCV cirrhosis who underwent protocol liver biopsies consecutively performed at our Gastroenterology Unit at 6, 12 and 24 months after LT were included in the study. Histological stage of fibrosis was evaluated according to Scheuer (score 0-4). The fibrosis progression rate (FPR) was expressed as fibrosis unit per month (FU/mo) and compared over 2 periods (6-12 mo; 12-24 mo after LT). When indicated, patients underwent PEG-IFN/Ribavirin antiviral therapy. Statistical analysis: Wilcoxon rank, Friedman and Kruskal Wallis tests. Results 54 patients underwent 3 serial and consecutive liver biopsies, M/F 20/34, age 55±7yrs, follow-up 24-95mo. Overall, at 6, 12 and 24 months after LT the stage of fibrosis 3 or 4 was reported in 3.7%, 7.4% and 13% of patients respectively, stage of fibrosis (mean value) was 1.17, 1.20, 1.70 respectively, FPR was 0.005 FU/mo (6-12 mo) and 0.0416 FU/mo (12-24 mo). 9/54 (16.7%) underwent antiviral therapy, SVR was seen in 4/9 (44.4%) patients. At 6, 12 and 24 months after LT the stage of fibrosis 3 or 4 was reported in 0%, 11%, and 22% of treated and in 4.4%, 6.7% and 11.1% of non-treated patients, the stage of fibrosis was 1.44, 1.61, 2.11 in treated (p<ns) and 1.12, 1.12, 1.61 (p=.003) in non treated patients, FPR was 0.0283 and 0.0416 in treated and 0 and 0.0416 in non treated patients at 6-12 and 12-24 mo respectively. According to SVR, at 6, 12 and 24 mo after LT, stage of fibrosis 3 or 4 was 0%, 0%, 0% in SVR+ and 0%, 20% and 40% in SVR- patients, stage of fibrosis was 1.25, 1.25 and 1.5 in SVR+ and 1.6, 1.9 and 2.6 in SVR- patients, FPR was 0.00 and 0.02 for SVR+ and 0.05 and 0.06 for no SVR at 6-12 and 12-24 mo after LT respectively (p<ns). Conclusion The fibrosis progression due to HCV recurrence is accelerated between the 1st and 2nd year compared to the early period after LT, with a lower stage and slower FPR seen in patients who were not selected for antiviral therapy. In patients without SVR, pre-cirrhosis or cirrhosis is seen in 40% of cases at 2 years after LT.

A PROSPECTIVE STUDY ON THE SAFETY AND EFFICACY OF LAMIVUDINE AND ADEFOVIR DIPIVOXIL PROPHYLAXIS IN HBSAG POSITIVE LIVER TRANSPLANTATION CANDIDATES

Ed Gane1, Simone I. Strasser2, Scott Patterson3, Geoff W. McCaughan2, Peter W. Angus1; 1NZ Liver Transplant Unit, Auckland Hospital, Auckland, New Zealand; 2AW Morrow GE and Liver Centre, Royal Prince Alfred Hospital, Sydney, NSW, Australia; 3Liver Transplant Unit, Austin Health, Melbourne, VIC, Australia

Combination lamivudine (LAM) plus high-dose intravenous heaptatitis B (HBV) immunoglobulin (HBIG) provides safe and effective prophylaxis against recurrent HBV following liver transplantation (OLTx) in HBsAg positive candidates, with recurrence rates less than 10%. However, this regimen is associated with life-long monthly clinic visits, parenteral administration of HBIG, and high cost (US$120K first year, 60-90K per annum thereafter). The aims of this study were to assess the safety and efficacy of oral antiviral prophylaxis with combination adefovir dipivoxil (ADV) and LAM without HBIG in the prevention of recurrent HBV. This prospective, open label, multi-centre study enrolled consecutive adult candidates for OLTx with HBsAg positive end-stage cirrhosis. Patients with prior LAM exposure were excluded if they had clinical or virological LAM resistance. Patients received LAM 100mg daily and ADV 10mg daily when listed for OLTx. Following OLTx, patients also received IM HBIG 8000IU daily for one week only. Primary endpoint was recurrence of HBsAg. Secondary endpoints were detection of HBV DNA, graft or patient loss, and significant renal dysfunction (increase in serum creatinine >50 µmol/L) Patients with a baseline creatinine of >180 µmol/L, HIV or HCV co-infection were excluded. No grafts were obtained from executed prisoners or other institutionalized persons. 26 patients were enrolled in the study, of whom 16 (62%) had hepatocellular carcinoma. 6 were delisted (2 for improvement, 4 for disease progression), 19 have been transplanted, and 1 remains listed at the time of writing. At baseline, 41% of patients were HBsAg positive and 81% had detectable HBV DNA, with a median level of 3.3 log10 IU/mL (range 0-8). Median duration of pre-OLTx antiviral therapy was 3.6 months (range 0-17). At OLTx 50% of patients had detectable HBV DNA and in these patients the median load was 2.6 log10 IU/mL (range 1.5-4.7), but no patient had genotypic LAM or ADV resistance. All 19 post-OLTx patients survived without recurrent hepatitis B with a median follow-up of 11.7 months (range 1-40). The median increase in serum creatinine from baseline for post-OLTx patients was 38 µmol/L. There have been no other treatment related adverse events. Combination ADV/LAM antiviral therapy is safe and effective in HBsAg positive candidates awaiting OLTx. Pre-OLTx therapy is well tolerated, achieves viral suppression, prevents LAM resistance and may rescue some patients from OLTx. Post-OLTx combination ADV/LAM therapy prevents HBV graft infection without the significant cost and inconvenience of long-term regular HBIG administration.

WHAT IS THE RISK OF HBV TRANSMISSION IN RECIPIENTS OF LIVER GRAFT FROM HBC POSITIVE ANTIBODY, HBS NEGATIVE ANTIGEN DONORS? A SINGLE CENTER EXPERIENCE OVER 10 YEARS

Bruno Roche1,2, Anne-Marie Roque-Alonso1, Teresa Antonini1, Michelle Gigou3,4, Denis Castaing1,4, Didier Samuel1,4; 1Centre Hépato-Biliaire, AP-HP Hôpital Paul Brousse, Villejuif F-94804, France; 2Département de Virologie, AP-HP Hôpital Paul Brousse, Villejuif F-94804, France; 3UMR 785, Inserm, Villejuif F-94804, France; 4UMR-S 785, Univ Paris-Sud, Villejuif F-94804, France

Background: Liver graft from HBc positive antibody (HBcAb), HBs antigen negative (HBsAg) donors are used to expand the pool of graft despite a known risk of HBV transmission. Various prophylaxis strategies were used in small series to prevent the risk of HBV transmission. The aim of the present study was to report our experience over 10 years using a prophylaxis with HBs antibody immunoglobulins (HBIG). Methods: From 1997 to 2006, 80 HBcAb + liver grafts out of 947 grafts (8.4%) were used. These grafts were used for 21 HBsAg positive recipients and 59 HBsAg negative recipients (HCV cirrhosis n=22, alcoholic cirrhosis n=14, amyloid neuropathy n=11, miscellaneous n=12). Among the 59 HBsAg negative recipients, 30 were HBsAb and HBcAb negative, 13 were HBsAb positive and HBcAb negative and 16 HBcAb positive +/- HBsAg positive. HBsAg positive recipients received a prophylaxis regimen using HBIG +/- antivirals according to pre-transplant HBV viral load. Among HBsAg negative recipients, 44 received HBIG prophylaxis using 10000 IU IV during anhepatic phase and reinjection of 5000 IU IV when HBsAb was below 100 IU/L. Results: Mean follow-up was 47.8 months (1-115.8). HBV infection occurred in 13 recipients (16.2%) during follow-up at a mean delay of 15 months (0-45) after transplantation. HBV DNA became positive in 13 patients and HBsAg in 12. No HBV infection occurred in HBsAg positive recipients. HBV infection occurred in 12 out of 30 HBsAb and HBcAb negative recipients (40%) and 1 out of 13 HBsAb positive recipients (7.7%). Among the 30 HBsAb and HBcAb negative recipients, HBV infection occurred in 7 out of 20 who received HBIG prophylaxis (35%) and 5 out of 9 who received no prophylaxis (55%). HBV infection of the graft was treated with lamivudine in 13 recipients and adefovir was added on in 6 lamivudine-resistant patients. A HBsAg / HBsAb seroconversion was observed in 3 recipients during follow-up. Conclusions: The use of liver grafts from HBcAb positive, HBsAg negative donors is relevant to expand the liver graft pool. These grafts should be used in priority for HBsAg positive or HBV immune recipients (past infection or HBV vaccination). This study confirms a high risk of HBV transmission for HBsAb and HBcAb negative recipients despite HBIG prophylaxis. Future studies should evaluate a combined prophylaxis with HBIG and antivirals in this group of recipients.

RESPONSE OF FIBROSING CHOLESTATIC RECURRENT HEPATITIS C FOLLOWING LIVER TRANSPLANTATION TO COMBINATION INTERFERON/RIBAVIRIN THERAPY

Les Lilly1, Marc Deschenes2, Paul J. Marotta3; 1Toronto General Hospital, Toronto, ON, Canada; 2Gastroenterology, McGill University, Montreal, QC, Canada; 3Gastroenterology, University of Western Ontario, London, ON, Canada

Introduction/Aim: Fibrosing cholestatic hepatitis C (FCHC) is an uncommon (<5%) presentation of recurrent HCV following liver
transplantation. It is characterized by very high bilirubin and alkaline phosphatase and modestly elevated transaminases, with a biopsy demonstrating marked cholestasis, minimal necroinflammation, bridging fibrosis, and numerous apoptotic bodies. Outcome is uniformly poor, and retransplantation generally unsuccessful. We examined the response of FCHC to interferon/ribavirin therapy, using data collected from three Canadian liver transplant programs. Patients: 15 patients from the University of Toronto, University of Western Ontario and McGill University Liver Transplant Programs who developed FCHC following liver transplantation from 2000-2005 and received combination therapy with interferon or PEG-interferon and ribavirin were included. All cases were biopsy-proven, and antiviral treatment was commenced at 30-75% of standard doses; growth factors were administered as required. Results: 10/15 patients were male; mean age at transplant was 54y [range 39-69y]. Nine received deceased donor, and six living donor, grafts. Mean time from transplant to FCHC diagnosis was 3m [range 1.5 to 6m]. Ten patients had Genotype 1, 2 G2, 3 G4. Mean pretreatment viral load was >1E6 IU/ml. 4 pts received standard IFN and 11 PEG IFN, in addition to ribavirin. 5/15 patients (33%) achieved an SVR, and 10/15 had no response. 9 of these patients succumbed to liver failure 2-22m following FCHC diagnosis; one patient is alive 6yrs after transplant with decompensated graft cirrhosis. Two of the five SVR patients have died, one from systemic sepsis 22m post transplant, and the other 17m post transplant from biliary tract complications. Conclusions: Combination therapy with interferon and ribavirin offers some hope in the management of FCHC, although the overall prognosis remains poor.

545 PREDICTING CARDIOVASCULAR EVENTS AFTER LIVER TRANSPLANTATION

Michael Herman, Surakit Pungpapong, Jaime Aranda-Michel, Barry Rosser, Denise M. Harnois, Rolland C. Dickson, Raj Satyanarayana, Daniel Yip, Andrew Keaveny; Department of Transplantation, Mayo Clinic, Jacksonville, FL

Cardiovascular disease (CVD) is a leading cause of late death post-liver transplantation (LT). CVD risk factors are common in LT patients. The optimal method and timing of risk stratification for CVD post-LT are not established. The Framingham risk score (FRS) estimates the risk of death or developing symptomatic coronary heart disease (CHD) in non-LT patients. In European cohorts, FRS increased post-LT, but had limited discriminatory capability. In our LT patients at a U.S. center, we evaluated changes in CV risk factors over time and subsequent CV events (CVE), defined as the need for intervention (surgical/medical) in CHD or peripheral vascular disease, transient ischemic attack, or cerebrovascular accident. Methods: This retrospective review of 120 consecutive first LT recipients (65% male, mean age of 55 ± 10 yrs) followed subjects for a mean of 1601 days [range 233-1907] post-LT. Fasting total, HDL and LDL-cholesterol (TC, HDL-C, LDL-C), glucose, weight and blood pressure (BP) were measured and FRS calculated at pre-LT and regular intervals post-LT (at 4 and 12 months, then annually). Diabetes mellitus (DM) was defined as plasma glucose >126 mg/dL and/or the continuing requirement for DM therapy. Hypertension (HTN) was defined as systolic BP >140, diastolic BP >90 or the use of anti-hypertensive agents. The change over time (slope) for risk factors was calculated and the association between risk factor trajectory and CV events were examined with logistic regression models. Results: 9 non-fatal CVE's occurred in our cohort over the follow-up period. CV risk factor data are shown (see Table) for selected visits. Increasing body mass index (BMI) increased the odds of developing DM (OR 1.07 [95% CI 1.07 - 1.13], p<0.01). The FRS slope correlated with CVE, (OR 1.4 [95% CI 1.19], p=0.04). Conclusions: CV risk factors are prevalent in U.S. LT patients. Changes in FRS over time identify patients at risk for CVE post-LT, with the odds of CVE increasing by 40% for each 1-unit increase in slope. Risk factor modification studies in this population appear warranted.

546 TRANSPLANTATION TRENDS IN RECIPIENTS OVER THE AGE OF 65

Nyingi Kemmer1,2, Kamran Safdar1, Tiffany E. Kaiser1, Victoria Zacharias1, Muslim Atiq1, Kashif Ahmed1, Nadia Maliki1, Guy W. Neff1; 1University of Cincinnati, Cincinnati, OH; 2VA Medical Center, Cincinnati, OH

Liver transplantation (LT) provides long-term survival for adults with end-stage liver disease. As a result of improved survival and an aging United States population the demand for LT in older patients is expected to increase. The aim of this study is to describe the transplantation trends in the older recipient (65 yrs and older). Method: Using the UNOS database, we identified all LT recipients between 1990 and 2006. The data collected included demographics, diagnosis, LT year, survival information and UNOS region. We used Kaplan Meier method to calculate overall survival (1, 3, 5 and 10 yr) and Cox regression modeling techniques for predictors of survival. Result: During the study period 5630 (7.6%) LT recipients were >65 years. Of these, there were 3030 (56.5%) males with a median age of 67 (range 65 – 87). There were 4256 (79.4%) Caucasians, Hispanic (10.3%), African Americans (3.6%) and rest (6.7%). Hepatitis C (21%) was the most common indication followed by cryptogenic (15.1%), alcoholic liver (13%), Hepato-cellular Carcinoma (10.4%), Primary biliary cirrhosis 9.2%, Primary sclerosing cholangitis 5.1% and others 26.2%. There was an increase in LT for older patients from 4.1% in 1990 to 10.2% in 2006 (p=0.002), as well as a regional variation (p<0.001). The 10-yr patient and graft survival was 60% and 57% for <65 yrs vs. 42% and 40% for >65 yrs (p <0.0001). With age stratification (65 – 75 yrs vs. >75yrs), there was no difference in overall survival but when adjusted for race there was a significant difference in graft survival with a 10 yr (Caucasian 40%, Hisp 44% and African Americans 19%) (p=0.04). No other predictors of survival were identified. Conclusion: The demand for LT in recipients older than 65...
years is increasing; there is regional variability and a change in LT indication (cryptogenic 2nd most common). Although their survival is reduced when compared to recipients <65 yrs, there appears to be no difference in unadjusted survival with age stratification above 65 years. Among ethnic minorities, African Americans have a disproportionately lower % LT and a decreased survival.

547
THE EFFECT OF DISEASE RECURRENCE ON GRAFT SURVIVAL FOLLOWING ORTHOTOPIC LIVER TRANSPLANTATION
Ian A. Rowe1, Kerry Webb1, Bridget K. Gunson1, Naimish Mehta1, Sayeed Haque2, James M. Neuberger1; 1Liver Unit, Queen Elizabeth Hospital, Birmingham, United Kingdom; 2Department of General Practice and Primary Care, University of Birmingham, Birmingham, United Kingdom

Disease recurrence following transplantation is well recognised but since the impact of recurrence on graft survival is less clear we undertook a retrospective analysis to determine both the frequency and impact of disease recurrence on graft survival. All 1840 adult patients who underwent liver transplantation between 1982 and 2004 were included. Disease recurrence was diagnosed on clinical, serological, histological or radiological grounds as appropriate. Where graft loss was due to factors associated with the indication (such as a return to alcohol consumption), the graft loss was attributed to disease recurrence. The most common disease indication was primary biliary cirrhosis (PBC) so these patients were used as the comparison group. To eliminate those grafts lost where recurrence was unlikely only those 1499 patients surviving more than 90 days after transplantation were included in the analysis. The risk of graft loss from disease recurrence for first grafts was calculated using the Cox regression model. The risk of graft loss from recurrent disease was greatest, when compared to PBC, in those transplanted for hepatitis C virus (HCV) (hazard ratio (HR) 11.6; 95% confidence interval (CI) 5.1-26.6), primary sclerosing cholangitis (PSC) (HR 6.0; 95% CI 2.5-14.2) and autoimmune hepatitis (AIH) (HR 4.1; 95% CI 1.3-12.6). The overall risk of graft loss was also significantly greater in HCV (HR 2.1 vs. PBC; 95% CI 1.5-3.0), PSC (HR 1.6 vs. PBC; 95% CI 1.2-2.3) and AIH (HR 1.6; 95% CI 1.0-2.4) although when recurrent disease was excluded as a cause of graft loss there was no difference in the overall risk of graft loss (HCV: HR 1.4; 95% CI 0.9-2.1, PSC: HR 1.4; 95% CI 0.9-2.0, AIH: 1.4; 0.9-2.2 all vs. PBC). When the rate of disease recurrence and the rate of graft loss from disease recurrence were compared, proportionally more grafts were lost in HCV (14.3% of grafts lost to recurrent disease vs. 77% of grafts affected), PSC (8.4% vs. 37%), and AIH (6.2% vs. 28%) than in PBC (1.3% vs. 24%). There was no statistically significant difference in the risk of graft loss due to recurrent disease, when compared with PBC, for patients transplanted for alcohol related liver disease (ALD) (HR 1.0;95% CI 0.2-4.9), non-alcoholic steatohepatitis (HR 2.2;95% CI 0.6-8.4) and fulminant hepatic failure (HR 1.7;95% CI 0.4-6.6). Disease recurrence is a significant cause of graft loss particularly in HCV, PSC and AIH. Graft loss from disease recurrence in part explains the increased overall rate of graft loss in these groups.

NATURAL HISTORY AND PROGNOSTIC INDICATORS IN CIRROTIC PATIENTS WITH PULMONARY HYPERTENSION
Matthias M. Dollinger1, Alexander Zipprich1, Stefan Rogowski1, Susanne Behl1, Wolfgang E. Fleig2; 1First Department of Medicine, Martin-Luther-University Halle-Wittenberg, Halle (Saale), Germany; 2University of Leipzig Hospitals and Clinics, Leipzig, Germany

Porto-pulmonary hypertension (pPH) is a circulatory complication defined by elevated pulmonary artery pressure (mPAP) and pulmonary vascular resistance (PVR) but normal pulmonary artery occlusion pressure (mPAOP). Recently, the transpulmonary gradient (TPG) (mPAP-mPAOP) has been proposed as another diagnostic tool. pPH may be reversible after liver transplantation and a debate has started on the evaluation of such patients on the waiting list, but data on the natural history of pulmonary hypertension (PH) in cirrhosis are scarce, in particular outside of pre-transplant cohorts. Aim: To assess natural history and prognostic indicators in cirrhotic patients with PH in a large single-centre cohort. Methods: 729 consecutive patients with suspected cirrhosis referred to our unit between 12/1995 and 12/2004 received full clinical and haemodynamic assessment which included Child-Pugh/MELD score, the hepatic venous pressure gradient (HVPG) and cardiopulmonary pressures. Survival time/time-to-transplant (ST/TtT) was calculated as a combined end point (Kaplan-Meier method; cut-off 31/11/2006), and MELD/Child-Pugh, HVPG and cardiopulmonary morbidity were introduced as variables in a multivariate cox-regression model. Results: 650 patients met study criteria (Child-Pugh A/B/C 28%/45%/27%; no malignancy) including 575 without PH (mPAP<25mmHg), their survival predicted by Child-Pugh/MELD and HVPG (4% transplanted). mPAP exceeded 25mmHg in 75 patients (12%), in 25 (4%) secondary to cardiopulmonary disease. Survival was similar without out PH and with secondary PH (ST/TtT 1905±71 vs. 1590±274 days / MELD 15±7 vs. 17±8, ns.), although liver-related scores lost their predictive value in the latter. In the remaining 50 patients TPG, but not mPAP or PVR, was an independent prognostic indicator (p<0.05), and 3-month-survival was best predicted by a TPG cut-off of 12mmHg using ROC curves. Thus, an mPAP>25mmHg and a TPG≥12mmHg (mPAP 35±13mmHg, mPAOP normal) were associated with the poorest outcome (15 patients [2%] with ST/TtT 734±196 vs. 1905±71 days in patients without PH, p<0.05; MELD 18±8 vs. 15±7, ns.). While liver-related scores failed to predict survival in this group (only one patient transplanted), the patients carried the same 3-month-prognosis as patients with MELD<26 but no PH, even with a MELD<14. Conclusion: In our cohort, an mPAP>25mmHg and TPG≥12mmHg in the absence of secondary PH selects cirrhotic patients with the worst prognosis. These
parameters may be sufficient to diagnose POPH in the presence of the hyperdynamic circulation following cirrhosis. The poor prognosis argues for prioritizing such patients on the waiting-list irrespective of low MELD scores.

549 EXCELLENT OUTCOME OF PATIENTS WITH ACUTE ALCOHOLIC HEPATITIS AFTER LIVER TRANSPLANTATION

Ivo Graziaiade1, Karin Nachbaur1, Barbara Sperner-Unterweger2, Walter Mark3, Raimund Margreiter4, Wolfgang Vogel5; 1Gastroenterology and Hepatology, Medical University Innsbruck, Innsbruck, Austria; 2Biological Psychiatry, Medical University Innsbruck, Innsbruck, Austria; 3Transplant Surgery, Medical University Innsbruck, Innsbruck, Austria

Liver transplantation (LT) is the only curative therapeutic option for patients with acute and chronic liver failure. Besides chronic hepatitis C liver cirrhosis due to alcoholic liver disease is the most common indication for LT. Patients with acute alcoholic hepatitis (AH) have an extremely poor prognosis, as this disease is associated with a 30-50% mortality within one month. No curative therapeutic strategies are available for patients with severe AH, except LT. However, the role of LT in the management of AH has been discussed controversially and so far, no data regarding long-term outcome of these patients following LT have been reported. The aim of this retrospective study was to analyse the long-term survival of patients who underwent LT due to severe AH in our center. Between 1995 and 2006 11 out of 651 patients (1.7%) with severe AH were transplanted. Three patients were female, 8 male with a median age of 43 (29-54) years. All patients had a Maddrey discriminant factor >32; the median MELD score was 27.5 (16-35). A thorough psychiatric evaluation, including family members and local physicians, was performed in all patients prior to LT. Patients with stable psychosocial environment, as an indirect parameter for a patient's compliance, were listed for LT. The period of abstinence ranged from few days to 3 months. A specific psychiatric therapy was started as soon as possible after LT. The patient survival rates of the AH group were compared to those of patients transplanted for alcoholic liver cirrhosis and of the overall LT cohort. The mean follow-up of AH patients was 3.9 ± 3.1 (0.6-9.4) years. Immunosuppression consisted of cyclosporine or tacrolimus in combination with prednisolone (taper within 3-6 ms) and mycophenolate mofetil. The actuarial patient survival of all AH patients at 1-, 2-, and 5 years were 100%, 100% and 98%, respectively; n=487). Including alcohol liver cirrhosis (90%, 88% and 78%, n=153), however, the differences were not statistically significant. Three patients with AH died 1.2, 3.9 and 9.4 years post LT due to cholangiopitis secondary to intrahepatic biliary strictures, suicide and oropharyngeal carcinoma. Two of these patients developed recurrent alcohol abuse, whereas nine patients had no evidence of recurrent disease and remained completely abstinent after LT. This study showed an excellent long-term survival of patients with acute alcoholic hepatitis. An extensive interdisciplinary management of these patients, especially in the postoperative care, is mandatory in order to achieve this excellent outcome.

550 EVALUATION OF THE BENEFIT ON RENAL FUNCTION OF A DELAYED INTRODUCTION OF TACROLIMUS IN LIVER TRANSPLANT RECIPIENTS AT 13 FRENCH CENTERS

Yvon Calmus1, Lionel Rostaing2, Jean Gugentheim3, Christophe Duvoux4, Christian Ducerf5, Philippe Wo1, Didier Samuel7, Claire Vanlemmens8, Martine Neau-Cransac9, Ephrem Salame10, Olivier Chazouillères11, Nicole Declerc12, Georges-Philippe Pageaux13; 1Hospital Cochin, Paris, France; 2Hospital Rangueil, Toulouse, France; 3Hospital Archet2, Nice, France; 4Hospital Henri Mondor, Créteil, France; 5Hospital Croix Rousse, Lyon, France; 6Hospital Hautepierre, Strasbourg, France; 7Hospital Paul Brousse, Villejuif, France; 8Hospital Minjoz, Besançon, France; 9Hospital Pellegrin, Bordeaux, France; 10Hospital Côte de Nacre, Caen, France; 11Hospital Saint-Antoine, Paris, France; 12Hospital Huriez, Lille, France; 13Hospital Saint Eloi, Montpellier, France

Although calcineurin inhibitors have demonstrated efficacy in liver transplantation, they have a potential to impair renal function. Delayed tacrolimus (TAC) administration may reduce the risk of renal dysfunction. Methods: A prospective study included primary LTx recipients randomised either to delayed introduction of TAC (Day 5) + Daclizumab (DAC) (Group A) or to immediate TAC administration (Group B). In both groups, TAC T0 was 15 ng/ml until Week 4 and 5−15 ng/ml thereafter. MMF was given at 2 g/d for 2 months, and corticosteroids (CS) at standard doses. Pts with a serum creatinine (Scr) > 180 umol/l at 12 hours (H12) were not included. The primary endpoint was the rate of pts with a mean Scr > 130 umol/l at Month 6. Results: Analyses were performed on 207 pts, 98 (Group A) and 101 pts (Group B) (ITT population). Baseline characteristics were similar. At Month 6, mean TAC T0 was 9.6 (Group A) and 11.2 ng/ml (Group B), and patient and graft survival were 100% and 98.9%, respectively. Two pts required dialysis sessions (DS) in group A (1 pt had 10 DS during the first month and 1 pt 1 DS thereafter). All six pts required DS within the first month in group B (1 of them required 37 DS). Incidence and time to first BPAR were 20.3% (A) and 24.2% (B) pts. At least one serious adverse event related to treatment was reported in 26.5% pts in Group A and 37.6% pts in Group B. Insulin therapy > 30 days was reported in 9.2% and 11.8% pts respectively. Conclusions: Delayed TAC administration with DAC and MMF is a safe immunosuppressive therapy for LTx pts with no increased BPAR. Benefit on renal function (Scr) at 6 months was not statistically different to that with immediate TAC administration. A trend towards better GFR was observed for pts with good renal function at H12 and with delayed TAC administration. The impact on longer-term renal function will be assessed at 1- and 2-year follow-up.

551 THE ISCHEMIC PRECONDITIONING (IPC) PARADOX IN LIVER TRANSPLANTATION (LT) – EVIDENCE FROM A PROSPECTIVE RANDOMIZED TRIAL

Kunj Desai, Asif Shareef, George Dikdan, Kenneth Klein, Andrew delaTorre, Meelie Debroy, Adrian Fisher, Dorian Wilson, Bo Peng, Arun Samanta, Baburao Koneru; UMDNJ - New Jersey Medical School, Newark, NJ

Introduction: Animal studies show that IPC of liver is uniformly beneficial in LT with potential to expand available deceased donor (DD) organ pool. However, evidence from the few clinical trials in LT is conflicting. Herein we report the results from a recently completed, largest prospective randomized study to date of IPC in DD-LT. Methods: Between Oct 2003 and June 2006, 101 DD were randomized based on donor age (< or ≥ 50) to either 10 min of IPC (N=50) or No IPC (N=51). IPC was induced by hepatic hilar clamping soon after laparotomy. All other care in DD and recipients was standard. The primary objective was to test the hypothesis that 10 min of IPC would improve post LT graft reperfusion (RP) injury and function. Secondary objectives were to determine whether IPC would decrease 1) systemic inflammatory cytokine response 2) biopsyc-confirmed acute rejection (AR) in the first month and 3) hospital stay. Intent-to-treat based analyses were applied. Results: Both groups of donors were comparable with an identical donor risk index of 1.5 ± 0.3. The recipient groups were comparable except for significantly fewer males (66 vs. 86%, p=0.01) and lower MELD score (median 18 vs.23, p=0.04) in the IPC group. Contrary to expectation IPC led to a significant increase in biochemical RP injury (Table). Donor and recipient TNF-α, IL-6 and donor IL-10 plasma levels at various time points were similar in both groups. IPC recipients had significantly higher median IL-10 levels on day 1. (237 vs. 112 pg/ml, p=0.03) and had fewer biopsy-confirmed moderate/severe AR (2/50 vs. 8/51, p=0.09). Median length of stay [11 days] was the same in both groups. One and two-year patient survival in IPC vs. No IPC were 88 and 81% vs. 79 and 64%, respectively (p=0.10). Graft survivals were 84 and 76% vs. 77 and 66%, respectively (p=0.25). Conclusions: Despite the initial worsening of biochemical RP injury, IPC increases circulating levels of the anti-inflammatory cytokine, IL-10, in liver recipients in association with a decreased risk of severe rejection – an IPC paradox. IPC alone provides limited benefit in DD-LT, and may need to be combined with other preconditioning measures to derive maximal benefit.

552 MELD-NA IS SUPERIOR TO OTHER ORGAN ALLOCATION SYSTEMS

Matthew R. Foxton, Paolo Muiesan, Nigel Heaton, John G. O’Grady, Michael A. Heneghan; Institute Of Liver Studies, Kings College Hospital, London, United Kingdom

Introduction There is ongoing analysis of the optimal method of organ allocation. The MELD system is inaccurate for up to 20% of the population on the liver transplant waiting list. This is most likely due to significant clinical variables such as ascites not being accounted for. We analyzed several scoring systems for end-stage liver disease to assess which predicted survival on the waiting list. Methods All patients listed with UK Transplant (UKT) at our centre, between January 2000 and December 2003, were included in the study. Patients were excluded if they were super-urgently listed, listed for multiple organ transplants, non-NHS entitled for liver transplant or their indication for transplant was amyloidosis. The scoring systems examined were the Child-Pugh score, MELD score, MELD-Na score and three variants of the Child Pugh score incorporating creatinine at the time of listing with UKT. A positive outcome was surviving to transplantation or being delisted due to improvement obviating the need for transplant. A negative outcome was death on the transplant list or being delisted due to the developments of contraindications for transplant. Receiver-operating characteristic (ROC) curves were generated for each scoring system based on these outcome measures and the areas under the curve (AUC) were compared using the Hanley-McNeil method. Results Seven hundred and eighty seven patients were listed. After exclusions, 490 patients were analysed in the study. The median age of the patients was 55 years and the predominant aetiologies were alcoholic liver disease and hepatitis C. The median Child-Pugh score was 9 and the median MELD score was 15. There were 416 patients with a positive outcome including 402 transplants. The remaining 74 patients with a negative outcome had significantly higher CPS (11 vs 9), MELD (18 vs 14), MELD-Na (38 vs 16) and modified CP scores (All p values <0.0001). There was no difference in time on the waiting list (64 vs 68 days; p=0.18). The AUC for all scoring systems was >0.705 (p<0.001) indicating that they performed well and were clinically applicable. However, MELD-Na was significantly better than the other scoring systems with an AUC of 0.828 (p<0.001). Conclusion All scoring systems analysed performed adequately in predicting a negative outcome on the transplant waiting list with no difference between CP score and MELD score. However, MELD-Na was significantly better than all the other scoring systems at predicting waiting list mortality and thus any changes in organ allocation warrant comparison with this scoring system.
553
LONG TERM RESULTS OF A RANDOMIZED TRIAL OF TACROLIMUS MONOTHERAPY VERSUS TRIPLE THERAPY IN HCV CIRRHOSIS LIVER TRANSPLANT RECIPIENTS

Pinelopi Manousou1, Dimitris Samonakis1, Alice Corbani1, E. Cholongitas1, Alexandros Sigalas1, Elias Xirochakis1, Vincenza Calvaruso1, Federica Grillo1, David Patch1, James O’Beirne1, Amar P. Dhillon2, Keith Rolles3, Brian Davidson3, Andrew K. Burroughs3;
1Liver Transplantation and Hepatobiliary Unit, Royal Free Hospital, London, United Kingdom; 2Dep of Histopathology, Royal Free Hospital, London, United Kingdom; 3Dep of Surgery, Royal Free Hospital, London, United Kingdom

Introduction
Less potent immunosuppression has been considered to be beneficial in reducing severity of HCV recurrence. However some reports suggest benefit with low dose steroid maintenance. Optimal immunosuppression regimen is unknown. Aim of the study To evaluate benefit of tacrolimus monotherapy versus triple therapy in a randomized trial. Patients and methods 88 consecutive patients with first transplant for HCV cirrhosis with/without HCC were randomized to tacrolimus (MT) 0.1 mg/kg/day in 2 divided doses, or the same tacrolimus dose with 1mg/kg azathioprine and 20mg prednisolone daily (TT) the latter was tapered off to zero at 3-6 months. Patients had scheduled biopsies with Hepatic Venous Pressure Gradient (HVPG) measurement yearly. Fibrosis was staged using Ishak score and stage 4(F4) was the predetermined end-point. Cox regression was used to evaluate factors associated with F4: age and gender of recipient and donor, histological acute hepatitis, rejection episodes, HCC before LT, addition of MMF, and allocated treatment. Results Randomization resulted in no significant differences in pre, peri or post operative variables (median follow up 48 months). Mortality was not significantly different: 8 of 43 in MT at 1m, 1m, 1m, 2m, 3m, 4m, 6m and 5 of 45 in TT at 5m, 7m, 11m, 37m, and 66m. Retransplantation in 3 MT and 3 TT; frequency of scheduled biopsies was similar. During follow up (re-transplants censored), 13 MT and 6 TT reached F4. Cox regression revealed that randomization to therapy and episodes of acute hepatitis were two factors independently associated with F4 (p=0.036). Kaplan Meier analysis showed TT patients had significantly slower progression (p=0.048) than MT patients. HVPG gradient was available in 33 MT and 30 TT patients. Kaplan Meier analysis showed a significantly shorter time to reach HVPG>10mmHg in MT group compared to TT group (p=0.038). Conclusion The use of low dose azathioprine long term and short term low dose prednisolone in addition to tacrolimus in HCV cirrhosis recipients resulted in a slower onset of histological severe fibrosis and portal hypertension compared to tacrolimus alone, independent of other factors known to affect fibrosis. This randomized trial supports observational reports of the benefit of low dose steroids, as well as azathioprine, used as maintenance immunosuppression after liver transplantation for HCV positive recipients.

GRAFT SURVIVAL AFTER LIVING DONOR OR CADAVERIC LIVER TRANSPLANTATION: AN ANALYSIS STRATIFIED BY DONOR RISK

Siddharth Patel1, Ian Lent1, Adel Bozorgzadeh1, Mark Orloff1, Georgios Tsoufas1, Randeep Kashyap1, Ashok Jain1, Peter Abt2;
1Surgery, Division of Transplantation, University of Rochester Medical Center, Rochester, NY; 2Surgery, Division of Transplantation, University of Pennsylvania, Philadelphia, PA

Introduction: Living donor liver transplantation (LDLT) has become an accepted alternative to transplantation with a cadaveric organ. Recently, cadaveric donor characteristics as codified by the Donor Risk Index (DRI) have illuminated the requirement to balance donor qualities and recipient risk of death on the wait list as a means to optimize the survival benefit of transplantation. Within this framework, the role of the living donor graft remains unclear. Methods: Utilizing United Network for Organ Sharing data from 2002 to 2006, we analyzed graft survival comparing 4 different graft types stratified by donor risk characteristics: low-risk living donor (LRD – Relative Risk [RR] of graft loss <1.7), high-risk living donor (HRRD, RR >1.7), low-risk deceased donor (LRDD, <1.7) and high-risk deceased donor (HRDD, RR >1.7). Graft survival was modeled using Cox regression while controlling for recipient characteristics, which included age, race, diagnosis, dialysis, medical condition, life support and Model for End-Stage Liver Disease (MELD) score. Results: 98% of LDLT transplants were performed in recipients with a MELD score of 25 or less. Overall 3 year graft survival for LRD, HRRD, LRDD, and HRDD was 77%, 65%, 80%, and 67%, respectively (p-value < 0.001) (Fig. 1). The relative risk of graft loss, in reference to the LRDD group, was 1.7 for HRRD (95% CI 1.05-2.75), 0.9 for LRDD (95% CI 0.72-1.12), and 1.4 for HRDD (95% CI 1.18-1.86). Conclusions: Survival with high risk living donor grafts is similar to high DRI cadaveric organs in patients with low to moderate MELD scores. Consideration of donor characteristics relative to recipient risk of wait list death should be considered in LDLT.

555 SERUM SODIUM LEVELS ARE NOT INDEPENDENT OF FLUID STATUS AND DISEASE SEVERITY IN LIVER TRANSPLANT WAITING LIST CANDIDATES

Patrick G. Northup1, Curtis K. Argo1, Abdullah M. Al-Osaimi1, Timothy M. Schmitt2; 1Gastroenterology and Hepatology, University of Virginia Health System, Charlottesville, VA; 2Surgery, University of Virginia Health System, Charlottesville, VA

Introduction: Serum sodium levels in liver transplant waiting list candidates have been shown to predict waiting list mortality. Controversy surrounds this because it is clinically evident that sodium levels are highly dependent on fluid status, renal function, diuretic use, TIPS, and general liver disease severity. We hypothesize that most fluctuations in sodium levels are dependent on other clinical measures and are not true independent factors in waiting list death risk. Methods: Organ Procurement and Transplantation Network (OPTN) liver transplant waiting list data between February 2002 and April 2004 were analyzed for all adult, non-status 1 candidates. All consecutive waiting list laboratory data, including serum sodium for each transplant candidate were analyzed. Waiting list death rates were calculated for patients with varying levels of hyponatremia. Multivariate survival models were constructed to analyze the independent predictors of sodium variation. Multivariate survival models were then constructed to compare 90-day waiting list death rates adjusting for those factors that influence sodium levels. Results: 100,133 serum sodium levels from 26,502 candidates on the waiting list were analyzed. 17.6% of all candidates had at least one sodium below 135 mg/dL and 6.9% had one sodium reported below 130 mg/dL. Statistically significant independent predictors of sodium levels less than 130 mg/dL included receiving a TIPS while on the waiting list (OR 1.70, 95%CI 1.14-2.54, p<0.01), large volume ascites (OR 4.00, 95%CI 3.25-4.93, p<0.0001), serum albumin (OR 0.43, 95%CI 0.40-0.46, p<0.0001), serum total bilirubin (OR 1.02, 95%CI 1.01-1.03, p<0.0001), and serum creatinine (OR 1.07, 95%CI 1.03-1.11, p<0.0001). These predictive variables were responsible for more than 75% of the variation in serum sodium. In a 90-day multivariate waiting list survival model including the above variables, serum sodium was not an independent predictor of mortality (p=0.17). In a similar proportional hazards model after adjusting for the above factors, serum sodium remained statistically significant (p<0.0001) but only improved the fit of the overall survival model by less than 0.08% Conclusions: Serum sodium measurements are highly dependent on other clinical factors and can be manipulated by addressing these clinical factors. When factors that influence sodium are adjusted, serum sodium has a minimal influence on liver transplant waiting list mortality. Including sodium in the allocation policy might add additional subjectivity to the MELD system.

556 SAFETY AND EFFICACY OF THYMoglobulin FOR STEROID RESISTANT ACUTE CELLULAR REJECTION FOLLOWING LIVER TRANSPLANTATION

Safety and Efficacy of Thymoglobulin for Steroid Resistant Acute Cellular Rejection Following Liver Transplantation A.K. Sahajpal, V. Madhok, K. Shivakumar, J.E. Hay, M.R. Charlton, C.B. Rosen, R.H. Wiesner, K.V.N. Menon Introduction: Steroid resistant acute cellular rejection (ACR) following liver transplantation (LT) is commonly treated with OKT3 which is often associated with serious adverse events. The most common adverse events associated with its use are fever, chills, leucopenia and thrombocytopenia. There is limited data on its role in the treatment or steroid resistant ACR in LT. Aim: The aim of our study was to assess the safety and efficacy of thymoglobulin for steroid resistant ACR compared to OKT3 in LT. Methods: Twenty-two consecutive patients (11 females) who received Thymoglobulin (ATG) for steroid resistant ACR following LT at the Mayo Clinic, Rochester from September 2003 to July 2006 were included in the analysis. They were compared with 19 patients who received OKT3 for the same indication during the study period. Patients were selected for antibody treatment if they continued to exhibit histological signs of ACR following bolus corticosteroid therapy for ACR (three doses of 1000 mg of methyl prednisolone or 200 mg of dexamethasone intravenously on alternate days). OKT3 was dosed at 5 mg/kg daily for 7 to 10 days while ATG was dosed at 1.5 mg/kg/dose for 7 doses over 10 days along with standard premedication. Results: The primary immunosuppression was tacrolimus in all but 2 patients in the OKT3 group who received Neoral. Following bolus corticosteroid therapy moderate cellular rejection was seen in 45% of patients in the ATG group and 19% of patients in the OKT3 group. ATG therapy was associated with a lower incidence of adverse effects (fever, hypotension, chills and infection) compared to OKT3 therapy (29% versus 71%, p = 0.002). The number of patients requiring intensive care for hypotension and infectious complications was higher in the OKT3 group compared to the ATG group (21% versus 0%, p = 0.045). No patient treated with ATG required dose adjustments for cytopenias, weight change or fever. Conclusion: ATG was as efficacious as and better tolerated than OKT3 for the treatment of steroid resistant ACR with a significantly greater number of patients on OKT3 requiring intensive care. ATG is therefore a safe and effective agent for the treatment of steroid resistant ACR following LT.

557 MYCOPHENolate MOFetil PLUS LOW DOSE CALCineurin INHIBITOR FOR RENAL DYSFUNCTION IN LIVER TRANSPLANT: A 24-MONTH CONTROLLED CLINICAL TRIAL

Maurizio Biselli1, Giovanni Vitale1, Annagialia Gramenzili1, Anna Ritiili1, Sonia Berardili1, Francesca Dazzani1, Carlo Camma2, Alessandra Scuteri1, Maria Cristina Morelli1, Claudia Sama1, Antonio Daniele Pinna2, Mauro Bernardi1, Pietro Andreone1, 1Dipartimento Malattie Apparato Digerente e Medicina Interna, Università di Bologna, Bologna, Italy; 2Cattedra di Gastroenterologia, Università di Palermo, Palermo, Italy; 3Unità Operativa di Chirurgia dei Trapianti di Fegato e Multiorgano, Policlinico S.Orsola-Malpighi, Bologna, Italy

Renal dysfunction is a major complication of long-term immunosuppressive therapy with calcineurin inhibitors (CNI) in liver transplantation (LT). In this setting, we tried to assess the long-term efficacy and outcome of tapering CNI to a low through level and introducing Mycophenolate Mofetil (MMF). Thirty patients were matched for sex, age, months after LT, immunosuppressive treatment, creatinine level, presence of diabetes and calculated glomerular filtration rate (GFR) via Cockroft-Gault method, with a parallel control group who had received
CNI only. MMF was introduced and CNI dose was progressively reduced. The following variables were analyzed: side effects and rate of rejection, serum creatinine reduction by at least 10% with respect to baseline value (10%-creatinine) and/or a GFR increase of at least 10% with respect to baseline value (10%-GFR), change from baseline of creatinine and GFR (Δserum creatinine = serum creatinine level at baseline – serum creatinine level at 24 month; ΔGFR = GFR at 24 month – GFR at baseline). Thirty patients (25 M; mean age 61±7 yrs; creatinine 1.77±0.51 mg/dL; GFR 48.4±14 mL/min) were converted to the combined therapy after a median of 63 months from LT and were compared with 30 patients (25 M; mean age 60±7 yrs; median time from LT 63 months; creatinine 1.62±0.25 mg/dL; GFR 48.9±11.2 mL/min) used as contemporaneous control group. After 2 years, serum creatinine decreased in the MMF to 1.57±0.71 mg/dL and GFR increased to 56.8±17.2 mL/min (p<0.001). The controls experienced a worsening of both serum creatinine (1.7±0.35 mg/dL, p=0.013) and GFR (47.3±11.1 mL/min, p=0.006). The logistic regression models employing 10%-creatinine and 10%-GFR as dependent variables, showed the use of MMF as the only statistically significant parameter associated with improvement of renal function (Odds Ratio (OR) 5.7 / 95% Confidence Interval (CI) 1.7-18.9, p=0.004; OR 3.8 / 95% CI 1.7-11.4, p=0.019; respectively). Multiple linear regression analysis identified only MMF as independent predictor of Δcreatinine (Regression coefficient B: -0.26 / 95% CI -0.1-0.41; p=0.002) and ΔGFR (Regression coefficient B: -9.05 / 95% CI -4.9-13.2; p<0.001). The mean decrease of Δcreatinine was 0.18±0.36 mg/dL in MMF group, whereas we observed a mean increase of 0.08±0.23 mg/dL in controls. In respect to ΔGFR, in MMF group we observed a mean increase of 7.4±8.3 mL/min versus a mean decrease of 1.7±7.7 mL/min in controls. No rejection episode was observed (3 in the controls). This study demonstrates the long-term efficacy and safety of MMF plus low dose CNI in reducing nephrotoxicity in LT recipients.

558
SMOKING RELATED MORBIDITY AND MORTALITY POST LIVER TRANSPLANTATION
Joanna A. Leithead1,2, James W. Ferguson2, Peter C. Hayes1,2; 1Department of Hepatology, University of Edinburgh, Edinburgh, United Kingdom; 2Scottish Liver Transplant Unit, Royal Infirmary of Edinburgh, Edinburgh, United Kingdom

Introduction: The negative health implications of cigarette smoking in the non-transplant setting are well recognised. However, the morbidity and mortality associated with tobacco use amongst liver transplant recipients specifically remains unclear. The aim of this study was therefore to assess the influence of smoking on both short and long term outcomes post liver transplantation. Methods: A single-centre retrospective case-note study of 135 consecutive patients transplanted between 01/01/96 and 31/12/00. Smoking status was based on documentation during liver transplant assessment. Patients who did not have smoking status recorded or who were described as ex-smokers were excluded from further analysis. Mean follow-up time was 8.8+/−1.4 years. Results: Of the remaining 108 patients, 29% were smokers and 71% were non-smokers. No difference was observed between the two groups with regards age, gender, prevalence of HCC, Child Pugh score, listing renal function, and the presence of pre-transplant diabetes, hypertension and cardiovascular disease. 35% of smokers had alcoholic liver disease compared with 13% of non-smokers (p<0.01). Post transplant a similar proportion of patients in each group received cyclosporin, and were treated for diabetes, hypertension and hypercholesterolaemia. During the immediate post-operative period smokers were more likely to develop pneumonia (p<0.01). However, there was no difference in the rate of systemic bacterial/fungal infection, CMV viraemia, acute cellular rejection, need for renal replacement therapy and survival to discharge. Long term the incidence of pneumonia, bacterial/fungal infection, CMV viraemia, late acute rejection and chronic rejection did not differ between the two groups although smokers had increased sepsis-related mortality (16% vs 4%, p=0.03). Smokers did not demonstrate increased incidence of cardiovascular disease but did have increased cardiovascular-related mortality (13% vs 1%, p<0.01). Non-smokers were more likely to develop de novo malignancy (26% vs 3%, p<0.01), although malignancy and de novo malignancy-related mortality between the two groups was similar. Smoking at the time of liver transplantation was associated with reduced survival during the followup period (58% vs 78%, p=0.04). On multivariate analysis smoking (OR 2.80; 95% CI 1.11-7.03, p=0.03) and post operative renal replacement therapy (OR 3.15; 95% CI 1.04-9.49, p=0.04) were the only independent predictors of mortality. Conclusions: Smoking is associated with significant morbidity and mortality post liver transplantation. Prospective studies are required to assess the impact of smoking cessation on long term outcome.

MULTICENTER, RANDOMIZED TRIAL OF CONVERSION TO EVEROLIMUS WITH CALCINEURIN INHIBITOR MINIMIZATION OR DISCONTINUATION IN LIVER TRANSPLANT PATIENTS WITH RENAL IMPAIRMENT
Frederic Nevens1, Martina Sterneck2, Heraldt Mestelaar2, Jérôme Dumortier1, Emiliano Giostra3, Karim Boudjema4, Evaristo Varó5, Paolo de Simone6; 1Department of Hepatology, Universiteit Ziekenhuis Gasthuisberg, Leuven, Belgium; 2Department of Internal Medicine, Erasmus Medical Center, Rotterdam, Netherlands; 3Unité de Transplantation Hépatique, Hôpital Edouard Herriot, Lyon, France; 4Department of Hepatobiliary Surgery, Universitätsklinikum Hamburg-Eppendorf, Hamburg, Germany; 5Département de Chirurgie Viscérale, Hôpital Pontchaillou, Rennes, France; 6Gastroentérologie et Hépatologie, Hôpital Cantonal, Geneva, Switzerland; 7Unidad de Trasplante Hepático, Hospital Clínico Universitario Santiago de Compostela, Santiago de Compostela, Spain; 8Liver Transplantation, Azienda Ospedaliero-Universitaria Pisana, Pisa, Italy

Liver transplant recipients frequently experience renal impairment due to calcineurin inhibitor (CNI)-related nephrotoxicity, adversely affecting quality of life and life expectancy. An investigational study was undertaken in which treatment with the proliferation signal inhibitor everolimus was initiated in liver transplant patients with impaired renal function, with concomitant reduction or discontinuation of CNI therapy. The objective was to determine the effect of this immunosuppressive protocol on renal function. Methods. This was a prospective, randomized, six-month, multicenter, open-label trial. A total of 144 adult liver transplant recipients with CNI-related renal impairment were randomized to one of two groups. Patients in Group A remained on the baseline dose of CNI and their baseline
adjunctive therapy (mycophenolic acid [MPA] or azathioprine, with or without corticosteroids). In Group B, MPA or azathioprine was discontinued on day 1 and everolimus initiated at 3mg/day. The everolimus dose was then adjusted to target post-defined trough (CO) ranges. The CNI dose was reduced by 50% on day 1, and by a further 50% if everolimus C0 was at least 3ng/mL and calculated glomerular filtration rate (cGFR) was <10mL/min above baseline. If cGFR did not reach 10mL/min or less above baseline, CNI was withdrawn. To be eligible for inclusion, patients had to (a) have received a primary liver transplant 12-60 months previously (b) have CNI minimum 20mL/min and maximum 60mL/min at baseline and (b) be receiving tacrolimus (Prograf®) or cyclosporine (CsA, Neoral®) immunosuppression. Key exclusion criteria were an identifiable reason for renal dysfunction other than CNI toxicity; proteinuria 1.0g/24h or greater; or acute rejection <6 months previously. The primary endpoint was the change in cGFR (Cockcroft-Gault formula) from baseline to month 6 after introduction of everolimus. Power calculations determined that the study has 80% power to detect a difference of 8mL/min in the change in cGFR from baseline to month 6. Results: Complete six-month data on the total study population (n=144) will be presented. Results will include the primary endpoint (change in cGFR), efficacy variables including biopsy-proven acute rejection, graft loss and death, and safety variables. Conclusion: Findings from this randomized trial will determine the effect of conversion to concentration-controlled everolimus with a minimized/eliminated CNI regimen on renal function and efficacy in liver transplant patients with renal impairment. Results at six months may suggest a novel therapeutic approach for patients experiencing renal insufficiency following liver transplantation.

560 LIVER TRANSPLANTATION FOR BUDD-CHIARI SYNDROME: A 20-YEAR NATIONAL REGISTRY ANALYSIS

Dorry L. Segev1, Geoffrey C. Nguyen2, Jayme E. Locke1, Christopher E. Simpkins1, Robert A. Montgomery1, Warren R. Maley1, Paul J. Thuluvath2; 1Transplant Surgery, Johns Hopkins Medical Institutions, Baltimore, MD; 2Hepatology, Johns Hopkins Medical Institutions, Baltimore, MD

Several treatment options exist for the management of Budd-Chiari syndrome (BCS), yet the relative role and timing of liver transplantation remain poorly defined. Small case series published to date have not been able to delineate the impact of comorbidities and thrombo-embolic complications of BCS on graft and patient survival after liver transplantation. To better understand the outcomes after liver transplantation for BCS, we analyzed 510 liver transplants performed for this disease in the United States between 1987 and 2006. Risk factors predicting graft loss or patient death included increased recipient age, hyperbilirubinemia, elevated creatinine, life support or hospitalization at the time of transplantation, prior transplantation, prior abdominal surgery, increased donor age, and prolonged cold ischemic time. Prior transjugular intrahepatic portosystemic shunt (TIPS) was not associated with worse outcomes. Transplantation in the MELD era was associated with significantly lower risk of graft loss (HR 0.50, 95% CI 0.30-0.86, p=0.012) and death (HR 0.52, 95% CI 0.29-0.93, p=0.027). Similarly, MELD era was associated with significantly lower risk of early graft loss (OR 0.35, 95% CI 0.16-0.79, p=0.012) and early death (OR 0.37, 95% CI 0.14-0.95, p=0.040). However, patients with BCS transplanted in the MELD era were less likely to have life support, hospitalization, prior transplants, and prolonged cold ischemia times. Conclusion: Outcomes of liver transplantation for BCS are excellent, with further improvements since 2002 associated with a selection shift imposed by MELD-based organ allocation.
graft rejection in five (10.9%) patients. Four (8.7%) patients developed malignancy involving the skin, the larynx, and unknown sites (n=2) at year 2 to 8 of follow-up. Only one case of CMV infection was reported. CONCLUSION: Combined liver-heart and liver-heart-kidney transplantation is a viable option for candidates who need the combined organ transplantation, with outcomes comparable to those of single organ recipients.

562 AMYLOID CARDIOMYOPATHY FOLLOWING LIVER TRANSPLANTATION FOR FAMILIAL AMYLOID POLYNEUROPATHY ATTR MET30 (PORTUGUESE TYPE); RESULTS FROM THE COLLABORATIVE BRITISH-SWEDISH STUDY

Arie J. Stangou1, Mark Monaghan2, John G. O’Grady1, Chris Bachman3, Thodore Kyriakides4, Mohamed Rela1, Bo-Goran Ericzon5, Nigel Heaton1, Ole Suhr2; 1Institute of Liver Studies, King's College Hospital, Amyloid Treatment Programme, London, United Kingdom; 2Amyloid Treatment Programme, Cardiology Dept, King’s College Hospital, London, United Kingdom; 3Amyloid Centre, Department of Medicine, Umeer, Sweden; 4Cyprus institute of Neurology and Genetics, Department of Neurology, Cyprus, Cyprus; 5Department of Surgery and Transplantation, Karolinska Institute, Stockholm, Sweden

Progressive amyloid cardiomyopathy following liver transplantation for familial amyloid polyneuropathy (FAP) is a paradoxic phenomenon due to continuing wild-type transthyretin deposition, observed in the rare, non-Met30 variants. Conflicting reports however have emerged, between US/ Northern European and South American/ Mediterranean series, regarding its potential occurrence in the commonest world-wide portuguese type Met30 mutation. We investigated the long term cardiac outcomes after LT for Met30, in a collaborative British-Swedish study comprising all Met30 patients transplanted in our centres in the past 13 years, amongst whom all major FAP European foci are represented. Eighty-five Met30 patients underwent LT between 1992-2005 at King’s College Hospital in London, UK, and Karolinska Institute in Sweden. 51 patients (60%) were of Scandinavian origin, and 34 (40%) Mediterranean (23 Cypriot, 7 Greek, 4 Portuguese). Median age at LT was 42 years (22-70) and symptoms duration 3 yrs (1-10). Median age at disease onset was 43 years in the Scandinavian and 34.5 in Mediterranean patients (p<0.01). Comprehensive echocardiography and intraventricular septal (IVS) readings were obtained before and annually after LT. IVS thickness changes of ≥2 mm were considered significant. Age of 40 years was used as the cut off between early- vs late-onset ATTRMet30. Forty five patients (52.9%) had early-onset and 40 (47.1%) late-onset Met30. Pre LT mean IVS thickness of 10.25±1.8 in early-onset was significantly different to 11.6±3.2mm in late-onset Met30 cases (p<0.015). At median follow up of 73 months after LT (12-174), 57.6% of patients (n=49) exhibited stable, and 15.3% (n=13) improved echo parameters; 3.5% (n=3) had IVS thickening with normal echoes, but 23.5% (n=20) showed IVS thickening and progression to amyloidotic echocardiograms; 2 cases developed heart failure. Autopsy confirmed cardiac amyloid with increased wild-type TTR content. Multiple linear regression and binary logistic regression analysis identified age at onset of FAP (<0.04), ethnic origin (p<0.01), and length of post-LT fol-up (<0.03) as factors with significant impact on amyloid cardiomyopathy post LT. There was no significant correlation with pre LT IVS thickness or disease duration, and no correlation with the post LT course of FAP features or rate of extracardiac amyloid turnover on amyloid scintigraphy. Late-onset presentation and North European origin were independent risk factors. Progressive amyloid cardiomyopathy can occur after LT in patients with the common ATTRMet30 variant. Late-onset disease and non-Mediterranean origin are independent risk factors.

563 A NATIONWIDE SURVEY OF ATTITUDES TOWARD LIVER TRANSPLANTATION IN ALCOHOLIC LIVER DISEASE

Rohit Satoskar, Andrew Aronsohn, Helen S. Te, Smruti R. Mohanty, Kapuluru G. Reddy, Nancy Reau, Donald M. Jensen, Medicine, Center for Liver Diseases, University of Chicago Hospitals, Chicago, IL

AIMS: To better understand the relative importance of various psychosocial factors involved in decision making surrounding liver transplantation (LT) for alcoholic liver disease (ALD). METHODS: A 36 item survey was sent to 89 transplant centers in the U.S. Recipients were asked to provide demographics and respond to questions aimed at determining the perceived importance of various psychosocial factors surrounding LT in ALD. Chi square analysis was used for comparison of categorical variables. RESULTS: 117 responses were received. 60% of responses were from physicians, and the remainder from nurses, transplant coordinators, social workers and PAs. The mean degree of favorability of each individual psychosocial parameter when initially considering an alcoholic for LT was determined. “In counseling regularly” and “good family support” were most favorable, while “lives alone” and “failure of 2 prior rehab attempts” were most unfavorable. Perceived compliance had a significant effect on transplant status (Table 1). When assigning relative importance to 8 different factors, ranking from highest to lowest was: 1) excellent family support,2) abstinent for >6 months,3) in counseling with good attendance,4) good insight into alcohol abuse,5) good compliance with office visits, 6) random alcohol screen negative x3,7) working full-time,8) has health insurance. 57% of respondents would consider LT in a patient with severe alcoholic hepatitis (AH) if medical therapy was unlikely to prevent death. In this scenario, the most common reason for denying LT was likelihood of recidivism. Non-physicians were more likely to consider LT in AH compared to physicians (73% vs. 46%, p<0.01). Transplant volume and provider experience had no effect on responses. CONCLUSIONS: There is considerable variability in opinions regarding the effect of psychosocial factors on select-
ing LT candidates in the setting of ALD, but good family support and 6 months abstinence were consistently important. About half of the respondents would consider LT for a patient with alcoholic hepatitis if death was imminent. A strong divergence in opinion among transplant team members highlights a need for a methodical, non-biased, evidence-based approach to evaluating psychosocial factors in considering LT eligibility of patients with ALD.

564 IMPLEMENTATION OF A LIVER ALLOCATION SYSTEM BASED ON MELD SCORE IN THREE TRANSPLANT CENTERS OF THE SAME CITY. CAN THE SCORE DIFFERENCES BE SOLVED?

Xavier Xiol¹, Pere Gines², Lluís Castells³, Alba Ribaldà³, Jorge Twose⁴, Clara Ventura⁴, Joan Carles Reverter², Xavier Fuentes³, Roser Deulofeu⁴; ¹Hospital de Bellvitge. Idibell, L'Hospitalet, Spain; ²Hospital Clinic, IDIBAPS, Barcelona, Spain; ³Hospital Vall d’Hebró, Barcelona, Spain; ⁴OCATT, Barcelona, Spain

MELD score is considered an objective and reproducible measure of liver disease severity. However, MELD score can be influenced by specific laboratory methodologies. In order to implement an organ allocation system based on MELD score in the three Hospitals of Barcelona with liver transplant program, all patients in the waiting list at the three centers were studied simultaneously: blood samples were obtained from each patient and divided in three aliquots, which were processed in the three laboratories. Two laboratories (A, C) expressed creatinine and bilirubin in mg/dl and one (B) in µmol/l. Therefore, a conversion factor was used in laboratory B [creatinine x 0.0113 and bilirubin x 0.0588]. MELD was calculated according to the reported mathematical formula. Results: 74 patients, 51 from hospital A, 15 from B and 8 from C, were studied; 4 cases had a missing value and were excluded. Overall, there were significant differences in the three laboratory parameters, the greatest difference being in INR. Mean values and 95% CI for each variable are shown in the table. MELD score was identical in 564 patients with ALD.

565 DECEPTION DURING PSYCHOLOGICAL EVALUATION FOR LIVER TRANSPLANT IN ALCOHOLIC CIRRHOSIS: A DUI CORROBORATION STUDY

Jasmohan S. Bajaj¹, Muhammad Hafeezullah¹, Andrea Thompson², Kia Saeian¹, Jose Franco¹, Rebecca C. Anderson²; ¹Gastroenterology and Hepatology, Medical College of Wisconsin, Milwaukee, WI; ²Psychology, Transplant Surgery, Medical College of Wisconsin, Milwaukee, WI

Allocation of livers to alcoholic patients is a controversial issue. Proper selection of alcoholic liver recipients is essential to avoid potential recidivism & ethical/societal conflict regarding liver donation. Psychological evaluation (PE), which includes interview/alcohol history, is one aspect of the process used to define transplant suitability. Deception is evidence of active disease in alcoholism. Driving under the influence (DUI) of alcohol is objective evidence of alcohol abuse. However, verifying DUI status during PE through official records is not the standard approach. The aim was to determine whether there is deception on the part of patients regarding their alcohol abuse as corroborated by official department of transportation (DOT) DUI rate during PE. Method: 69 charts of alcoholic cirrhotics who underwent PE were reviewed for demographic data, detailed alcohol abuse/abstinence history & DUIs admitted on PE. The Wisconsin DOT was queried for DUIs before PE. Discrepancies between PE DUI and DOT DUIs were compared. The case was then presented to the psychologist who had conducted the original PE without identifiers. Psychosocial recommendation for transplant was then re-evaluated in light of discrepancies between PE & DOT DUI numbers. Results: 6 non-drivers were excluded; the remaining had a mean age of 53±1 yrs, 17F, 15 also had HCV & had 29±2 yrs of alcohol abuse. They had been alcohol abstinent 2.8±0.8 yrs before PE and 30% had received formal abstinence therapy. DUIs that were not originally admitted were found in 16 cases; 63% were in the period patients claimed to be sober. Two of 16 had been rejected for transplant due to other causes. Representing the case to the psychologist with the new knowledge of DUIs would have changed the recommendation for transplant for the remaining 14 (22%) cases because of the deception it uncovered as a sign of active alcoholism, which is significantly different from the pre-DOT record recommendation (Table). Importantly, there were no other significant differences in other variables during PE between groups. Conclusions: Evaluation of official driving records to exclude DUI in alcoholic cirrhotic patients may increase identification of active alcoholism during PE. Prospective follow-up of these patients post-transplant will be helpful in identifying recidivism.
OUTCOMES OF TRANSPLANTATION WITH PREVIOUSLY REFUSED DONOR LIVERS IN REGION 8
Sheila L. Eswaran, Elizabeth R. Lyden, Timothy M. McCashland; Gastroenterology and Hepatology, University of Nebraska Medical Center, Omaha, NE

Intro: There is a 10-20% mortality for patients awaiting liver transplantation (LT). There are various refusal reasons (RR) for donor livers (DLs). After refusal, DLs may be offered to another patient or center. Aim: Evaluate the frequency of RR and outcomes of LT with previously refused DLs. Methods: We requested data from UNOS-OPTN between July 2004-June 2006 in Region 8 regarding donors and recipients who received living and deceased livers on the first offer (Group A) and who received previously refused livers (Group B). We determined graft survival (GS) and patient survival (PS). Split livers were excluded. Results: Eleven centers were offered 764 DLs (Group A=315; 41% and Group B=437; 59%). The mean number of DL refusals was 12.64 (range 1-221). The most common RRs were donor age/quality (37%), donor size/weight (35%) and transplant center personnel limitations (10%), including heavy work load, operational, or surgeon unavailable. Group B had more male recipients (59% vs 72%; p=0.0003), older donor age (35 vs 38 yrs; p=0.013), longer cold ischemic times (CIT) (6.23 vs 7.42 hrs; p=0.0001), shorter warm ischemic times (WIT) (47.18 vs 42.8 hrs; p=0.003) and shorter length of hospitalization post LT (19 vs 14 days; p=0.003). There was no difference in 1 month (92% vs 94%) or 1 year (83% vs 85%) GS (p=0.20, 95% CI). There was no difference in 1 month (92% vs 94%) and 1 year (83% vs 85%) GS (p=0.20, 95% CI). (Figure) Group B had a longer PS (86% vs 91%) at one year (p=0.0069, 95% CI); however, when adjusted for gender, donor age, CIT, WIT and length of hospitalization post LT, a previously refused status was no longer associated with a longer PS. Conclusion: There were differences between recipients who received first offer DLs and recipients who received refused DLs with respect to recipient gender, donor age, CIT, WIT and length of hospitalization post LT; however, there was no difference in PS of the two groups after adjusting for these LT variables. GS is equivalent in LT with previously refused DLs compared with first offer DLs.

567 DOWNSTAGING/BRIDGING OF HCC PATIENTS TO TRANSPLANTATION USING Y90 RADIOTHERAPY: PATHOLOGIC RESULTS FROM 21 EXPLANTS
Laura M. Kulik, Bassel Atassi, Robert Lewandowski, Mary Mulcahy, Michael Abecassis, Riad Salem; Northwestern University, Chicago, IL

Purpose: To present pathologic explant and survival outcomes in 21 patients with unresectable HCC that were bridged or downstaged to transplantation using Y90 radiotherapy. Material and Methods: 251 patients with unresectable HCC were treated over a 7 years period with Y90 intra-arterial radiotherapy (TheraSphere). Of these, 21 patients were transplanted. Pathologic analysis was performed in all explants. Findings were stratified by complete or partial necrosis of the target lesion. Survival analysis was performed from first treatment (intention-to-treat) and from transplantation. Results: There were 18 males and 3 females. Mean age was 60. Etiology of disease was: Hep C (n=6), Hep B (n=4), PBC (n=1), Hep C + alcohol (n=4), alcohol (n=3) and cryptogenic (n=3). There were 10, 10 and 1 patients with Child A, B and C disease respectively. There were 9 patients with Okuda 1 and 12 with Okuda 2 disease. Tumor distribution was: 16 unilobar and 5 bilobar. Target tumor dose was 120 Gy. Toxicities included fatigue (42%), anorexia (7%), pain (5%) and nausea (5%). Mean AFP at time of treatment for the 21 patients was 1647.4 ng/ml. Mean AFP prior to transplantation was 1105.2 ng/ml (n=17). Median time from first treatment to transplant was 114 days (mean 142 days, range 10-311). Complete necrosis by pathologic analysis was noted in 14 of 21 patients (66%). Pathologic findings included coagulative necrosis and peripheral ring fibrosis containing benign tissue. Recurrence has been documented in 4 patients; 2 with complete necrosis and 2 with partial necrosis. Mean time to recurrence was 250 days (median: 167 days). 19 of 21 patients are still alive with a median follow-up of 142 days (range 10-311). Complete necrosis by pathologic analysis was noted in 14 of 21 patients (66%). Pathologic findings included coagulative necrosis and peripheral ring fibrosis containing benign tissue. Recurrence has been documented in 4 patients; 2 with complete necrosis and 2 with partial necrosis. Mean time to recurrence was 250 days (median: 167 days). 19 of 21 patients are still alive with a median follow-up of time of treatment of 428 days (range: 131-1461) and 219 days (range: 63-1390) from time of transplantation. The 2 deaths were attributed to disease recurrence. Conclusion: Treatment with Y90 achieves complete pathologic necrosis in the majority of targeted lesions in patients bridged or downstaged to transplantation. Longer follow-up will be required to assess treatment benefit with regards to recurrence-free and overall survival.

The following people have nothing to disclose: Sheila Eswaran, Elizabeth R. Lyden, Timothy M. McCashland
Background: While malnutrition reduces survival after OLT, it remains unclear whether obesity, which is increasingly present in American recipients, has similar deleterious effects. Aim: To compare the impact of obesity on patient and graft survival after OLT in a large, multi-institutional cohort of adult American patients. Methods: The United Network for Organ Sharing (UNOS) database identified 47,796 adult patients who underwent 53,719 OLT’s between 1987 and 2005. BMI groups (A: <20, B: 20–24, C: 25-34, D: 35-39, E: 40+) were compared using log-rank and chi-squared statistics. Patient and graft survivals were assessed using Kaplan-Meier survival curves. Demographic and medical variables were studied using univariate and multivariate analyses. Results: At a median follow-up interval of 1,018 d (range: 0-6,261 d), 5-yr patient survivals were: Group A=69%, B=73%, C=74%, D=73% and E=69% (p=0.001 for A and E). Five-yr graft survivals were: Group A=58%, B=63%, C=64%, D=64% and E=60% (p=0.001 for A and E). The 30-d post-transplant mortality rate was 10% for E, compared to only 6% for A, B, C, and D (p<0.001). Patients with BMI >or=35 (D+E), had a higher proportion of cardiovascular deaths (15% vs. 11% for A, B, and C; p<0.001) and higher incidence of myocardial infarction (5% vs. 3% for A, B, and C; p=0.04). In contrast, group A had a higher proportion of deaths due to infection (23% vs. 21% for B, C, D, and E, p=0.02) or complications of rejection (3% vs. 2% for B, C, D, and E, p=0.009). Patients with BMI >or=35 (D+E) had a higher proportion of infection-related graft failure (20% vs. 17% for A, B, and C, p=0.04). Group A had the highest proportion of graft failure due to chronic rejection (14% vs. 9% for B, C, D, and E, p=0.005) Univariate analysis showed race, era of transplantation, preoperative ICU care, and the need for mechanical ventilation to be significant prognostic variables (p=0.001 to 0.03). Multivariate analysis identified era (p=0.006) and the need for mechanical ventilation (p=0.030) as independent prognostic variables. Interestingly, the presence of obesity did not significantly affect 5-yr patient and graft survivals in HCV+ patients. Conclusions: Malnutrition (BMI <20) and morbid obesity (BMI >40) are associated with significant decreases in patient and allograft survivals after OLT. BMI >40 was associated with significantly higher 30 d mortality than any other group. BMI >or=35 was associated with significantly higher cardiovascular mortality and infection-related allograft failure. The adverse impact of obesity on post-OLT survival indicates that OLT should be delayed, whenever possible, until a BMI<35 is achieved.

C4D IN DE NOVO IMMUNE HEPATITIS AFTER LIVER TRANSPLANTATION

Body: In contrast to other solid organs, the liver allograft appears to be relatively resistant to antibody-mediated rejection. C4d staining plus documentation of circulating donor specific antibodies in the presence of graft dysfunction is accepted by most clinicians as evidence of active humoral rejection in renal and heart transplantation. In liver, there are a few reports in which the use of C4d immunostaining is analyzed as a possible marker of humoral rejection in ABO-incompatible liver transplantation (1) or to differentiate acute rejection from recurrent hepatitis C (2). Objective: To study immunohistochemical C4d staining in patients diagnosed of de novo immune hepatitis (IH). Results: We retrospectively analyzed a total of 7 biopsies obtained from patients with the null GSTT1 genotype that have received a graft from a positive donor. We have described that in about 80% of the cases the recipients with this mismatch produce anti-GSTT1 antibodies and in most of the cases develop de novo immune hepatitis. Biopsies were always performed for clinical indications and specimens ranged from 12 to 85 months post-transplant. We have followed a scoring system of capillaries, arteries and veins is evaluated in a scale of 0, none; 1+, weak; 2+, moderate and 3+, strong (Table 1). Six patients present C4d deposits in portal areas with different degrees of extension. Only one of them is C4d negative in a biopsy performed after treatment coinciding with disappear-

Heating after Liver Transplantation

Body: Abstract

C4d staining in patients diagnosed of de novo immune hepatitis (IH). Results: We retrospectively analyzed a total of 7 biopsies obtained from patients with the null GSTT1 genotype that have received a graft from a positive donor. We have described that in about 80% of the cases the recipients with this mismatch produce anti-GSTT1 antibodies and in most of the cases develop de novo immune hepatitis. Biopsies were always performed for clinical indications and specimens ranged from 12 to 85 months post-transplant. We have followed a scoring method described by Troxell ML (3) in which C4d positive staining is achieved.

C4d staining plus documentation of circulating donor specific antibodies in the presence of graft dysfunction is accepted by most clinicians as evidence of active humoral rejection in renal and heart transplantation. 570 NO U.S. ORTHOTOPIC LIVER TRANSPLANT (OLT) OUTCOMES FOR ACUTE LIVER FAILURE (ALF) IMPROVED IN THE LAST DECADE?

Christine A. O’Mahony, Sanjeet Patel, Jessica Suarez, John M. Vierling, Neal R. Barashes, Natasha S. Becker, Norma Flores, Wanda Samuels, Rise Stribling, Norman L. Sussman, John A. Goss; Baylor College of Medicine, Houston, TX

BACKGROUND: OLT for ALF has been associated with decreased patient and allograft survival rates. The risk factors causing these decreased survival rates remain largely undefined. AIM: To determine if patient and allograft survival rates have improved in the current era of transplantation and to identify risk factors leading to mortality and allograft failure in patients undergoing OLT for ALF. METHODS: Data from all patients who underwent OLT for ALF between 1990-1993 (Era-1) and 2000-2003 (Era-2) were obtained from the United Network for Organ Sharing. Multigorgan transplant recipients and patients <18 years old were excluded. Group comparisons were performed using Chi squared and student’s T-test. Unadjusted survival rates were estimated with the Kaplan-Meier product limit estimate. A multivariate Cox proportional hazards model was then used to compare patient mortality or graft failure rates after adjusting for important donor, graft, and recipient characteristics. RESULTS: A total of 1037 patients who underwent OLT for ALF were identified from the UNOS database. The average age (29 years), gender (61% female), SGPT (1335 U/L), creatinine (1.8 mg/dl), bilirubin (21 mg/dl), albumin (2.85 g/dl) and time on the waitlist (3.3 days) were similar for both groups. However, the patients transplanted in Era-2 experienced a significantly shorter cold ischemia time (10.8 hrs vs. 7.8 hrs, p<0.05) as well as a shorter warm ischemia time (65 minutes vs. 43 minutes, p=0.05). One year patient as well as allograft survival rates were significantly higher in the patients who underwent OLT in Era-2 with a one year patient survival of 73% in Era 1 compared to 82% in Era-2 (p<0.05) and a graft survival of 63% in Era-1 and 75% in Era-2 (p=0.05). In patients that underwent OLT in Era-1, factors that independently influenced survival were a cold ischemia time greater than 12 hours (HR 2.26, p<0.05), and mechanical ventilation at the time of transplant (HR 1.63, p<0.05). In patients that underwent OLT in Era-2, recipient age > 60 yrs (HR 2.13, p<0.05), donor age > 60 yrs (HR 1.94, p<0.05), and mechanical ventilation at the time of transplant (HR 1.84, p=0.05) were independent risk factors for mortality. CONCLUSION: Over the last decade there has been little change in demographics in the patient population undergoing OLT for ALF. However, patient mortality and allograft failure rates have decreased significantly.

Disclosures: The following people have nothing to disclose: Christine A. O’Mahony, Sanjeet Patel, Jessica Suarez, John M. Vierling, Neal R. Barashes, Natasha S. Becker, Norma Flores, Wanda Samuels, Rise Stribling, Norman L. Sussman, John A. Goss

571 PRETRANSPLANT RISK FACTORS FOR ADVANCED CHRONIC KIDNEY DISEASE IN LIVER TRANSPLANTATION

Santiago Tome1,2, Julio Pascual2, Milagros Samaniego2, Adnan Said2, Luis Fernandez2, Tony D’Alessandro2, Aji Djamali2, Michael R. Lucey2, John Pirsch2, Hans Sollinger2, Stuart J. Knechtle2; 1Hospital Universitario de Santiago, Santiago de Compostela, Spain; 2Division of Transplantation, Departments of Surgery and Medicine, University of Wisconsin, Madison, WI

Body: Severe renal failure is increasingly frequent after liver transplantation (LT). The US Registry showed a 18% cumulative incidence of severe chronic kidney disease (sCKD) [estimated glomerular filtration rate eGFR<30mL/min] 5 years after LT. To select the population in whom a special effort is needed for nephroprotection, we have evaluated the impact of patient characteristics on the development of sCKD as the primary endpoint. All adult primary LT performed at our institution between 1994 and 2005 were analyzed. Patients with pre-LT dialysis need, pre-LT Scr>2.5 mg/dL, recipients of retransplants or combined organs, and patients surviving <30 days after LT were excluded. Univariate analysis and Cox proportional hazards model were used for determining pre-LT factors related with the end-point. Finally, 651 patients fulfilled these criteria. Kaplan-Meier estimates of freedom of sCKD were 92% at 3 months, 84% at 1 year, 81.2% at 3 yr, 77% at 5 yr and only 69% at 10 yr. Risk factors for sCKD in the univariate analysis were: age at LT (HR 1.05/yr, p=0.0001), body mass index (protective: HR 0.92/unit, p<0.0001), calcium status (protective: HR 0.55, p=0.03), male sex (protective: HR 0.30, p<0.0001), pre-LT Scr (HR 1.73 each mg/dl, p=0.0065), pre-LT eGFR (protective: HR 0.98 each ml/min, p<0.0001), pre-LT ALT (protective: HR 0.99/unit, p=0.04). Donor factors, other analytical parameters (pre-LT albumin, INR, bilirubin, MELD), liver disease type, HCV+ status, need of TIPS, clinical situation (ascites, encephalopathy) and perioperative factors (v v bypass need and time, blood products) were all non-significant factors for sCKD during the follow-up. The Cox multivariate analysis confirmed that age at LT (HR 1.032/yr, p=0.002), body mass index (protective: HR 0.94/unit, p=0.0006), calcium status (protective: HR 0.50, p=0.02), male sex (protective: HR 0.31, p=0.0001), and pre-LT eGFR (protective: HR 0.98 each ml/min) were the only significant risk factors. Pre-LT Scr lost significance when eGFR was included. The 10-year incidence estimate for developing severe-CKD almost doubles the previously reported rate at 5 years. Preventive measures based on the described risk factors are urgently needed. Nephroprotection would be particularly relevant in older, non-caucasian, females with pre-LT renal mild dysfunction.

Disclosures: The following people have nothing to disclose: Santiago Tome, Julio Pascual, Milagros Samaniego, Adnan Said, Luis Fernandez, Tony D’Alessandro, Aji Djamali, Michael R. Lucey, John Pirsch, Hans Sollinger, Stuart J. Knechtle

572 THE EFFECT OF HEPATIC ENCEPHALOPATHY ON POST LIVER TRANSPLANTATION (LT) MORBIDITY AND MORTALITY: D. BRANDMAN, S.W. BIGGINS, J.P. ROBERTS, N.A. TERRAULT

Danielle Brandman1, Scott W. Biggins1, John P. Roberts2, Norah Terraault1; 1Medicine, University of California, San Francisco, San Francisco, CA; 2Surgery, University of California, San Francisco, San Francisco, CA

BACKGROUND: Hepatic encephalopathy (HE) does not enhance the prediction of wait-list mortality of MELD. However, the effect of HE of post-LT morbidity and mortality is largely
unknown. AIM: To determine the effect of severe HE on post-LT outcomes and to evaluate the relationship serum sodium and severe HE. METHODS: In this retrospective cohort of adult patients undergoing first LT for end-stage liver disease from 02/2002-12/2005, severity of HE was determined by the transplant surgeon immediately prior to LT (grade 0-2 non-severe HE, grade 3-4 severe HE), with re-review of those with grade 2 HE to include additional severe HE cases. The primary outcomes were survival at 90 days and 1-year post-LT, and length of stay (LOS). RESULTS: Of the 450 LT recipients during the study period, 368 met eligibility criteria (MELD 28 ±8.5; age 55 ± 8.9; 36% HCC), and 44 (12%) had severe HE. Gender, race, and underlying liver disease were similar between groups. MELD score at LT was higher in the severe HE group (36 ±5.8 vs 27 ±8.2 non-severe HE, p<0.0001), and severe HE subjects were less likely to have HCC at LT (11.4% vs. 38.9%, p<0.0001). Compared to the non-severe HE group, patients with severe HE more frequently had serum sodium (Na+) changes of ≥15 points in the peri-LT period (1 wk prior to LT to 1 wk post-LT), 25% vs 6% (p<0.001), as well as lower pre-LT nadir Na+ (133 ±0.95 vs 135 ±0.31, p=0.04). No difference was detected between the groups in the proportion with pre-LT <126 (18% vs. 14%, 95% CI 0.59:3.18, p=0.46). While 90-day mortality was not significantly different between groups, there was a trend toward higher 1-year mortality in the severe HE group (86.4%, CI 72.1-93.6 vs. 93.2%, CI 89.9-95.5 in non-severe HE group, p=0.11). In Cox models, severe HE was associated with 1-yr mortality (HR 2.06, 95% CI 0.84:5.09, p=0.12) compared to non-severe HE, but as expected, the association was weakened when MELD was included (HR 1.42, 95% CI 0.53:3.83 in bivariate model). LOS (days) was significantly longer for severe HE than non-severe HE patients (28 ±34 vs. 12 ±22, p=0.0001), and the association between severe HE and LOS was independent of MELD, recipient age, presence of HCC, pre-LT Na+ <126, peri-LT change in Na+, or rejection episodes. CONCLUSIONS: Severe HE was associated with a higher 1-year mortality, but this effect was, in large part, accounted for by MELD. Patients with severe HE have significantly longer LOS, a marker of increased morbidity, and this association was independent of MELD. Whether the large changes in peri-LT serum Na+, more frequently seen in the severe HE group, contribute to post-LT morbidity requires further study.

574 USE OF MULTIVISCERAL TRANSPLANTATION IN THE MANAGEMENT OF CIRRHTIC PATIENTS WITH DIFFUSE PORTOMESENTERIC THROMBOSIS
Richard S. Mangus, A Joseph Tector, Jonathan A. Fridell, Marwan Kazimi, Rodrigo Vianna; Transplant Division, Dept of Surgery, Indiana University, School of Medicine, Indianapolis, IN

Introduction. The presence of portal vein thrombus in a cirrhotic patient is a poor prognostic indicator and can be exclusionary criteria for orthotopic liver transplantation (OLT). The majority of these patients can be successfully managed intraoperatively at the time of transplant with either low dissection and thrombectomy or portal vein bypass. The absence of a large tributary can preclude the anastomosis of the donor portal vein. In this situation, alternative vascular reconstructions have been proposed, including cavo-portal hemitransposition, renalportal vein graft interposition and utilization of the hepatic artery for portal flow. Although these techniques are able to restore blood flow to the donor portal vein, portal hypertension and its complications continue to exist after OLT. We describe our experience with 15 patients with diffuse portomesenteric thrombosis who were listed for OLT with multivisceral transplant (MVT) back-up. Patients in whom portal flow could not be established intraoperatively underwent MVT to completely replace the portomesenteric system. Methods. All cirrhotic patients at our center referred for OLT evaluation undergo abdominal imaging with dual-phase computed tomography (CT) scanning. Those with portal or mesenteric thrombus undergo additional imaging with magnetic resonance (MR) scanning. We identified 15 patients with diffuse mesenteric thrombosis who were listed for OLT with MVT back-up. At the time of transplantation, organs were procured on-block as a donor graft. In patients in whom portal flow could not be established, MVT was performed, which included transplantation of the liver, pancreaticoduodenal complex, small intestine and stomach. Results. Fifteen survival is 97.3% (109/112) and 94% (109/116) respectively, at a mean follow-up time of 34.4 m +/-.16.3 (range 6.1-67.9 m). 3 children died from recurrent hepatic malignancy (n=2), and cardiac arrest (n=1). Re-transplantation was performed successfully in 3 patients; one patient required two re-transplants for thrombotic complications. Steroid responsive rejection was seen in 45 (40.1%) patients within the first 90 days post-transplant. IS maintenance at current follow-up is: TAC (TID n=1, BID n=48; QD n=39, QOD or less n=12), SRL (QD n=4, BID n=2, single dose or less n=2). 85 children (78%) are free of maintenance steroids and the others are being weaned off steroids instituted during treatment of ACR. Viral drug associated complications (hypertension, renal insufficiency) and infection is favorable as compared to historical controls.

573 LONG-TERM OUTCOME WITH RATG INDUCTION AND STEROID-FREE IMMUNOSUPPRESSION IN PEDIATRIC LIVER TRANSPLANTATION(PLTX)
George V. Mazariegos, Zurab Machaidze, Kyle Sohys, Geoffrey Bond, Robert Squires, Rakesh Sindhi; Transplant Surgery, Children’s Hospital of Pittsburgh, Pittsburgh, PA

Background: Steroid-free immunosuppression (IS) has significant potential benefits in pediatric liver transplantation. Methods: Outcomes with a steroid-free IS protocol with a rATG pre-conditioning regimen and tacrolimus (TAC) monotherapy were reviewed. Results: Between 8/2001-9/2006, 112 consecutive patients with a median age of 5.4 y (range 1.4 m-21.7 y) received 116 liver allografts (90 whole organs, 6 cadaveric split, 20 living donor, and 5 simultaneous cadaveric kidney allografts). Pre-treatment and induction therapy was with 4.5 mg/kg rATG. Oral tacrolimus (TAC) was started within 24 hours post-transplant to achieve a target trough of 10-15 ng/ml. 8 patients were switched to sirolimus (SRL) to minimize potential long-term calcineurin toxicity. Overall patient and graft
patients were listed for OLT with MVT back-up. Thirteen patients had no identifiable portal flow upon exploration and underwent MVT. Two patients had adequate portal vein flow and underwent standard OLT. There was one perioperative death, in an MVT patient related to heart failure. All patients had good initial graft function. Ninety-day survival was 92% (12/13) for patients receiving MVT and 100% (2/2) for patients undergoing OLT. Conclusions: For cirrhotic patients with inadequate portal vein inflow, multivisceral transplantation offers a life-saving alternative. This management option has been successfully utilized at our center in 15 patients.

575
LONG-TERM OUTCOMES FOR PATIENTS TRANSPLANTED FOR ACETAMINOPHEN INDUCED ACUTE LIVER FAILURE; NO WORSE THAN FOR OTHER ETILOGIES
Constantine J. Karvellas, Julia Wendon, Niloufar Safinia, Georg Auzinger, Elizabeth Sizer, Andrew J. Portal, Nigel Heaton, Mohammed Rela, Paolo Muijesan, Michael A. Heneghan, John G. O’Grady, William Bernal; Institute of Liver Studies, King’s College Hospital, London, United Kingdom

Introduction: Acetaminophen hepatotoxicity is the most common cause of acute liver failure (ALF) in the UK. Concern has been raised about compliance and long-term outcomes of liver transplantation (LT) in this patient group, given the frequent history of suicide, substance abuse and difficulty in psychological assessment of encephalopathic patients requiring emergency LT. We compared medical, psychosocial and long-term outcome of patients who had undergone emergency LT for acetaminophen induced ALF (AALF) with age and sex matched patients undergoing emergency LT for non-acetaminophen etiologies of ALF (NAALF) and elective LT for chronic liver disease (CLD). Design: A review was undertaken of all patients transplanted for AALF (n=36) between 1999-2004 at King’s College Hospital; comparing to those transplanted for NAALF (n=35) and CLD (n=34) during the same period. Patients transplanted for AALF and NAALF met King’s College Criteria for super-urgent listing. The CLD cohort had been listed as part of standard multidisciplinary process. Statistical analysis utilized non-parametric testing and survival analysis used log-rank testing. Results: AALF patients had a higher median INR (P < 0.004) and APACHE II score on the day of listing (P < 0.02) compared to the NAALF and CLD groups. More AALF patients required hemofiltration pre-LT (AALF 94%, NAALF 43%, CLD 3%, P < 0.001). More than 95% of AALF patients were mechanically ventilated prior to LT (vs. 3% CLD, P < 0.001). Median follow-up for all groups was 1068 (585-1467) days with no differences in 1 or 3-year survival (AALF 1yr 84% 3yr 78%, NAALF 88%/82%, CLD 83/73%, P >0.8 log rank). There were no significant differences in frequency of acute cellular rejection, chronic ductopenic rejection or graft failure between groups. Twenty (56%) AALF patients had a formal psychiatric diagnosis prior to LT (NAALF 0%, CLD 6%; P < 0.001). Nine (25%) AALF patients had previously attempted suicide. All AALF patients underwent psychiatric review following recovery. Post-LT, one AALF patient attempted suicide requiring psychiatric admission. Twenty AALF patients required long term psychiatric follow-up post-LT (P < 0.001 vs. both) and 11 psychiatric medications (P < 0.01 vs. both). During follow-up, AALF patients attended 79% of their appointments, fewer than controls (CLD 91%, P = 0.104, NAALF 93%, P = 0.009). Conclusions: Despite a high prevalence of psychiatric disturbance, short and long term outcomes in patients undergoing super-urgent LT for AALF were comparable to those with NAALF and those transplanted electively for CLD. Long term psychiatric follow-up may contribute to low post-LT rates of suicide and graft loss.

The following people have nothing to disclose: Constantine J. Karvellas, Julia Wendon, Niloufar Safinia, Georg Auzinger, Elizabeth Sizer, Andrew J. Portal, Nigel Heaton, Mohammed Rela, Paolo Muijesan, Michael A. Heneghan, John G. O’Grady, William Bernal.

576
SEXUAL DYSFUNCTION BEFORE AND AFTER LIVER TRANSPLANTATION (LT)
Laure Grellet1, Pascal Perney1, Hélène Rigole1, Yohan Duny2, Dominique Larrey2, François Blanc1, Georges-Philippe Pageaux3; 1Medecine E, CHU St Eloi, Montpellier, France; 2Biostatistics Department, IURC, Montpellier, France; 3Digestive Department, CHU St Eloi, Montpellier, France

Sexual disorders are frequently described in patients with cirrhosis, often related to the endocrine consequences of advanced liver disease. It is assumed that LT will help to recover from these symptoms. Aim: To report on the prevalence of sexual dysfunction in liver transplant patients before and after LT, emphasizing the potential recovery of pre-LT disorders and the occurrence of de novo post-LT disorders. Methods: During a direct interview, a sexual history was taken by a sexology medicine specialist in all liver transplant recipients seen at the outpatient clinic between May and December 2006. Exclusion criteria were: age < 18 or > 70, LT < 6 months, evolutive cancer, interferon treatment for HCV reinfection, severe renal or cardiac dysfunction. The following domains were assessed: hypoactive sexual desire in men and women, erectile dysfunction in men and inadequate vaginal lubrication in women, premature or delayed or absent ejaculation in men, orgasmic disorder in women, pain with intercourse in men, dyspareunia or vaginismus in women. Results: 93 pts fulfilled the inclusion criteria and 89 accepted to complete the study. There were 64 males, mean age 54 ± 9 yrs and 25 females, mean age 51 ± 10 yrs. Indication for LT were: alcoholic liver disease in 52, virus in 15, alcohol plus virus in 9, others in 13. The mean delay form LT was 55 months (6-225). Evolution of sexual disorders before and after LT: hypoactive sexual desire was present in 29% of male and 40% of female, and improved in 73.6% of male and 0% of female. Erectile dysfunction was present in 39% of male and improved in 68% of them. Inadequate lubrication was present in 24% of female and improved in none. Premature ejaculation was present in 21% of male and improved in 7% of them. Orgasmic disorder was present in 14% of male and 36% of female and improved in 66% of male and 11% of female. Pain was absent in male and present in 1 female before and after LT. De novo sexual disorders after LT: hypoactive sexual desire was present in 6.2% of male and 12% of female. Erectile dysfunction was present in 14% of male. Premature ejaculation was present in 3% of male. Orgasmic disorder was present in 3% of male. Conclusion: Sexual disorders were frequent in liver transplant patients before LT. They frequently improved after LT in male, but almost never in female. This point emphasizes the unclear impact of advanced liver disease in women’s sexual dysfunction. De novo sexual disorders after LT were unusual. Overall, 34.8% of liver transplant recipients experienced sexual disorder. This will need further attention.

577 IMPLICATIONS OF PREOPERATIVE PULMONARY FUNCTION TESTING FOR POST LIVER-TRANSPLANT OUTCOMES

Peter Ghali1, Marc Deschenes1, Jeffrey Barkun2, Philip Wong3, Nir Hilzenrat3, Peter Metrakos2, Jean Tchervenkov3, Marcelo Cantarovich1, Kevin Schwartzman1;

1Medicine, McGill University Health Centre, Montreal, QC, Canada; 2Surgery, McGill University Health Centre, Montreal, QC, Canada; 3Medicine, SMBD Jewish General Hospital, McGill University, Montreal, QC, Canada

Aim: To assess whether prolonged ICU stay, post-operative pulmonary complications (PPCs) and death post-liver transplant are predicted by pre-transplant pulmonary function tests (PFTs). Background: Pulmonary complications are common post-transplant with an estimated incidence of 41 to 98%. Up to 25% of deaths within the first week of any surgical procedure are attributable to pulmonary complications and the highest risk procedures are abdominal. Although PFTs are routinely obtained to assess surgical risk, their usefulness in liver transplantation has not been evaluated. Methods: The study cohort encompasses all liver transplants at our center between 1990 and 2005. Outcomes including death, length of ICU stay, and PPCs such as pneumonia, pneumothorax, and ARDS were verified using both medical records and an existing transplant database. PFTs are routinely measured before transplant at our center and are expressed as percentage of predicted values, based on the European Community for Coal and Steel reference set. Other data collected included age, gender, race, smoking history, etiology of liver disease, BMI, MELD score, cold and warm ischemia time. Individuals with hepatopulmonary syndrome or portopulmonary hypertension were excluded. Multiple linear regression was performed to assess the impact of these independent variables on length of ICU stay, while logistic regression and Cox proportional hazards models assessed their impact on PPCs and mortality. Results: Of 537 transplants, preoperative PFT data were available for 325. 5 year mortality was 34%. Length of ICU stay varied from 0 to 101 days. The cumulative incidence of pneumonia, pneumothorax, and ARDS was 12%, 6%, and 5% respectively; for PPCs overall it was 15%. Total lung capacity (TLC) was a predictor of length of ICU stay (p=0.018; CI: -0.04 to -0.004). A measured TLC 50% below predicted translates to an increase in ICU length of stay of 1 day. There were no significant predictors of PPCs. Independent predictors of mortality included TLC with hazard ratio 0.95 (p-value 0.011; CI 0.91-0.99) and residual volume (RV): hazard ratio 1.02 (p=0.04; CI: 1.0-1.04). For each 1% decrease in TLC the mortality risk at any time is increased by 5%. Smoking history and MELD score were not significant independent predictors. Discussion: These data suggest that post-transplant pulmonary complications are common and that while impaired PFTs do not predict PPCs they do predict length of ICU stay and mortality. PFT abnormalities may reflect severity of underlying liver disease as well as intrinsic lung disease.

578 SIROLIMUS IN LIVER TRANSPLANT RECIPIENTS WITH RENAL DYSFUNCTION OFFERS NO ADVANTAGE OVER LOW DOSE CALCINEURIN INHIBITORS

Derek Dubay, Leslie Lilly, Robert Smith, Gary A. Levy, George Therapondos; MultiOrgan Transplant Program, University Health Network, University of Toronto, Toronto, ON, Canada

Aim: The purpose of this study is to compare the clinical experience with sirolimus in liver transplant recipients with chronic renal insufficiency with a matched control group maintained on reduced dose calcineurin inhibitors. Methods: This is a retrospective study of patients transplanted between 2001 and 2006. 57 liver patients with renal insufficiency and on sirolimus were matched for gender, year of transplant, and baseline creatinine clearance to a control group of 57 liver patients on low dose calcineurin inhibitors. Results: Baseline characteristics were similar between the 2 groups. a) Sirolimus tolerability and rejection: Drug-related side effects were more common in the sirolimus group compared with the control group (36 vs 24 patients, p=0.025). Rejection, retransplantation and death rates were similar. b) Renal function: Renal replacement rate was similar between the 2 groups (sirolimus=21% v control=12%, p=NS). The creatinine clearance of both the sirolimus (37 +/- 1.6 vs. 35 +/- 14 ml/min, p=ns) and the control groups (38 +/- 1.4 vs 37 +/- 1.6 ml/min, p=ns) was unchanged at 12 months after intervention. However, the change in creatinine clearance relative to the time of intervention was significantly worse in the sirolimus group compared with the control group at 6 (p=0.045) and 12 months after intervention (p=0.001). Stratification according to creatinine clearance at baseline, showed no difference between the groups with creatinine clearances of 30-45 ml/min or 45-60 ml/min. However, in the lower creatinine clearance group(< 30 ml/min), the sirolimus group (n=17) demonstrated significantly worse creatinine clearance at the 3 (20 +/- 1.4 vs 25 +/- 1.1 ml/min, p<0.012) and 6 months (19 +/- 2 vs 25 +/- 1.5 ml/min, p<0.035) post intervention. Conclusion: This study demonstrates that conversion from a calcineurin inhibitor protocol to sirolimus in liver transplant patients with chronic renal insufficiency is associated with stabilization of renal function, but confers no advantage over low dose calcineurin inhibitors. In addition, at creatinine clearance levels lower than 30 ml/min, the sirolimus group deteriorated faster than the control group. This finding as well as the excess number of side effects seen in the sirolimus group make the conservative approach of reduced calcineurin inhibition the preferable option.

579 THE IMPACT OF ISCHAEMIC PRECONDITIONING ON GENE EXPRESSION IN HUMAN LIVER TRANSPLANTATION

Wayel Jassem1, Richard J. Thompson1, Susan Fuggle2, Nigel Heaton1, Mohamed Rela1; 1Institute of Liver Studies, London, United Kingdom; 2Nuffield Department of Surgery, Oxford, United Kingdom

Introduction In liver transplantation ischaemia / reperfusion (IR) is associated with an inflammatory process that leads to cell loss and affects allograft outcome. Ischaemic preconditioning (IP) has been demonstrated to be effective in protecting organs from IR. The molecular basis of this protective effect is poorly understood. This study assesses the gene expression profile in liver allografts during transplantation and evaluates the impact
of IP. Methods IP in cadaver donor livers was performed by clamping the porta-hepatis for 10 minutes followed by 30 minutes of reperfusion prior to organ removal. Pre- and post-transplant liver biopsies were obtained from livers subjected to IP (n=19) or no preconditioning (IR) (n=16). Total RNA was extracted and hybridised to GeneChip oligonucleotide microarrays (HG-U133A; Affymetrix) (3 allografts from each group). Real-time RT-PCR was subsequently performed in all pre- and post-transplant biopsies obtained from both groups to revalidate the findings. Results IP livers showed better liver function in terms of serum transaminases, INR and lactate following transplantation. Microarray analysis of IR group showed increased expression of 55 genes involved in cell death, immune response, cell stress, proliferation and metabolism. IP group showed attenuation of expression of these genes. Expression of most significant 10 genes was revalidated in all patients using real time RT-PCR and correlated with clinical outcome. In the IR group, elevated expression of ADAMTS1 was associated with higher levels of day 2 serum lactate (r=0.502; p=0.04), day 7 (r=0.639; p=0.008) and 14 (r=0.515; p=0.04) bilirubin post-transplant. High expression of CCL20 was associated with higher day 7 (r=0.648; p=0.01) and day 14 (r=0.621; p=0.01) serum bilirubin. High expression of DUSP6 was associated with higher day 1 (r=0.601; p=0.01) and day 2 (r=0.601; p=0.01) INR. Increased IL8 was also associated with high levels of serum bilirubin in day 7 (r=0.517; p=0.04) and day 14 (r=0.629; p=0.009). In the IP group increased expression of WEE1 was associated with a lower incidence of acute rejection (r=0.478; p=0.03). Conclusions IP protection to liver allografts is mediated by reduced expression of genes that have an impact on graft function following transplantation.

580
A MULTI-INSTITUTIONAL ANALYSIS OF 235 PATIENTS UNDERGOING OLT FOR HEPATOPULMONARY SYNDROME

Natasha S. Becker, Jessica Suarez, Thomas A. Aloia, Joel A. Rodriguez, Rise Stribling, Norman L. Sussman, John M. Vierling, Christine A. O’Mathony, John A. Goss; Michael E. DeBakey Department of Surgery, Baylor College of Medicine, Houston, TX

Introduction: Orthotopic liver transplantation (OLT) is the only curative treatment for hepatopulmonary syndrome (HPS). Given the irreversibility of lung disease after the disease process becomes advanced, patients with HPS should have expedited evaluation and prioritization for OLT. The UNOS liver allograft allocation policy has been modified to reflect this, with MELD exception points given to candidates with HPS. Aim: To review the United States experience with OLT for hepatopulmonary syndrome and to determine the current effect of wait-list time on outcomes after OLT in this patient population. Methods: The UNOS database was used to identify 235 patients who underwent primary OLT with an exception for hepatopulmonary syndrome. Demographic, clinical, and disease severity variables were collected and analyzed. Survival was calculated using Kaplan-Meier analyses and compared with log-rank tests. Univariate analysis was performed to determine prognostic factors for patient survival after OLT. Wait-list time was analyzed in detail to determine its effect on patient survival after OLT. Results: The 235 study patients with HPS were 59% male and 76% Caucasian. The median age was 50 years (range: 0-70 years). Compared to patients undergoing OLT for other indications (n=16,828), HPS patients waited longer (median wait time: 152 days vs. 83 days; p=0.001), were less likely to be Status 1 (1% vs. 7%; p=0.001), and had a lower PELD/MELD score (13 vs. 17; p=0.001). Additionally, HPS patients had a lower bilirubin (median: 2.3 mg/dL vs. 3.3 mg/dL, respectively; p=0.001) and a lower creatinine (median: 0.8 mg/dL vs. 1.0 mg/dL, respectively; p<0.005) at transplant. One and 3-year patient survival rates were similar: for HPS patients 88% and 85% and for all other patients 87% and 79% (p=0.5425). In univariate analysis, only creatinine greater than 1.6 mg/dL predicted poor survival (p<0.05). Wait-time analyses showed no effect on patient survival after OLT (all p-values >0.05; Table 1).

Conclusions: Patients undergoing OLT with HPS have less severe liver disease when compared to patients undergoing OLT for other indications. They experience similar survivals to the overall population of patients undergoing OLT. Shortening wait-time further for HPS patients will not currently improve patient survivals.

581
ABUNDANCE OF PD-1 AND PD-L1 EXPRESSING CD8 T-CELLS IN THE LIVER MAY BE KEY TO HEPATIC TOLEROGENICITY

Pengyun Wang, Wayel Jassem, Maria Serena Longhi, Nigel Heaton, Giorgina Miel-Verani, Diego Vergani, Mohamed Rela, Yun Ma; Institute of Liver Studies, King’s College London School of Medicine at King’s College Hospital, London, United Kingdom

Background: The reason for the high tolerogenicity of the liver is unknown. CD4+CD25+ regulatory T-cells (T-regs) and expression of programmed death-1 (PD-1) and its ligands - members of the CD28/B7 super-family - on activated T, B, and dendritic cells (DCs), are central to the maintenance of tolerance in the experimental animal. Aims: To compare the frequency of regulatory cells and molecules within peripheral blood (PBMC) and hepatic (HMC) mononuclear cells in health. Methods: HMC were isolated from 12 liver perfusates collected from donor livers before allograft implantation, while PBMC were obtained from 9 healthy subjects (median age 31 years, range 21-48; all females). T-regs, PD-1 and PD-L1 expressing cells were evaluated by FACS using anti-CD4, -CD8, -CD25 and -PD-L1 monoclonal antibodies. Up-regulation of PD-1 and PD-L1 was induced by 500 ng/ml lipopolysaccharide (LPS) 4-hour stimulation. Results: CD4/CD8 T-cell ratio was 0.3 for HMC and 1.1 for PBMC. The frequencies of PD-1 expressing cells (10.47±0.19 vs 6.31±0.78, P=0.04) and PD-L1 expressing CD8 T-cells (4.57±1.58 vs 1.38±0.27, P=0.03) and PD-L1 expressing CD8 T-cells (0.36±0.01 vs 0.12±0.03, P=0.05) were higher in HMC than PBMC. Amongst CD8 T-cells, the percentage of PD-1 (14.4±3.29 vs 5.6±1.9, P=0.04) and PD-L1 (1.34±0.05 vs 0.5±0.001, P=0.01) was higher in HMC than PBMC. Frequencies of CD4/PD-1 (2.86±0.74 vs 2.67±0.28), PD-L1 (0.85±0.25 vs 1.35±0.43), BDCA-1/PD-L1 (0.54±0.19 vs 0.48±0.09) and CD4/PD-L1 (0.3±0.09 vs 0.26±0.06) expressing cells were similar in HMC and PBMC. After LPS stimulation, the CD4/CD8 T-cell ratio remained the same.
same in HMC and PBMC; PD-1 expressing cells (11.1±2.62 vs 7.37±1.32, P=0.12); CD8-PD-1 (5.47±1.91 vs 1.0±0.13, P=0.05) and CD8-PD-L1 T-cells (0.72±0.39 vs 0.26±0.03, P=0.09) remained higher in HMC than PBMC; amongst CD8 T-cells, the percentage of PD-1 remained also higher in HMC than PBMC (12.3±3.3 vs 4.95±0.78, P=0.07). The frequencies of all other cells were similar in HMC and PBMC. In contrast, the frequency of Tregs was lower in HMC than in PBMC before (1.43±0.38 vs 4.15±1.02, P=0.03) and after LPS stimulation (2.74±0.54 vs 4.66±0.95, P=0.06). Summary and conclusion: PD-1 and PD-L1 expressing CD8 T-cells are significantly more frequent in the liver than in the peripheral blood. These cells may be more important than conventional Tregs, which are fewer in the liver than in the blood, in imparting tolerogenicity.

582 STEROID AVOIDANCE IN LIVER TRANSPLANTATION: META-ANALYSIS AND META-REGRESSION OF RANDOMIZED TRIALS

Dorry L. Segev1, Stephen Sozio2, Eun Ji Shin2, Susanna L. Matsen1, Hari Nathan1, Paul J. Thuluvath1, Robert A. Montgomery1, Andrew M. Cameron1, Warren R. Maley1; 1Transplant Surgery, Johns Hopkins Medical Institutions, Baltimore, MD; 2Hepatology, Johns Hopkins Medical Institutions, Baltimore, MD

Steroid use after liver transplantation (LT) has been associated with post-transplant diabetes, hypertension, hyperlipidemia, obesity, and hepatitis C (HCV) recurrence. With the dramatic rise in HCV as an indication for LT, efforts to decrease the recurrence of this disease after LT are critical. We performed meta-analysis and meta-regression of 30 publications representing 19 unique randomized trials that compared steroid-free with steroid-based immunosuppression (IS). There were no differences in terms of death, graft loss, and infection. Steroid-free recipients demonstrated a trend towards reduced hypertension (RR 0.84, p=0.08), as well as statistically significant decreases in cholesterol (SMD -0.41, p=0.001) and CMV infection (RR 0.52, p=0.001). In studies where steroids were replaced by another IS agent, the risk of diabetes (RR 0.29, p<0.001), rejection (RR 0.68, p=0.03), and severe rejection (RR 0.37, p=0.001) were markedly lower in the steroid-free arms. In studies where steroids were not replaced, the rates of rejection were somewhat higher in the steroid-free arms (RR 1.31, p=0.02) and the advantage of reduced diabetes was attenuated (RR 0.74, p=0.2). HCV recurrence was lower with steroid avoidance and, although no individual trial reached statistical significance, meta-analysis was able to demonstrate this important effect (RR 0.90, p=0.03). We conclude that there are no short-term detrimental effects with steroid avoidance but, in light of the heterogeneity and relatively small size of the trials performed to date, we believe that only a large, multi-center trial will define the role of steroid free regimens in LT.

583 LIVER TRANSPLANTATION FOR HEPATIC COMPLICATIONS OF SICKLE CELL DISEASE - FEASIBLE BUT WATCH OUT FOR SPECIFIC MORBIDITY

Monika Hurtova1, Alexis Laurent2, Dora Bachis3, Pablo Bartolucci3, Daniel Cherqui1, Christophe Duvoix1; 1Hepatology Department, Hopital Henri Mondor, Creteil, France; 2Digestive surgery, Hopital Henri Mondor, Creteil, France; 3Internal Medicine, Hopital Henri Mondor, Creteil, France

Introduction: Patients with sickle cell disease (SCD) often develop severe hepatic complications. The experience with liver transplantation (LT) in patients with SCD and subsequent liver failure is limited. We describe a series of five adult patients transplanted in our center for liver complications associated with SCD between 1992 and 2006. Patients and methods: We reviewed charts of 5 patients (3 M, 2 F; mean age 37.6 yrs [35-47]). Type of SCD was S/S in 2 patients, S/C in 1, S/B in 2. Conclusions: LT is a feasible option for patients with SCD hepatopathy if liver failure is the
major threat to survival. However, LT is associated with unusual morbidity. In order to improve the outcome we therefore suggest a careful pretransplant screening for co morbidities, in particular neurological. Postoperatively, attention should be paid to neurological toxicity of calcineurine inhibitors and induction treatment might be necessary in these patients at high risk of acute rejection. Measures have to be taken to prevent sickle cell crisis post transplant by maintaining hemoglobin S fraction below 30% and total hemoglobin count above 8 g/dl at least during the first six months.

584 HIGH CIRCULATING REGULATORY T CELL LEVELS IN LONG-TERM STABLE LIVER TRANSPLANTS TREATED WITH CYCLOSPORINE COMPARED TO TACROLIMUS

Hyun Young Woo, Jong Young Choi, Chan Ran You, Si Hyun Bae, Seung Kew Yoon, Jin Mo Yang, Sang Wook Choi, Young Seok Lee, Chang Don Lee, Kuy Won Chung; Internal Medicine, The Catholic University of Korea, College of Medicine, Seoul, South Korea

Background/Aims: Regulatory T cell (Tregs) has been identified to play a pivotal role in the control of solid organ transplantation. In the setting of adult orthotopic liver transplantation (OLT), little is known about the extent of these cells in long-term stable transplantation recipients with maintenance immunosuppression. Methods: This prospective study enrolled total 85 (58 living donor, 27 deceased donor) consecutive recipients with sustained stable liver function over 2 years (range, 2-13 years) after OLT. We determined the frequency of CD4+CD25+ T cell in peripheral blood mononuclear cell (PBMC) of 85 liver transplantation recipients annually between January 2005 and December 2006. In 10 liver biopsy tissue during study period, Foxp3+ cells were analyzed using immunohistochemistry. We investigated the possible link between immunosuppressive drug and the frequency of CD4+CD25+ T cell. Results: In overall patients, the mean frequency of Tregs was 4.7% (range, 1-17.3). When the cut-off level of high frequency of CD4+CD25+ Treg cell was arbitrarily defined over 6% among CD4+ T cells, 29.4% (25/85) of long-term stable recipients showed high frequency of Tregs cell over 2 years after OLT. The proportion of patients with high Tregs over 6% was 41.1% (12/29) in CsA group, 13.8% (4/29) in FK506 group, especially in living donor liver transplantation (LDLT) (P=0.03). Eight of 10 patients had Foxp3 positive cells in liver biopsy tissue. Conclusions: If 6% Tregs among PBMC was arbitrarily the cut off level of Tregs cell frequency predicting clinical tolerance, approximately one fourth of 85 long-term stable liver transplantation recipients meet this criteria. In addition, this study suggests that cyclosporin A may induce the tolerance than FK506 in long-term stable LDLT patients.

585 TRENDS IN LIVER TRANSPLANTATION FOR HEPATOCELULAR CARCINOMA IN THE UNITED STATES

Benjamin H. Leach, Jonathan Prather, David Scott, Douglas Norman, Jonathan M. Schwartz; Oregon Health and Sciences University, Portland, OR

Background: Liver transplantation (LT) is an effective treatment for select patients with hepatocellular carcinoma (HCC). HCC patients who meet criteria are prioritized for liver allocation in 11 US geographic regions. It is unclear if the priority allocated for HCC accurately reflects risk of death or withdrawal from the waiting list. Furthermore, details regarding regional differences in transplantation rates, deaths on the waiting list or waiting list removal for HCC are unknown. Aims: 1) To evaluate transplantation rates and waiting list mortality for HCC patients and non-HCC patients listed for LT, and 2) To compare regional rates of LT, waiting list mortality and waiting list removal in patients with HCC. Methods: Data regarding 71,428 adult deceased donor LT candidates who were on the list between February 2001 and January 2007 were obtained from the United Network of Organ Sharing. Patients with a primary or secondary diagnosis of HCC or those with an HCC exception were identified. Rates of transplantation, waiting list removal and death on the waiting list were expressed as the number of events/patient year according to the pre-MELD period and four periods of MELD priority assigned to HCC patients. Rates of transplantation, regional rates of transplantation for HCC, waiting list removal and waiting list mortality were compared using unadjusted crude rate analysis. Results: LT rates for HCC increased from 0.2/patient year prior to the MELD era to 1.5/patient year in MELD era 4 (P<0.05). HCC LT rates increased during the 4 MELD eras (1.1/patient year-1.5/patient year, P<0.05). LT rates for HCC varied according to UNOS region (range 0.77/patient year in region 5 to 3.68/patient year in region 3, P<0.05). LT rates were higher for HCC patients compared to non-HCC patients (1.25/patient year vs. 0.28/patient year respectively, P<0.05), and death rates on the waiting list were lower in HCC patients (0.08/patient year vs. 0.11/patient year, P<0.05). Waiting list removals were similar for HCC patients and non-HCC patients (0.27/patient year vs. 0.26/patient year respectively, P=NS). Conclusions: 1) Rates of LT for HCC have increased, however, rates vary substantially according to geographic region; 2) Unadjusted waiting list mortality is lower in HCC patients than non-HCC patients despite equivalent drop out rates. Appraisal of the long term impact of allocation policies for HCC is therefore necessary to provide equitable access to LT.

586 HOMA-IR AND MICROALBUMINURIA ARE ASSOCIATED WITH MICROVASCULAR COMPLICATIONS IN PRE-LIVER TRANSPLANT PATIENTS - A CASE-CONTROL STUDY

Karen L. Kroek, Farida Millwala, Anurag Maheshwari, Paul J. Thuluvath; Medicine, Johns Hopkins Hospital, Baltimore, MD

BACKGROUND: Death from cardiovascular disease (CVD) is the most common cause of late mortality in liver transplant (LT) recipients. Many patients with macrovascular complications are not listed for a LT, but the presence and significance of microvascular complications has not been well established in the LT population. Microalbuminuria is an established risk factor for CVD, but its importance in cirrhotics also is not well characterized. METHODS: In this case-control study, we examined the prevalence of microalbuminuria and microvascular complications in 45 cirrhotics with diabetes (DM) and 45 cirrhotics without DM awaiting LT. Patients were matched by age, sex, race and etiology of liver disease. We collected demographic and laboratory data including fasting serum insulin and glucose levels, urine creatinine and microalbumin, macro-
and micro-vascular complications, and other established risk factors for CVD. The homeostatic model assessment for determining insulin resistance (HOMA-IR) was also calculated.

RESULTS: The DM and non-DM groups did not differ in body mass index, tobacco use, presence of hypertension (HTN), or family history (FH) of CVD; the presence of peripheral vascular disease (p=0.041), microvascular complications (p=0.0001), hyperlipidemia (p=0.029), hypertriglyceridemia (p=0.0001), and HOMA-IR (p=0.233) differed between the two groups.

34 (38%) patients had microvascular complications; the patient’s sex, race, FH of DM and CVD, tobacco use and microvascular complications were not significant between the groups. Elevated triglycerides, microalbuminuria, serum creatinine, duration of DM, duration of HTN and insulin requirement were significantly associated with the presence of microvascular complications. 14 (15%) patients had significant microalbuminuria, defined as an albumin/creatinine ratio >0.03. There was a significant association between microalbuminuria and the presence of HTN (p=0.014), hypertriglyceridemia (p=0.008) and a trend toward a higher MELD score (p=0.058). The HOMA-IR was not associated with microalbuminuria, but was associated significantly with the presence of microvascular complications (p=0.015). CONCLUSIONS: At our transplant center, 38% of patients awaiting LT have microvascular complications and 15% have significant microalbuminuria. The HOMA-IR and microalbuminuria are associated with microvascular complications. Microalbuminuria and HOMA-IR could be used to risk-stratify patients for CVD prior to LT and aid in selecting patients who need more rigorous testing for the presence of CVD prior to LT.

588 RECURRENT AUTOIMMUNE HEPATITIS AFTER LIVER TRANSPLANTATION AT A CENTER PRACTICING CORTICOSTEROID MINIMIZATION

Jeffrey Campsen, Michael Zimmerman, James Trotter, Thomas Bak, Michael Wachs, Tracy Steinberg, Maria Kaplan, Igol Kam; Transplant Surgery, University of Colorado Health Science Center, Denver, CO

Introduction: Since 1997 our center has attempted to minimize corticosteroid (CS) use in all of our liver transplantation (OLT) recipients. In the mid-1990’s we initiated a prednisone-withdrawal protocol for chronic patients. In 1997, we began a series of trials to minimize CS use in all of our de novo liver recipients starting from the time of transplantation. In 1997, CS were administered for only 14 days after transplantation and then in 2000, CS use was reduced to only 3 days after transplantation. In 1997, patients with autoimmune hepatitis (AIH) typically require CS after transplantation, we reviewed our experience in this cohort of patients to determine 1) patient outcome including recurrent disease and 2) long-term requirement for CS use in AIH patients. Methods: From 1988 to 2006, 1,102 OLTs were performed in 1,032 adults at the University of Colorado. Of these, 66 patients (6 %) with AIH received 68 allografts. Recurrence was defined by a clinically worsening exam and histological evidence from biopsy. Bivariate and multivariate analyses were used to evaluate predictors of CS withdrawal. Twelve potential predictors of CS discontinuation were considered: age, gender, presence of inflammatory bowel disease (IBD), type of graft (cadaver or living donor), recurrence of AIH, warm ischemia time, follow up time (time since transplant), and immunosuppressant (IS) regimen (cyclosporine, tacrolimus, sirolimus, azathioprine, and mycophenolate mofetil). Results: Overall survival at 5 years was 91%. The 1, 5 year recurrence-free survival was 86, 59 %, respectively. Risk of recurrent AIH at 1, 3, and 5 years was 12, 36, and 41 %.
respectively. The incidence of disease recurrence was 23 of 66 patients or 34.8%. Of the 23 patients that developed recurrent disease none received a second transplant because of recurrent disease. At time of review 36% of patients were on IS monotherapy verses 56% on two drug and 8% on three IS drug therapy. CS was withdrawn in 50% of patients at time of review. Only two factors on the multivariate analyzes were associated negatively with PD withdrawal: 1) an increasing dose of IS and 2) the presence of IBD. Recurrent disease did not influence CS withdrawal. Conclusions: 1) Outcomes in AIH patients were quite favorable and none of the patients required re-transplantation for recurrent AIH. 2) Using a CS minimization approach, one-half of the patients were able to remain CS-free.

PRE-TRANSPLANT VARIABLES PREDICT QUALIFY OF LIFE IN LIVER TRANSPLANT RECIPIENTS
Sammy Saab, Bijal Surti, Ayman Ibrahim, Francisco A. Durazo, Steven-Huy B. Han, Hasan Yersiz, Douglas Farmer, R M. Ghobrial, Leonard Goldstein, Myron J. Tong, Ronald Busuttil; Medicine and Surgery, UCLA Medical Center, Los Angeles, CA

Introduction: With an increasing number of liver transplant recipients living, understanding quality of life issues is essential. Our goal is to specifically identify the pre-transplant predictors of post-transplant quality of life in liver transplant recipients. Understanding how these variables will affect quality of life can help determine if specific interventions will further improve quality of life post-transplant. Methods: Three hundred and eight adult liver transplant recipients seen at UCLA were administered the Short Form 36 and a questionnaire regarding work history and insurance coverage. Variables associated with post-transplant quality of life were studied in a multivariate analysis. Interaction terms were used to examine effect modification.

Results: The mean age of participants (± standard deviation [SD]) was 51 (± 13.99) years. Most patients (50%) were transplanted for viral hepatitis. Post-transplant quality of life domains were associated with a number of pre-transplant factors: Physical Functioning (work hours, gender, ethnicity), Role-Physical (work hours, body mass index, renal failure, ascites, and pay change post transplant), Bodily Pain (ascites, pay change), General Health (encephalopathy, ascites), Vitality (ascites), Social Functioning (disease etiology, ascites), Role-Emotional (ascites), and Mental Health Factors (work hours). Conclusions: Our results demonstrate that pre-transplant factors such as work hours, body mass index, renal failure, and disease etiology predicted impaired quality of life in liver transplant recipients. In addition, pre-transplant manifestations of portal hypertension such as ascites and encephalopathy continue to affect patients even after transplantation. Interventions to modify these pre-transplant variables may further improve quality of life in liver transplant recipients.

MICROVASCULAR INVASION DOES NOT IMPACT SURVIVAL IN PATIENTS UNDERGOING ORTHOTOPIC LIVER TRANSPLANTATION (OLT) FOR HEPATOCELLULAR CARCINOMA (HCC) WHO HAD PRE-OLT LOCAL THERAPY
Christine A. O’Mahony, Sanjeev Patel, John M. Vierling, Natasha S. Becker, Norman L. Sussman, Norma Flores, Kimberly Talley, Rise Shribling, John A. Goss; Baylor College of Medicine, Houston, TX

BACKGROUND: The increasing incidence of HCC in the U.S. has resulted in the transplantation of a larger proportion of patients with HCC. Despite advances in preoperative staging, the risk factors for recurrent HCC remain poorly defined, especially in patients undergoing pre-OLT transarterial chemoembolization (TACE) and/or radiofrequency ablation (RFA). AIM: To identify prognostic variables for recurrence of HCC post-OLT in patients receiving pre-OLT local therapy. METHODS: We conducted a retrospective review of all patients transplanted with HCC at our institution from February 1997-May 2006. Patient survival rates were determined using the Kaplan-Meier product-limit estimate. Demographic, tumor, and pathologic characteristics were tested for their prognostic significance using univariate and multivariate analyses. RESULTS: There were 131 patients with HCC identified among 715 adult OLT recipients in this time period with a mean follow-up of 35 months. 88% of the patients underwent pre-OLT TACE, while 48% of the patients underwent pre-OLT TACE combined with RFA. 12% (15/131) of the patients did not receive pre-OLT local therapy. Of these 15 patients, 6/15 tumors were discovered incidentally, 3/15 were transplanted prior to pre-OLT local therapy, 2/15 were too ill for TACE, and 4/15 were unknown. The overall patient survival was 96%, 89%, and 85% at 1, 3, and 5 years, respectively. 9/131 patients experienced recurrence of the tumor. The average time for recurrence was 1.5 years with all recurrences occurring by 3 years post-OLT. As shown in table 1, a total of 23 tumors had microvascular invasion. Only 2 of these tumors recurred. 3 tumors exhibited macrovascular invasion, with no recurrences. 5/20 patients with tumors >5cm experienced a recurrence (p<0.05) while none of the 13 patients with <3 tumors had a recurrence. Only 2/11 of the poorly differentiated tumors recurred. Tumor size > 5 cm was associated with a significant increase in the risk for recurrence (HR 2.44, p<.05) Microvascular invasion, macrovascular invasion, >3 tumors, pre-OLT TACE and/or RFA,
and tumor grade did not predict tumor free survival (Table 1).

**CONCLUSION:** Patients with HCC can undergo OLT with the expectation of excellent outcomes. Tumor size > 5cm significantly increased the risk of recurrence. In contrast, neither microvascular invasion, nor macrovascular invasion predicted recurrence in these patients undergoing pre-OLT local therapy.

**OCCURRENCE OF ADRENAL INSUFFICIENCY AFTER LIVER TRANSPLANTATION: RISK FACTORS FOR AN UNEXPECTEDLY FREQUENT COMPLICATION**

**Elisa Fumolo¹, Elisabetta Rossi¹, Silvia Fumagalli¹, Davide Bitetto¹, Ezio Forisari¹, Carlo Fabris¹, Edmondo Falletti¹, Rosalba Minisini², Mario Pirisi², Pierluigi Toniutto¹.¹Medical Liver Transplant Unit, Azienda Ospedaliero-Universitaria, Udine, Italy; ²Dpt of Clinical & Experimental Medicine, University of Eastern Piedmont “A. Avogadro, Novara, Italy**

Introduction. Immune-suppressive therapy after liver transplantation (OLT) is based on the use of calcineurin inhibitors in association with corticosteroids. This can lead to the development of adrenal insufficiency after the cessation of prolonged corticosteroid administration. This study aimed to investigate the prevalence and associated factors to the development of adrenal insufficiency after OLT. Methods. Eighty seven patients who underwent OLT were studied. Adrenal function testing was performed when the patients were taking 5 mg of prednisone daily for at least one week. The adrenal function was evaluated by means of the 250 µg standard corticotrophin test. Serum cortisol levels were assessed basally, 30’ and 60’ after corticotrophin administration; the test was defined pathological when serum cortisol did not double the basal value and did not reach at least 20 µg/dL. Results. The corticotrophin test was found to be pathological in 23/87 patients, more frequently in patients who had taken a total dose of prednisone >1350 mg (19/52 Vs 4/35, p<0.01) and in those who were treated with prednisone for >105 days (17/49 Vs 6/38, p<0.05). Furthermore, a pathological test was found to be associated at a level of p<0.10 with recipient male gender, recipient body mass index (BMI) ≤25 Kg/m2 and the alcoholic aetiology of liver disease. No significant association was found between corticotrophin test and duration of ischaemia and of transplant operation, number of blood transfusions, days of stay and presence of septic episodes in intensive care unit. Total dose of prednisone (p<0.01), BMI ≤25 Kg/m2 (p<0.05) and alcoholic aetiology of liver disease (p<0.05) were the variables independently associated with the presence of a pathological corticotrophin test. No significant difference was detected between patients with normal and pathological test regarding the parameters classically considered to be associated with adrenal insufficiency. Conclusions. Adrenal insufficiency is frequent in liver transplanted patients and cannot be suspected on the basis of the common clinical and laboratory pertinent parameters. Thus it may be suggested to perform the corticotrophin test in all liver transplanted patients especially in those malnourished patients with alcoholic liver disease who were treated with higher doses of prednisone.

**RENAL DYSFUNCTION FOLLOWING LIVER TRANSPLANTATION: A COMPARISON OF NOVEL RENAL BIOMARKERS IN THE POST TRANSPLANT PERIOD**

**Andrew J. Portal¹, Matthew Bruce¹, Mark Austin¹, Constantine J. Karvellas¹, Mark McPhail¹, Funmi Awopevi¹, Roy Sherwood¹, John G. O’Grady¹, Nigel Heaton¹, Paolo Muiesan¹, Julia Wendon¹, Michael Heneghan¹, Institute of Liver Studies, Kings College Hospital, London, United Kingdom; ²Department of Biochemistry, Kings College Hospital, London, United Kingdom**

Introduction Renal dysfunction is a common occurrence both before and after liver transplantation (LT). Because standard markers of renal function are poor reflections of true glomerular filtration (GFR) in liver disease patients, we assessed the ability of two novel markers, Cystatin C (CysC) and Neutrophil Gelatinase Associated Lipocalin (NGAL), to predict renal impairment in 80 patients following LT. Methods CysC and NGAL were collected within the first 24 hours of following LT and compared with standard markers of renal function up to 3 months post transplantation. CysC was measured by nephelometry and NGAL by sandwich ELISA (AntibodyShop®). Biochemical and physiological data were collected prospectively and patients were followed for 3 months. Renal dysfunction was classified using either need for renal replacement therapy (RRT) or by the Chronic Kidney Disease (CKD) staging system. Results are expressed as median and interquartile range (IQR). Results: 61 patients underwent LT for chronic liver disease with 19 undergoing LT for acute liver failure or urgent retransplantation. Median pre-operative serum creatinine (sCr) was 99 µmol/L (81-129); MELD 15.5 (12-27); Estimated GFR (eGFR) 66(50-81). Admission NGAL correlated with day 7 sCr (r = 0.6, p <0.001) as did to CysC (r =0.6, p=0.001). There was an association between higher admission NGAL and longer intensive care stay (r=0.5, p<0.01). Both CysC and NGAL were significantly higher in those patients requiring haemofiltration on day 1 when compared with those not needing RRT [CysC 2.84mg/L (2.26-3.43) vs 1.67mg/L (1.23-2.18), p=0.001; NGAL 420ng/mL (290-500) vs 158ng/mL (100-260), p<0.001]. These findings persisted up to day 5 post LT, and admission NGAL was significantly higher in those that had renal impairment at day 14 (classified by eGFR <60). Using receiver operator characteristic curve analysis, area under the curve (AUC) was higher for NGAL when compared with CysC, sCr and eGFR at both day 7 and day 14 post LT, especially in patients with lower eGFRs. Admission NGAL was better at predicting more severe renal impairment on day 7 post LT than admission sCr (NGAL >347ng/ml AUC 0.94, 0.85 – 0.979, p<0.0001, sensitivity 100%, specificity 86%; sCr > 125µmol/L AUC 0.82 (0.715 – 0.897), p=0.001 sensitivity 87.5%, specificity 66.7%). By day 14, all markers performed less well than at day 7 although NGAL retained high sensitivity and specificity (86%, 80% respectively). Conclusion. Cystatin C and NGAL are good predictors of renal dysfunction following LT.
Further studies are needed to assess their clinical utility, especially in relation to manipulation of nephrotoxic immunosuppression.

GB VIRUS-C INFECTION IS ASSOCIATED WITH BETTER 10-YEAR-SURVIVAL OF LIVER TRANSPLANT RECIPIENTS

Kinan Rifai 1, Sven Pischke 1, Stefan Heringlake 1, Heiner Wedemeyer 1, Jürgen Klempnauer 1, Michael P. Manns 1, Hans L. Tillmann 1,3; 1Gastroenterology, Hepatology & Endocrinology, Medizinische Hochschule Hannover, Hannover, Germany; 2Visceral and Transplant Surgery, Medizinische Hochschule Hannover, Hannover, Germany; 3Medical Dept. II, University Leipzig, Leipzig, Germany

Background & Aims: We earlier demonstrated a beneficial influence of the GB virus C (GBV-C, or hepatitis G virus) on the long-term course of HIV infection. An influence of GBV-C on the short-term survival of liver transplant recipients was not observed. Here we describe the long-term outcome of patients with GBV-C after liver transplantation (OLT).

Methods: We studied overall survival rates of 200 patients transplanted at our center between 1992 and 1996. GBV-C envelope antibodies (anti-E2) and RNA were tested directly before transplantation. 63/200 patients had anti-E2, 17 patients were viremic and in 8 patients both GBV-C antibodies and RNA were found. There were no differences regarding diagnosis, age or sex between the different groups. Survival rates were assessed in 2006, thus 10 years after OLT, by using Kaplan-Meier and Cox’s regression analysis.

Results: Overall 1-, 3- and 10-year patient survival rates were 75%, 69% and 56%. Mean patient and graft survival was 7.8±5.5 and 7.1±5.5 years, respectively. A worse outcome was found for patients requiring retransplantation (p<0.0001) and those with tumor disease (p<0.0001). If patients surviving at least 3 years were analysed, those who were GBV-C RNA positive had a significantly longer survival than RNA-negative patients (figure 1; p<0.03). In Cox’s regression including patient age and sex, need of retransplantation and presence of tumor disease, GBV-C viremia (p=0.006) and absence of retransplantation (p=0.04) were independently associated with patient survival.

Conclusions: Patients with active GBV-C infection had an improved long-term outcome after liver transplantation, actually in line with similar data from renal transplant recipients.

BLOOD GROUP A2 DONORS FOR BLOOD GROUP O RECIPIENTS IN PEDIATRIC OLT: AN 18-YEAR CASE-CONTROL MULTI-INSTITUTIONAL ANALYSIS

Natasha S. Becker, Thomas A. Aloia, Joel A. Rodriguez, Rise Stirling, John M. Vierling, Norman L. Sussman, Christine A. O’Mahony, John A. Goss; Michael E. DeBakey Department of Surgery, Baylor College of Medicine, Houston, TX

Introduction: The shortage of pediatric liver allografts has necessitated expansion of the donor pool, including the utilization of blood group A2 liver allografts for blood group O recipients (A2-O). Aim: To determine pediatric patient and allograft survival rates after A2-O orthotopic liver transplantation (OLT).

Methods: The UNOS database for the years 1987-2005 was used to identify 23 pediatric patients who underwent A2-O OLT. These patients were matched 2:1 with controls who underwent ABO-Identical (ABO-I) OLT. Matching variables included: recipient age, donor age, ventilator status, Status 1 categorization, PELD/MELD score, donor type (living vs. deceased), indication for transplantation (acute liver failure vs. other), and era of OLT (prior to 2000 vs. 2000-2005). Similarity of cases and controls was confirmed through chi-squared (for categorical variables), and Mann-Whitney-U tests (for continuous variables). Survivals were calculated using Kaplan-Meier analysis and compared with log-rank tests. Results: The study cohort included 23 A2-O patients. Median recipient age was 2 years (range 0-18 years), 65% of patients were male, and 52% were Caucasian. Median donor age was 3 years (range: 0-56). Seven study patients were ventilated at time of OLT (30%) and 13 were Status 1 (57%). Median PELD/MELD score was 20 (range: 15-22). One patient received a living donor allograft (4%). Acute liver failure was the final diagnosis in 7 OLTs (30%), and 14 OLTs (61%) were performed prior to 2000. 46 controls matched for all eight variables were selected from the 5,904 patients transplanted with ABO-I liver allografts. Similarity of cases and controls was confirmed (all comparisons: p > 0.50). One, 3-, and 5-year patient survivals were 71%, 71%, and 64% for A2-O cases; and 84%, 82%, and 75% for ABO-I controls (p=0.4587; Figure 2).
were 67%, 62%, and 56% for A2-O cases, and 80%, 78%, and 71% for ABO-I controls (p=0.1802). One A2-O patient died within 30 days of OLT, yielding a 30-day operative mortality of 4.3%. This was similar to the 7% 30-day mortality for ABO-I patients (p=0.511). Six patients in the A2-O group and 8 patients in the ABO-I group died after 30 days. Analysis of cause of death showed no difference in the percentage of patients dying from graft failure (33% vs.13%, p=0.347) or dying from infection (17% vs. 25%, p=0.707). Discussion: In pediatric patients, A2-O OLT yields patient and allograft survivals similar to those experienced after ABO-I OLT. The use of this alternative will allow for better utilization of available donor organs in the current era of liver allograft shortage.

RENAL FAILURE FOLLOWING LIVER TRANSPLANTATION

Alex Aspinall1,2, Robert J. Hilsden1, Bridget K. Gunson2, Barbara L. Aspinall1,2, James M. Neuberger1,2; 1UCMC Area 2, Division of United Kingdom

Background: Following liver transplantation there is long term morbidity and high mortality due to renal failure. Risk factors associated with renal failure include female gender, age, calcineurin use, diabetes and hypertension. While this provides the clinician with a context in which to be vigilant for renal failure, a predictive tool would be more useful. Methods: Baseline and post-transplant data was analyzed from the University of Birmingham liver transplantation database for 587 consecutive patients 1998-2004. Risk factors for the development of chronic renal failure were recorded. The MDRD creatinine clearance was calculated up to 24 mo after transplantation. Renal impairment was defined as a CrCL <60 and renal failure as <30 mL/min or the need for dialysis. Results: Two yr after transplantation, 2.3% of patients had renal failure and 65.2% had renal impairment. Increasing age was a risk factor for renal failure (OR = 1.08, CI 1.05-1.11) and male gender was protective (OR = 0.29, CI 0.17-0.52). When compared to patients transplanted for acute (fulminant) liver disease, patients with chronic liver diseases had greater likelihoods of developing renal failure (OR for alcohol, hepatitis B/C, PBC and other diseases, 2.67 CI 0.82-8.69), 1.94 CI 0.63-5.97, 5.78 CI 1.84-18.2), and 1.4 CI 0.49-4.06 respectively. Importantly, 89.3% of patients with a CrCL of <60 mL/min 6 mo after transplantation continued to have renal impairment 2 yr after transplantation (OR 10.20, CI 5.9-18.2) (Graph). Conclusions: Our data confirm previously identified risk factors associated with developing renal failure. Six mo after transplantation a CrCL <60 mL/min is predictive of future renal impairment and is an important early tool for clinicians treating liver transplant recipients to use in decreasing long term morbidity and mortality following liver transplantation.

597 EVALUATION OF PATIENTS WITH ALCOHOLIC LIVER DISEASE FOR LIVER TRANSPLANTATION

Elske Sibma1, Gregory Gores1, Russell H. Wiesner1, Walter Kremer1, Sheila G. Jowsey1, Terry D. Schneekloth1, Julie K. Heimbach1, Michael R. Charlton1, Charles B. Rosen1, KV Narayanan Menon1, 1Mayo Clinic, Rochester, MN

Alcoholic liver disease (ALD) is a common indication for liver transplantation (LT) in the United States. Many transplant centers require patients with ALD to be abstinent for 6 months before being listed for LT. Evidence for the ‘6 month rule’ to prevent relapse is conflicting and some patients too sick to wait 6 months may die before being listed for LT. Alternative models to evaluate patients with ALD for LT are lacking. Since 2003 we have evaluated patients with ALD for LT by stratifying them into relapse risk categories (low/medium/high) depending on their probability of relapse after LT based on predetermined criteria such as duration of abstinence, completion of a treatment program, family history of alcoholism and other factors derived partly from the model of Gish et al. AIM. To determine the feasibility and outcome of evaluating patients with ALD for LT by stratifying them into relapse risk categories. METHODS. Patients evaluated for LT between September 2003 and September 2006 meeting DSM IV criteria for alcohol abuse or dependence were included in the study. Patients were stratified into relapse risk categories following addiction psychiatry assessment. Low and medium risk patients were generally considered suitable for listing and high risk patients were deferred or declined until they fulfilled the requirements of the addiction psychiatry team. In addition to the risk score, final listing was based on other medical and social conditions as well. We undertook a chart review to determine the psychosocial and demographic characteristics of the patients and their outcome after evaluation for LT. RESULTS. 220 patients were included (139 high risk, 50 medium risk, 31 low risk) in the study. During a median follow-up period of 11 months (range 0-41) 54% (n=119) of the patients were listed, comprising 67% of the low risk, 82% of the medium risk and 41% of the high risk patients. Of these listed patients 42% (n=50) underwent LT, 10% (n=12) died, 3% (n=3) was lost to follow-up. 45% (n=54) are waiting for LT. Among the 101 patients not listed, 35% died and 25% were lost to follow-up. During a median post-transplant follow-up of 18 months (range 0.4-39 months) 12% (67% were high risk) of patients relapsed to alcohol use. CONCLUSION. 1. Evaluating patients with ALD for LT by using this relapse risk stratification system is feasible with greater than 50% of evaluated patients being listed and may prevent exclusion of candidates too sick to wait 6 months before being considered for LT. 2. Further studies are needed to determine ways to prevent death and loss to follow up of patients with ALD following initial evaluation for liver transplantation.

598 HEPATOCELLULAR CARCINOMA (HCC) IN PATIENTS WITH HCV VERSUS NON-HCV CIRRHOSIS: GRAFT AND PATIENT SURVIVAL AFTER LIVER TRANSPLANTATION (LT) IN PRE-MELD AND MELD ERA

Paul J. Thuluvath, Dorry L. Segev; Medicine & Surgery, Johns Hopkins University School of Medicine, Baltimore, MD

HCC in the presence of HCV may have a worse outcome after LT because of the confounding effects of recurrent HCV and higher HCC recurrence. Our objective was to assess the survival of patients with HCC in those with HCV and non-HCV cirrhosis using UNOS database from 1994-2006. Methods: Patients with HCC were stratified into HCV (HCC-HCV) and non-HCC (HCC-non HCV) and also into MELD and pre-MELD era because of the potential impact of MELD on outcomes. In the pre-MELD era, there were 1,886 HCC patients (639 HCV, 1,079 non-HCV, HCV status unknown in 168) and during MELD era, there were 798 patients (283 HCV, 431 non-HCV and 84 unknown). For the purpose of this study, we analyzed patients with unknown HCV status separately (not shown). Comparative analysis was made of HCV (HCV) and non-HCV (non-HCV) patients without HCC after stratification as discussed above. We calculated unadjusted graft and patient survival rates (%) at 1, 3 and 5 years for pre-MELD and 1 and 3 years for MELD patients. Results: Pre-MELD era – graft survival rates for HCC-non HCV was higher than HCC-HCV patients at 1-yr (77.7 vs. 73.8), 3-yr (63.3 vs. 58.2) and 5 years (56.8 vs. 48.7); pre-MELD era patient survival was similar at 1-yr (80.7 vs. 79.4) and 3-yr (66.2 vs. 64.5), and higher at 5-yr (59.9 vs. 55.2) for HCC-non HCV. Pre-MELD era graft survival rates for patients without HCC in non-HCV at 1-yr (80.6 vs. 79.7), 3-yr (74.4 vs. 69.3) and 5-yr (69.2 vs. 61.8) was also higher than HCV patients as expected; similar trend was also seen for patient survival at 1-yr (85.2 vs. 84.1), 3-yr (79.7 vs. 74.5) and 5-yr (74.8 vs. 67.3). MELD era – graft survival rates were similar for HCC-non HCV and HCC-HCV patients at 1-yr (83.7 vs. 82.7), but was higher at 3-yr (72.2 vs. 65.7); MELD era patient survival was similar at 1-yr (87.1 vs. 86.6) and was higher at 3-yr (73.7 vs. 71.9). MELD era graft survival rates for patients without HCC in non-HCV at 1-yr (82.1 vs. 82.7) and 3-yr (74.5 vs. 69.7), and patient survival 1-yr (86.7 vs. 84.3) and 3-yr (81.3 vs. 76.5) showed similar trend. Survival differences showed similar trends as shown in the table. Conclusions: There has been an improvement in 3-year graft (8.9% for non-HCV, 7.5% for HCV) and patient (14.8% for non-HCV, 13.1% for HCV) survival in MELD era compared to pre-MELD era for HCC patients with similar trends in survival rates in HCV and non-HCV patients with and without HCC suggesting that lower survival in patients with HCV and HCC is mainly due to the confounding effect of HCV.

EFFECTIVENESS OF PERCUTANEOUS LASER ABLATION AS BRIDGE TREATMENT TO LIVER TRANSPLANTATION IN CIRRHOTIC PATIENTS WITH HEPATOCELLULAR CARCINOMA

Maurizio Pompili1, Erica Nicolardi1, Giampiero Francica2, Alessandra Petrolati3, Mario Angelico1, Giuseppe Tisoni4, Giuseppe Santeusanio5, Paolo Craboledda6, Bonaventura Cine, Catholic University of Sacred Heart, Rome, Italy; 2Ultrasound Unit, S.Maria della Pietà Hospital, Casoria, Italy; 3Hepatology Unit, Tor Vergata University, Roma, Italy; 4Liver Transplant Unit, Tor Vergata University, Roma, Italy; 5Pathology, Tor Vergata University, Roma, Italy; 6Pathology, S.Eugenio Hospital, Roma, Italy; 7Hepatology and Gastroenterology, Regina Apostolorum Hospital, Albano, Italy; 8Imaging Diagnosis and Interventional Radiology, Regina Apostolorum Hospital, Albano, Italy

Percutaneous laser ablation (PLA) is an effective ablative procedure of hepatocellular carcinoma (HCC) and metastatic liver lesions. To the best of our knowledge, this procedure has never been used as bridge treatment in cirrhotic patients with HCC listed for liver transplantation (LT). In this study, the data of 10 patients (all males, mean age 52.8 yrs, Child-Pugh class A 6 cases, B 4 cases, C 1 case) with HCC complicating liver cirrhosis treated by PLA and undergoing LT between 2002 and 2006 were retrospectively reviewed. At the moment of the evaluation for LT, all the patients but one had no more than 3 nodules each smaller than 3 cm, and 6 of them showed a single tumor nodule. Twelve biopsy-proven HCC nodules (mean diameter 2 cm, range 1.5-3 cm) underwent PLA carried out by inserting 300 nm optical fibers through 21-g needles (from two to four) positioned under US guidance into the target lesions. A continuous wave Nd:YAG laser operating at a wave length of 1,064 nm was used. Seven tumors underwent a single PLA session. No procedure-related major side effects were recorded. Transarterial chemoembolization (TACE) prior to LT was performed in three tumors resulted to be incompletely ablated on imaging studies. The mean waiting time to LT after PLA was 1.1 months. Complete necrosis at histological examination of the explanted livers was found in 7 nodules (58%, all treated exclusively with PLA), partial necrosis > 50% in 3 nodules (25%, 2 treated with a combination of PLA and TACE), partial necrosis < 50% in 1 nodule, absent necrosis in 1 nodule (treated with both PLA and TACE). In the latter case the final histological diagnosis was that of an hepatic yolk sac tumor. Mean follow-up length after LT was 22 months: 5 patients are alive without tumor recurrence. The remaining 5 patients died; in only one case HCC recurrence was detected and resulted to be the cause of death. Our preliminary data suggest that PLA is an effective bridge treatment in cirrhotic patients with HCC smaller than 3 cm waiting for LT.

FOLLOW-UP OF PATIENTS AFTER LIVER TRANSPLANTATION USING DOMINO GRAFTS

Ana P. Barreiros1, Rosa Walz1,2, Christian Geber1, Frank Birklein2, Cathrin Theis4, Christian Weiss2, Felix Post4, Karl F. Kreitner2, Michael Heise2, Marcus Schuchmann1, Peter R. Galle1, Gerd Otto2; 1Department of Internal Medicine, Johannes Gutenberg-University, Mainz, Germany; 2Department of Transplantation Surgery, Johannes Gutenberg-University, Mainz, Germany; 3Department of Neurology, Johannes Gutenberg-University, Mainz, Germany; 4II. Department of Internal Medicine, Johannes Gutenberg-University, Mainz, Germany

Introduction: In recipients of domino grafts retrieved from patients with hereditary amyloidosis symptoms of the disease transmitted by the graft have been reported. Therefore, we implemented a special follow-up in these patients. The results are reported herein. Patients and Methods: In our center 17 patients underwent a domino liver transplantation (DLT) since 09/98. The longest follow-up was 9 years after transplantation (median 31 months, range 6 - 107 months). The domino-transplanted patients were enrolled in a special post-transplantation protocol, beginning 3 months after transplantation. In addition to physical examination and blood tests, 5-day electrocardiogram (ECG), 24-hour blood pressure measurement, echocardiography, cardiac MRI, cardiac electrophysiological examinations, rectoscopy with microendoscopic technique and biopsy, and extensive neurological examination including quantitative sensory testing, autonomic testing (sympathetic skin response, heart rate variability, orthostatic function) as well as sensory and motor electroneurography were performed. This workup was repeated 3 years and 5 years after DLT and thereafter annually. Results: Six of the 17 transplanted patients died after median 20 months (range 6 – 39 months), due to recurrence of HCC (n=4), recurrence of hepatitis C (n=1) and cardiac arrest (n=1). Since the fatal cardiac complication occurred 3 years after transplantation, deposition of amyloid is unlikely in this short time. So far none of our surviving 12 patients shows a definite onset of amyloidosis after DLT, with a follow-up of the surviving patients between 6 months and 9 years. After 5 years one patient developed isolated neurologic symptoms presenting as painful sensory neuropathy with predominant loss of small nerve fibers, however without any motor or autonomic signs, obviously caused by calcineurin inhibitors. All cardiological examinations were normal. All blood tests were within the common range. Conclusion: From our data, there is no evidence that patients after DLT develop clinical signs of amyloidosis even if the follow-up time is limited. In the face of organ shortage, the use of domino grafts for elderly patients seems to be justified so far. Nevertheless, a close follow-up including physical, neurological, cardiologic, and laboratory examinations is deemed advisable in order to exclude a manifestation of the disease in the recipient of the domino graft and to learn more about the pathophysiology of amyloidosis.

DISCLOSURES:

The following people have nothing to disclose: Ana P. Barreiros, Rosa Walz, Christian Geber, Frank Birklein, Cathrin Theis, Christian Weiss, Felix Post, Karl F. Kreitner, Michael Heise, Marcus Schuchmann, Peter R. Galle, Gerd Otto
601 ASSESSMENT OF LIVER TRANSPLANT CANDIDATES BY AN ADDICTION MEDICINE SPECIALIST: A PROSPECTIVE STUDY

Hélène Rigole1, Pascale Perney1, Michaël Bismuth2, Francis Navarro2, Dominique Larrey2, François Blanc1, Georges-Philippe Pageaux2; 1Medicine E, CHU St Eloi, Montpellier, France; 2Digestive Department, CHU St Eloi, Montpellier, France

It is important, but not always performed, to ascertain an alcohol history in all patients undergoing liver transplantation (LT). However, the points of view of addiction specialists and LT specialists differ about their consideration of alcoholic disease. Aim: Assessment of alcohol behavior in LT candidates by an addiction specialist in order to appreciate this specific approach. Methods: All patients were seen during the pre-transplant evaluation by an addiction specialist. The diagnostic systems used to assess alcohol disorders were WHO classification, DSM-IV and Babor’s classification. The following characteristics were considered as predictive of severe alcohol relapse after LT: alcohol dependence, young age, number of withdrawals, family history of alcohol abuse, associated drugs and alcoholism. During the evaluation, a brief intervention about alcohol disorders was performed, and a specific management of alcohol abuse was proposed, not imposed, to all patients with predictive factors of severe relapse after LT. Results: 80 patients have been studied. The primary indication for LT was alcoholic liver disease (ALD) in 39 patients, HCV in 20 patients, HBV in 11 patients, others in 10 patients. Abnormal alcohol behavior was present in 57 of the 80 patients: the 39 ALD patients, 13 of 20 HCV patients, 5 of 11 HBV patients. Among these 57 alcohol abusers, 28 were excessive drinkers without dependence and 29 were alcohol-dependent: 19 of 39 ALD patients, 6 of 13 HCV patients, 4 of 5 HBV patients. Predictive factors of severe alcohol relapse after LT were found in 19 patients, 17 of alcohol-dependent patients and 2 of excessive drinkers. Only one of these 19 patients had accepted a pre-LT management of alcohol disorder. During the follow-up, 3 patients died, 1 was withdrawn from the waiting list, 41 are still on the waiting list and 35 have been transplanted: 20 ALD, 8 HCV, 7 others. With a mean follow-up of 6 months (3-16), no severe relapse was observed. Conclusion: A specific assessment of LT candidates by an addiction specialist has detected 71 % of alcohol abusers and 36 % of alcoholic dependant patients. Moreover, among patients with viral liver disease, 58 % were alcohol abusers and 32 % were alcohol-dependant. Predictive factors of severe alcohol relapse after LT were found in 23,7 % of patients. Among these, the majority did not adhere to a rehabilitation program. The impact of the pre-LT brief intervention is under evaluation. These preliminary results are in favor of the intervention of an addiction specialist during the evaluation of LT candidates.

602 THE READABILITY OF HEALTH EDUCATION MATERIALS FOR LIVER TRANSPLANT PATIENTS

Noel M. Lee1, Andrew Muir2, Carla Brady2; 1Department of Medicine, Duke University Medical Center, Durham, NC; 2Department of Medicine, Division of Gastroenterology, Duke University Medical Center, Durham, NC

The listing process for liver transplantation (LT) is complex and requires patients to comprehend their disease and aspects of LT care. However, millions of adult Americans are illiterate and may not benefit from printed LT educational tools. Laws require many public documents to be written at an eighth-grade level or lower to ensure readability. Aims: (1) To determine the readability of printed LT educational brochures, (2) to quantify educational levels of patients listed for LT, and (3) to determine if demographic factors are associated with patient educational level. Methods: We used the United Network for Organ Sharing database to identify U.S. citizens listed for LT from 1987 to 2005. Chi-squared analysis and Hests determined the relationship between patient demographic factors and educational level. Readability of brochures was determined by using computer software that measured Flesch Reading Ease scores and Flesch-Kincaid grade levels. Reading ease scores range from 0 to 100, with lower scores indicating increased difficulty in readability. Results: Of 60,222 patients, 22,533 (37.42%) were female and 37,689 (62.58%) were male; 3043 (5.05%) had less than high school education; 57,179 (94.95%) had a high school education or above. Patients with less than high school education were more likely to be female, of older age, have Medicare or Medicaid, and be of Hispanic, Asian, or other race (table). Calculated Flesch-Kincaid grade levels and Reading Ease scores for brochures were: American Society of Transplantation: Getting a New Liver (6.2, 74.7), American Liver Foundation (ALF) Liver Transplant (6.6, 71.9), National Institutes of Health: What I Need to Know About Liver Transplantation (7.2, 67.5), American Liver Society LT brochure (7.3, 67.3), and ALF Facts on Liver Transplantation (11.4, 42.1). Conclusions: Most LT patients have completed at least the eighth grade and are likely to understand LT educational brochures. However, the LT evaluation process may exclude many patients with poor literacy skills, and current brochures may be too advanced for those who are beginning to consider LT.

603 LONG TERM OUTCOMES OF LIVER TRANSPLANTATION IN A HIGH-MELD COHORT

Jason Lee1,2, Maximillian Lee1, Lynn Shapiro1, Alice L. Yang1, Alex S. Lapasaran1, Sanah Parvez1, Ahmad Kamali3, Emmet B. Kefee1, Charles O. Esquivel1, Aijaz Ahmed1; 1Liver Transplant Program, Stanford University School of Medicine, Stanford, CA; 2Center for Primary Care and Outcomes Research, Stanford University School of Medicine, Stanford, CA; 3Division of Gastroenterology, Santa Clara Valley Medical Center, San Jose, CA

BACKGROUND: MELD scores predict both pre-transplant and post-transplant mortality. Diabetes mellitus has also been shown to predict post-transplant mortality, but the relative importance of these two factors remains unknown. METHODS: We reviewed all adult liver transplants performed at our institution between February 1995 and June 2006. Of 530 transplants performed, information regarding MELD score and the pres-
ence or absence of diabetes was available for 431. Patients with acute liver failure (n=17), those undergoing kidney-liver transplant (n=28), and those who died prior to discharge (n=51) were excluded. The remaining 370 patients were divided into four groups, based on MELD score (<30 or ≥30) and the presence or absence of diabetes. RESULTS: As expected, survival was poorer in the high MELD group (log-rank statistic 23.2, p<0.001). However, patients with a MELD score ≥30 and without diabetes had a similar outcome as patients with a MELD score less than 30 and with diabetes (log-rank statistic 0.51, p =0.47). The outcome was poor in patients with diabetes and MELD ≥30, but the observation in this group was limited by a small sample size and needs to be studied further. CONCLUSIONS: Our results suggest that patients with MELD score ≥30 in the absence of diabetes have a favorable post-transplant outcome. The presence or absence of diabetes appears to limit the reliability of MELD score as an allocation system for liver transplantation and its ability to predict post-transplant survival outcomes. Further validation studies are needed to assess the impact of diabetes on MELD score.

### 604 CORONARY ARTERY DISEASE SCREENING IN LIVER TRANSPLANTATION CANDIDATES

Daniela Fili¹, Giovanni Vizzini¹, Domenico Biondo², Riccardo Volpes¹, Giada Pietrosi¹, Marzia Montalbano¹, Ioannis Petridis¹, Adele D'Antoni¹, Cesare Scardulla¹, Cesar Hernandez Baravoglia², Angela Luca³, Bruno Gridelli³, ¹Hepatology, ISMETT, UPMC Italy, Palermo, Italy; ²Surgery, ISMETT, UPMC Italy, Palermo, Italy; ³Office of Research Health and Biomedical Sciences, ISMETT, UPMC Italy, Palermo, Italy

Background/Aim: In order to identify coronary artery disease in patients with end stage liver disease candidates to liver transplantation (LT), pre LT cardiac evaluation and instrumental screening for coronary artery disease is usually performed. We reviewed through a retrospective analysis accuracy and utility of our coronary artery disease screening protocol in LT candidates. Methods: LT candidates undergo a detailed clinical history with detection of coronary artery disease clinical predictors and definition of risk profile. Patients with medium/high risk profile (1 or more risk factors) perform stress test and, if positive, selective coronary angiography (SCA). Results: Between July 1999 and January 2006, 627 patients with end stage liver disease due to liver cirrhosis were evaluated for LT. 569 were listed and 235 transplanted. 16 patients had a previous diagnosis of coronary artery disease (2.5%). Risk profile analysis showed that 360 male were aged more the 49 years (58.7%), 83 female were aged more than 54 years (13.2%); 229 patients (36.5%) were smokers, 161 (25.7%) had diabetes, 71 hypertension (11.3%), 83 obesity (13.2%), 20 hypercholesterolemia (3.2%), 75 family history (12%). Analysis of the group of patients without a known coronary artery disease (611) showed: 101 patients without risk factors did not have any stress test. 510 patients with medium/high risk profile underwent stress test: 480 resulted negative and 30 positive. 29 patients with positive stress test underwent SCA: we found 2 patients with not critical coronary artery disease not requiring angioplasty. No coronary events occurred during the waiting time (f-up 32 months, SD 24, median 30) in all the population of 611 patients, and no peri-operative mortality related to CAD occurred in the 235 transplanted patients. Conclusions: The observed prevalence of silent myocardial ischemia in this study was extremely low, as well as the positive predictive value of the stress test. Patient’s clinical history and careful identification of risk factors gave the major contribution to the screening process.

### 605 EARLY HEPATOCYTE C4D EXPRESSION AND FAILURE TO RESTORE BASAL HEPATIC TOTAL PROTEIN CONTENT AFTER ISCHEMIA REPERFUSION INJURY ARE ASSOCIATED WITH ONE YEAR GRAFT LOSS IN HUMAN LIVER TRANSPLANTATION

Paola Barsotti¹, Maria Siciliano², Rosanna De Marco², Antonio Molinaro², Andrea Onetti Muda¹, Novella Gualtieri¹, Manuela Merli², Adolfo Francesco Athili², Pasquale Bertolo², Massimo Rossi², Stefano Ginanni Corradini², ¹Experimental Medicine, Universita’ La Sapienza Roma, Roma, Italy; ²Clinical Medicine, Universita’ La Sapienza Roma, Roma, Italy; ³General Surgery Paride Stefanini, Universita’ La Sapienza Roma, Roma, Italy

Hepatic expression of several proteins, including albumin, is reduced during ischemia and restored upon reperfusion in human liver transplantation [J Pathol 2005;207:111–118]. Complement activation during ischemia reperfusion injury has been reported in renal, liver, intestine and heart allografts. A link between proteolysis and complement activation has been demonstrated in myocardial ischemia reperfusion damage [Proteomics 2002;2:988–995]. To better elucidate the mechanism and prognostic significance of complement activation in hepatic ischemia reperfusion injury we measured early changes of liver graft C4d expression and total protein content during liver transplantation. Liver graft samples were obtained from heartbeating donors before the aorta was clamped (T1) and 2 hours after reperfusion in the recipient (T2) during primary whole organ liver transplantation. Total protein content was measured by the Bio-Rad protein assay method in freeze-dried liver homogenates from 47 grafts. In a subgroup of 29 grafts C4d immunohistochemistry was performed on paraffin sections and positive hepatocytes were scored on a semiquantitative scale. The data were evaluated comparing grafts which were lost for liver–related reasons or surviving at one year follow up. Intergroup differences were assessed by the Mann-Whitney U test. Correlations were analysed by the Spearman rank test. Lost grafts [n=10] had a significantly [P<0.05] higher difference between total protein content in T1 and in T2 than surviving grafts [n=37] [31.55±31.51 vs 2.41±33.16 µg/mg dry liver, respectively]. C4d hepatocyte immunohistochemistry was negative in both lost and surviving grafts T1 samples. Lost grafts [n=9] showed a significantly [P<0.05] higher T2 C4d hepatocyte-score than surviving grafts [n=20] [4.44±1.67 vs 2.55±2.28 C4d, respectively]. When lost and surviving grafts
were considered together, a positive correlation was found between T2 C4d hepatocyte score and the difference between total protein content in T1 and in T2 (r= 0.547, P<0.01). Early complement activation and impaired restoring of graft protein content after reperfusion are linked events in hepatic ischemia reperfusion injury and are associated with graft loss within the first year after human liver transplantation.

607 RESECTION OF HEPATOCELLULAR CARCINOMA: LONG-TERM OUTCOME

Stefan Grune1, Hans-Juergen Schlitt2, Reiner Wiest1, Frank Klebl1, Aiman Obed2, Juergen Schoelmerich3, Gabi I. Kirchner1; 1Internal Medicine I, University Hospital of Regensburg, Regensburg, Germany; 2Clinic of Surgery, University Hospital of Regensburg, Regensburg, Germany

Partial liver resection and liver transplantation are potential curative therapies for hepatocellular carcinomas (HCC). Only few patients are suitable for these therapies. The aim of our study was to investigate the long-term outcome for patients who underwent liver resection for HCC. Patients: In a retrospective study data of 67 HCC patients, who had partial liver resection, were analyzed. The mean age at time of resection was 63±12 yrs (56±9w). Forty-one patients had a liver cirrhosis Child A, 26 patients had no cirrhosis. Patients underwent either resection of liver segments or extended hemihepatectomy. Alpha-fetoprotein of >400 ng/ml was found in 11 of 67 patients. The mean time of follow-up after liver resection was 29±30 months. We analyzed duration of stay in hospital, complications after surgery, age, size of tumor, CLIP-stages, tumor grading at time of operation and incidence and localization of tumor recurrence. Results: The 1- and 4-yr survival time of our patients amounted to 69% and 37%, respectively. The tumor-free survival time was 62% and 37%, respectively. The mean stay in hospital was 17±13 days. After surgery 7 patients (sepsis n=6, myocardial infarction n=1; thereof 5 were cirrhotic patients) died. Tumor size, presence of cirrhosis, CLIP-stage and tumor grading did not significantly influence long-term survival. In contrast, patients with an age <65 yrs at time of resection had a significantly better 4-yr-survival (54%) than older patients (16%; p=0.026). Forty-six percent of patients suffered from tumor recurrence within 4 months to 8 yrs. In 30% of patients the first tumor recurrence occurred in the liver. Time of tumor recurrence was nearly the same in cirrhotic versus non cirrhotic patients (15±14 vs. 18±25 months, respectively). Metastases occurred in lung, bone, adrenal gland, lymph nodes, cardio and peritoneal carcinomatosis. Conclusion: Resection of HCC is a promising therapeutic option in well selected patients. An age over 65 years was a negative predictive factor for long-term outcome after HCC resection.

608 MINIMISING BILIARY COMPLICATIONS AFTER TRANSPLANTATION OF LIVERS FROM DONORS AFTER CARDIAC DEATH

Paolo Muesian, Adam Bartlett, Wayel Jassem, Walid Faraj, Mohamed Rela, Nigel Heaton; Institute of Liver Studies, King's College Hospital, London, United Kingdom

Background: Liver transplantation (LT) using grafts from donors after cardiac death (DCD) is troubled by a high rate of biliary complications and ischemic cholangiopathy (IC). We report a low rate of biliary complications and IC in the largest liver DCD programme in Europe. Methods: From April 2001 131 livers were retrieved from DCD. Of these, 74 were transplanted. The
ALLOGRAFT SURVIVAL IS DECREASED IN PATIENTS WITH RECURRENT PRIMARY SCLEROSING CHOLANGITIS

Cynthia Levy1,2, Claudia O. Zein3, Chaoru Chen2, David R. Nelson2, 1Division of Gastroenterology and Hepatology, Malcolm Randall VAMC, Gainesville, FL; 2Division of Gastroenterology, Hepatology and Nutrition, University of Florida, Gainesville, FL; 3Division of Gastroenterology and Hepatology, Cleveland Clinic, Cleveland, OH

Background: Recurrence of primary sclerosing cholangitis (r-PSC) is a well-recognized complication after orthotopic liver transplantation (OLT). However, its prevalence, predictors and impact on graft and patient survival remain poorly characterized. Aims: The goals of this study were (1) to estimate the prevalence of r-PSC, (2) to determine the predictors of r-PSC and (3) to determine the impact of r-PSC on allograft and patient survival. Methods: All 54 patients who underwent OLT at the University of Florida between 1990 and 2006 for primary sclerosing cholangitis were considered for the study. Those with follow-up less than 4 months (n=5) were excluded. Associations between potential predictive variables and r-PSC were measured using appropriate statistical tests. Variables explored as potential predictors of r-PSC were recipient age/gender, donor age/gender, gender mismatch, cold and warm ischemic times, CMV infection, rejection, use of OKT3, concomitant inflammatory bowel disease, prior colectomy, duration of PSC and immunosuppressive agent. Logistic regression was performed to identify independent predictors of r-PSC post OLT. The Log-rank test was applied to test the difference between stratified survival curves. Similar methods were used to test an independent group of 41 patients transplanted between 1995 and 2004 at the Cleveland Clinic and with follow-up of at least 4 months. Results: Forty nine patients, 78% males, with mean follow-up of 60.7 ± 43.6 months constituted our original cohort. Mean age at the time of OLT was 41.9 ± 13.4 years. r-PSC was diagnosed in 12 (24.5%) cases. The mean time to recurrence was 35.2 ± 26.2 months. Variables found to predict r-PSC were CMV infection (p=0.013) and multiple, but not single, rejection episodes (p=0.037). On multivariate analysis, CMV infection was a strong predictor of r-PSC in patients without history of multiple episodes of rejection (Relative Risk=17, p=0.046). There were 4 re-transplantations, all among patients with r-PSC. Overall patient survival was not different between patients with and without r-PSC, but allograft survival was shorter in those with r-PSC (p=0.001). In the Cleveland Clinic cohort, 6 of 41 patients had r-PSC (15%); CMV infection was the only independent predictor of r-PSC (p=0.035). Six patients underwent re-transplantation, 4 had r-PSC. Allograft survival was decreased in patients with r-PSC (p=0.0006). Conclusion: In two independent cohorts from 2 large transplant centers, r-PSC occurred in 15% and 25% of patients. CMV infection and multiple episodes of rejection appear to increase the risk of r-PSC. Development of r-PSC significantly impacts graft survival.

611 DEVELOPMENT OF A UK SCORE FOR PATIENTS WITH END-STAGE LIVER DISEASE

Kerri M. Barber1, Sue E. Pioli1, Joanne E. Blackwell1, Dave Collett1, James M. Neuberger2, Alexander E. Gimson2; 1Statistics and Audit, UK Transplant, Bristol, United Kingdom; 2Hepatobiliary and Liver Transplant Unit, Addenbrooke’s Hospital, Cambridge, United Kingdom; 3Liver Unit, Queen Elizabeth Hospital, Birmingham, United Kingdom

Background: Although the MELD score is widely used to predict mortality on the liver transplant list, it has not been validated for use in the UK. A score for UK patients with end-stage liver disease has therefore been developed. Methods: The study cohort comprised adult elective patients registered for their first liver transplant at the 7 UK centres between 1 April 2003 and 31 March 2006. Patients were followed-up until death, liver transplantation or last known follow-up. Patients with any type of cancer recorded as their primary liver disease were excluded. The resulting cohort comprised 1,103 patients. Cox proportional hazards models were used in modelling the hazard of death on the list. The clinical components considered for inclusion in the UK specific score, termed UKELD, were INR, serum creatinine, bilirubin and sodium, and the UKELD score was expressed as a linear combination of the logarithms of the clinical components. The UKELD score was compared to MELD and MELD-Na by computing the change in the log likelihood (2logl) statistic on adding each of the three scores to a Cox model that included relevant patient-specific factors. The UKELD score was validated using data from the 7 UK centres on adult elective patients registered for their first liver transplant between 1 April 2006 and 31 March 2007. The resulting cohort comprised 452 patients. The patients in the validation cohort were divided into 3 groups based on their risk score, with patients having a high, medium and low score. The Kaplan-Meier estimate of the survivor function for each group was then compared to the model based estimates of the survivor function, adjusted for patient-specific factors. Results: The UKELD score is calculated using the following formula: UKELD=[(5.395xln(INR))+{1.485xln(creatinine)}]+{3.13xln(bilirubin)}-{81.565xln(sodium)}]-435. The results from the validation cohort confirmed this score is an appropriate measure of disease severity for UK patients. As UKELD increases the risk of death on the transplant list also increases. UKELD was found to be a superior predictor of mortality on the transplant list compared to MELD and MELD-Na. Conclusion: The UKELD score is deemed appropriate to use to predict mortality on the transplant list for UK patients with end-stage liver disease. Patients with cancer and those with other variant diseases may need to be awarded additional UKELD points to avoid disadvantaging them.

612 PROPOSAL OF NEW SELECTION CRITERIA FOR LIVING DONOR LIVER TRANSPLANTATION CANDIDATES FOR HEPATOCELLULAR CARCINOMA

Akinobu Taketomi, Kensaku Sanefuji, Tomohiro Iguchi, Hiroto Kayashima, Noboru Harada, Keishi Sugimachi, Yo-ichi Yamashita, Tohru Ikegami, Tomoharu Yoshizumi, Yui Soejima, Yoshihiko Maehara; Department of Surgery and Science, Kyushu University, Fukuoka, Japan

Introduction: The Milan criteria have been accepted as the selection criteria for hepatocellular carcinoma (HCC) patients. However, many patients who did not meet the Milan criteria have survived after undergoing living donor liver transplantation (LDLT). As a result, different patient selection criteria are thus considered to be necessary in LDLT in order to save as many individuals as possible with advanced HCC. Patients and Methods: Of 214 adult-to-adult LDLT patients, 90 with concurrent HCC were included in the study. The mean age of the patients was 56.8 years old (range: 21 to 70). Sixty-five patients (72.2%) suffered from a hepatitis C virus infection. The overall survival rates according to various factors were compared to identify the risk factors for survival and to establish new selection criteria for LDLT candidates for HCC. Results: Fifty-three patients (58.9%) preoperatively exceeded the Milan criteria. The 1-, 3- and 5-year overall survival rates of the patients who fulfilled the Milan criteria were 100%, 100%, and 100%, respectively, whereas those for patients who exceeded the criteria were 85.5%, 82.8%, and 85.8%, respectively. In a multivariate analysis, both the tumor diameter (p=0.0187) and the des-gamma-carboxy prothrombin value (DCP; p=0.026) were found to be favorable independent factors of survival after LDLT. Therefore, the authors devised new selection criteria for HCC patients (which are named the KU criteria; a tumor diameter of less than 5 cm or a DCP of less than 300 mAU/ml). The 1-, 3- and 5-year overall or recurrence-free survival rates of the 85 patients who met the KU criteria were 92.1 / 85.2 / 85.2% or 90.6 / 87.1 / 87.1%, respectively, which were significantly different from those of the 5 patients who did not meet the KU criteria (80 / 20 / - % or 20 / 0 / 0 %; p< 0.0001). Conclusions: A combination of two factors, namely the tumor size and the DCP level, was found to be useful for predicting survival after LDLT. These new selection criteria (the KU criteria) might therefore be useful for expanding the selection of LDLT candidates for HCC.

Disclosures: The following people have nothing to disclose: Akinobu Taketomi, Kensaku Sanefuji, Tomohiro Iguchi, Hiroto Kayashima, Noboru Harada, Keishi Sugimachi, Yo-ichi Yamashita, Tohru Ikegami, Tomoharu Yoshizumi, Yui Soejima, Yoshihiko Maehara

613 C4D IMMUNOHISTOCHEMICAL (IHC) REACTIVITY AS AN ADJUNCT IN DISTINGUISHING BETWEEN ACUTE CELLULAR REJECTION (ACR) AND RECURRENT HEPATITIS C VIRAL (HCV) INFECTION IN LIVER TRANSPLANTS

Luminita Marinescu1, Danisa Mandrich1, Richard Cartun1, David Hull2, John Polio2, Mike Grupka2, Saverio Ligato1; 1Pathology, Hartford Hospital, Hartford, CT; 2Transplant Surgery, Hartford Hospital, Hartford, CT

End stage liver disease due to Hepatitis C is the most common indication for liver transplant in the US. Distinguishing between acute cellular rejection (ACR) and recurrent hepatitis C virus (HCV) infection is notoriously difficult since these entities lack specific morphological features. In this study we evaluated the
value of immunohistochemical stain for C4d in facilitating the distinction between ACR and rHCV infection. Material and methods: Fifteen (15) cases with the histologic diagnosis of ACR, 16 cases with the histologic diagnosis of rHCV infection, and a control group of 16 cases of non-transplanted liver (9 cases of normal liver, 7 cases of chronic hepatitis C) were studied. Each case was stained with a polyclonal antibody for C4d (American Research Products. Inc, Belmont, MA) and evaluated for C4d immunoreactivity. Positive staining was evaluated in the portal veins, portal stroma portal capillaries, portal arteries and central veins. The intensity of stain was semi-quantitatively reported as 1+, 2+ and 3+. Clinical information including time after transplant, medication, viral status, treatment after the biopsy, and outcome were retrospectively reviewed and correlated with the pathologic diagnosis and C4d reactivity. Results: Ten of 15 cases with pathologic diagnosis of ACR, 8 met clinical criteria and were treated. Of these 8, 6(75%) were C4d positive. Of the remaining seven cases (46.6%) histologically interpreted as ACR, 4 were treated as rHCV infection. In this second group, C4d was positive in only 1/4 cases (25%). The remaining 3 cases, showed hepatic artery thrombosis in 2 (with 1/2 cases C4d +) and hepatic vein thrombosis in 1 case (C4d +). In summary, C4d was expressed in 75% of cases histologically and clinically proven as ACR, and showed a specificity of 71%, a PPV of 75% and a NPV of 71%. In the group of 16 cases with histological and clinically proven rHCV infection, C4d was positive in 3/16 cases (18.7%). In the control group, only 1/16 cases was C4d +. Difference in detection of C4d was statistically significant when comparing rejection cases to controls (p<0.001) as well as between rejection and rHVC-cases (p<0.021). Conclusion: IHC stain for C4d is expressed in 75% of cases of histologically and clinically proven ACR; in 18.7% of cases of liver transplant with rHCV infection, and 6% of the controls. In conclusion, this study suggests that C4d may be helpful in differentiating ACR from rHCV infection in liver transplants. Our findings suggest that C4d could be used as an adjunct to complement the conventional histopathological criteria in the distinction between rHCV infection and ACR.

615 OUTCOME DIFFERENCES AFTER LIVING DONOR LIVER TRANSPLANTATION (LDLT) IN ADULTS WITH AUTOIMMUNE AND CHOLESTATIC LIVER DISEASES: SRTR ANALYSIS

Adel Bozorgzadeh1, Parvez S. Mantry1,2, Randeep Kashyap2; 1Division of Gastroenterology and Hepatology, Strong Memorial Hospital, Rochester, NY; 2Division of Solid Organ Transplantation and Hepatology Surgery, Strong Memorial Hospital, Rochester, NY

Introduction: Autoimmune hepatitis (AIH), Primary Biliary Cirrhosis (PBC) and Primary Sclerosing Cholangitis (PSC) all lead to progressive liver disease needing liver transplantation. Living Donor Liver Transplantation (LDLT) has been used in adults with complications linked to these conditions as an alternative to deceased donor liver transplantation (DDLT). There are no comparative data between autoimmune and cholestatic liver diseases in terms of outcomes after LDLT. Our objective was to determine outcome differences between AIH, PBC and PSC after LDLT using the SRTR database and to explain these differences based on the known natural history of these diseases and recurrence after liver transplantation. Methods: We reviewed all LDLTs done in the US for autoimmune (AIH) and cholestatic liver disease (PBC and PSC) between 1995 and 2006. The results were analyzed using SPSS vs. 14.0. Results: 502 LDLTs were performed for PSC (34%), PBC (31%) and AIH (12%) in this time period. The overall female to male ratio was 1.4:1. The median age of the recipients was 47 yrs. The median MELD scores at time of transplant for patients in all 3 groups were similar (however 60% of all transplants were done after MELD score started being utilized). The median age of the recipients...
at time of transplant was PBC (53.3yrs) being the oldest compared to those with AIH (42.9yrs) and PSC (44.7yrs). The mean survival of all the 3 conditions was as follows: PBC 1786 days; PSC 2228 days and AIH 2136 days. The 1, 3 and 5 yrs survival were as follows: AIH (84.7%,84.7%, 77.6%), PBC (81%,76.6%,66.4%) and PSC (87.4%,86.8%,74.3%) respectively. We found that patients with PBC had a worse outcome compared to AIH and PSC after LDLT (p value 0.024).

**Discussion:** LDLT is a very favorable alternative to DDLT in patients with autoimmune liver disease awaiting liver transplantation. In this analysis, patients with PBC had a worse survival as compared to PSC and AIH after LDLT. We found that PBC patients were older at the time of transplantation compared to AIH and PSC recipients. An earlier study reported 5 yr survival after LDLT for PBC to be 80% 1. PBC has the highest rate of recurrence after liver transplantation. The poorer outcome of PBC compared to AIH and PSC may be linked to older recipient age at time of LDLT and higher rate of recurrence. This sheds light on a previously unreported aspect of autoimmune and cholestatic liver diseases with regards to living donor liver transplantation. Reference: Hasegawa et al. Living Donor Liver Transplantation for Primary Biliary Cirrhosis- retrospective analysis of 50 patients at a single center. Transplant International Vol.18:7,794-799 July 2005

**616 TRANSPLANT COSTS OF ADULT LIVING DONOR LIVER TRANSPLANTATION AT AN EXPERIENCED TRANSPLANT CENTER ARE SIMILAR TO DECEASED DONOR LIVER TRANSPLANTATION DESPITE INCREASED SURGICAL COSTS**

Jennifer C. Lai1, Jean C. Emond2,4, Robert S. Brown3,4; 1Medicine, New York Presbyterian Hospital, Columbia, New York, NY; 2Surgery, Columbia University College of Physicians & Surgeons, New York, NY; 3Medicine, Columbia University College of Physicians & Surgeons, New York, NY; 4Center for Liver Disease & Transplantation, Columbia University College of Physicians & Surgeons, New York, NY

**BACKGROUND:** The growing deficit of organs available for transplantation warrants continued evaluation of the application of adult living donor liver transplantation (LDLT). Several studies have reported the costs of deceased donor liver transplantation (DDLT), but data regarding the costs of LDLT are limited by including early experience, which is associated with increased complication rates, and small sample sizes. AIM: To provide a comparison of transplant hospitalization costs of LDLT vs DDLT after the initial experience. METHODS: This was a retrospective cohort of consecutive patients who received liver transplants at our institution from 1/1/00-12/31/06 for whom financial data were available. Our primary outcome was cost, estimated from total charges of the transplant hospitalization (converted into relative cost units), including donor charges for LDLT. All charges were classified into cost categories, including: floor services, diagnostics, laboratory, surgical, pharmacy, and other services. Our independent variable was type of transplant (LDLT/DDLT). Covariates included age, sex, race, insurance status, MELD, and length of stay (LOS).

Any variable associated with total costs (p<.2) in bivariate analysis was included in multivariate analysis (MVA) with and without LOS as a covariate. RESULTS: This study included 469 patients (n=84 LDLT vs n=385 DDLT). Baseline characteristics differed substantially between LDLT and DDLT, including age (50 vs 54 yrs, respectively), %male (51% vs 74%), pre-transplant MELD (20.6 vs 23), %white (62% vs 48%), %black (1% vs 12%), %Hispanic-white (30% vs 18%), and %other (7% vs 22%). LOS and insurance status were similar. Total charges for LDLT were 5% lower than for DDLT, but this was not statistically significant (Table). Cost category analysis revealed increased surgical charges for LDLT, but decreased charges for labs and pharmacy (Table). In MVA, LDLT was similar in cost to DDLT after adjustment for age, black race, private insurance, and MELD score, both with (p=0.53) and without (p=0.31) adjustment for LOS. Age, MELD, and black race did predict higher cost.

**CONCLUSION:** In a comparison of the financial costs of LDLT vs DDLT at an experienced transplant center, overall transplant costs of LDLT were similar to DDLT, despite increased surgical costs.

**Table: Comparison of total and select cost category charges, in relative cost units**

**617 SUCCESSFUL ALGORITHM FOR SELECTIVE LIVER BIOPSY IN THE RIGHT LOBE LIVER DONOR (RLD)**

Mary Ann Simpson, Jennifer E. Verbesey, Urmila Khettry, Fredric Gordon, James J. Pomposelli, Roger L. Jenkins, Elizabeth A. Pomfret; Liver transplantation, Lahey Clinic, Burlington, MA

**Background:** Routine vs. selective pre-donation liver biopsy (LBx) remains controversial for assuring the safety of RLD. We report the results of our selective algorithm for LBx in RLD. Methods: Between 12/99 and 3/07, 380 potential RLD were evaluated and 131 donated. Indications for selective LBx were: abnormal liver function tests, abnormalities noted on imaging studies, BMI>28, and a genetic relation to a recipient with immune mediated liver disease. All donors had a LBx at the time of surgery. The same pathologist reviewed all LBx. Results: Of the 380 potential RLD evaluated (53.9% male, mean age 37.6), 139(36.6%) were accepted as donors, 140(36.8%) were rejected for either donor or recipient reasons, 68(17.9%) withdrew from the process, 23(6.1%) had their recipient receive a deceased donor graft, and 10(2.6%) are currently completing evaluation. 81(21.3%) met criteria and had a selective LBx. 7 results are still pending. 58(78.4%) had either normal (n=21) or mild macrosteatosis of 0-5%(n=37) and 40 of these went on to LD right hepatectomy (LDRH). 12 RLD were eliminated as donors as a result of abnormal LBx. Of the 89 who did not have LBx, none had abnormal liver histology at LDRH. 3/81 (3.7%) had complications from the LBx resulting in overnight admission (2 for pain, 1 for bleeding, transfusion not required).Conclusions: Use of this algorithm for selective pre-donation LBx in the RLD resulted in 78.7% of potential donors avoiding biopsy and potential complications. No significant liver pathology was identified in donors not meeting criteria for LBx. Routine pre-donation LBx is unnecessary in potential RLD.

**Disclosures:** The following people have nothing to disclose: Mary Ann Simpson, Jennifer E. Verbesey, Urmila Khettry, Fredric Gordon, James J. Pomposelli, Roger L. Jenkins, Elizabeth A. Pomfret
618 HIGH MELD SCORES DO NOT PREDICT ONE-YEAR SURVIVAL RATE OF PATIENTS WITH A SMALL-FOR-SIZE GRAFT IN ADULT LIVING DONOR LIVER TRANSPLANTATION

Nam-Joon Yi1, Kyung-Suk Suh1, Hae Won Lee1, Woo Young Shin1, Jung-Hwan Yoon1, Kuhn Uk Lee1; 1Surgery, Seoul National University College of Medicine, Seoul, South Korea; 2Internal Medicine, Seoul National University College of Medicine, Seoul, South Korea

Adul living donor liver transplantation (ALDLT) has shown comparable outcome to the deceased donor recipients because of being better risk candidates. However, outcome of very ill patients with high MELD score is fairly elusive especially in small grafts (< 0.8% of graft-to-recipient weight ratio, GRWR) in ALDLT. Between 1999 and 2005, consecutive 167 hepatitis B virus-infected recipients underwent ALDLT at our center. Based on pre-transplant MELD, recipients were stratified as low risk (<25, Group L, n=105) and high risk (>25, Group H, n=62). To analyze the risk of graft size in very ill patients, patients were divided HR (high risk group; MELD score >25 and GRWR < 0.8%), LR (low risk group; MELD >25 or GRWR <0.8%), and NR (no risk group; MELD ≤25 and GRWR ≥ 0.8%) group. Primary end points were one-year patient survival. Post-transplant follow-up was 32.6 months. Mean MELD scores were 17.1 in Group L and 32.6 in Group H. In pre-transplant recipients' data, Group H more frequently had uncontrolled ascites (50.0%), encephalopathy (64.5%), bacterial peritonitis (48.4%), and UNOS status 2A (38.7%) than Group L (27.6%, 30.5%, 27.6% and 4.8%) (p<0.05). Accompanying hepatocellular carcinoma (HCC) was more common in Group L (61.0%) than in Group H (22.6%) (p=0.000). Mean hospital stay were 33 days in Group L and 47 days in Group H (p=0.000). One-year patient survival rate (1-YSR) was 86.7% in Group L and 83.8% in Group H, respectively (p=0.48). There was no significant difference in 1-YSR among HR (72.7%), LR (84.6%), and NR (88.5%) group, respectively (p=0.278). Multivariate analysis revealed accompanying HCC and early transplant year to be risk factors of poor outcome (1-YSR) (p<0.05). In conclusion, high MELD scores (>25) do not predict 1-YSR of recipients with small-for-size grafts in ALDLT for hepatitis B related liver disease. Because, factors associated with 1-YSR were accompanying HCC and early transplant year, accumulation of center’s experience may improve the early post-transplant survival even in very ill patients.

619 IMPACT OF ISCHEMIC PRECONDITIONING IN GRAFT FUNCTION AND INFLAMMATORY MEDIATORS IN ORTHOTOPIC LIVER TRANSPLANTATION

Linda E. Muñoz Espinosa1,2, Homero Zapata2, Paula Cordero1, Miguel Escobedo2, Liliana Torres1, Belia Garduño2, Edelmiro Perez2, Magadalena Cepeda1, Marcela De Luna1, Amanda Mercado1, Briceluid Garza1, Eloy Caballero1, Joan Roselló5; 1Liver Unit, University Hospital "Dr. Jose Eleuterio Gonzalez", Monterrey, Mexico; 2Transplants Department, University Hospital, Monterrey, Mexico; 3Pathology Department, University Hospital, Monterrey, Mexico; 4Department of Experimental Pathology, Biomedical Investigation Institute of Barcelona, Barcelona, Spain

INTRODUCTION: Ischemic preconditioning (IP) has been proposed to improve graft function in orthotopic liver transplantation (OLT). The aim of this study was to determine whether IP in OLT improves graft function, to study inflammatory mediators implicated in IR injury and to correlate the liver biopsies. Material and methods: this is a randomized and prospective study, this includes 12 patients with OLT and their cadaveric donors, we made 2 groups, with and without IP. Ischemic preconditioning was performed in 5 donors for 10 min. followed by 10 reperfusion min. Seven patients were transplanted with the classic technique. The etiologies of the liver cirrhosis were alcohol and autoimmune 25% each one, virus C 17%, virus B and hepatocellular carcinoma, cryptogenic, secondary biliary cirrhosis and Budd Chiari 8.3% each one. The myeloperoxidase (MPO), p-selectin (PS), leuocriinin B4 (LTB4), and ICAM1 were measured by ELISA in the different phases of the transplant (prepararatomy (phase R1), preperfusion (phase R2) and postreperfusion (phase R3). Liver biopsies were performed before procurement in the 3 phases of the receptor mention above. RESULTS: The PS in the group with IP in the donor (D) phase showed high levels (24 ng/mL), while in the other phases the levels diminished, the R3 phase of the group without PI showed higher levels (33 ng/mL) with respect to the other phases. The ICAM1 in the group with IP were diminished in the R3 phase (391 ng/mL), the patients with IP maintained similar levels. LTB4 levels were increased in the group with IP in the R3 phase (29 ng/mL), and diminished in the same phase of the group without IP (8 ng/mL). MPO showed similar levels in both groups. The AST in the group with IP vs without IP in the phase R3 was 26 vs 11.8 times above the upper normal limit (TAUNL). The ALT was similar in both groups. Histopathology: the introtoclasticm vacuolisation, confluent necrosis and nuclear focal picnosis were similar in both groups, the neutrophilic infiltration was observed in all patients with IP vs 2/7 of the group without IP. One patient with more than 50% steatosis (group with IP). There were no cases of primary dysfunction of the graft. The mortality was 17% (2 without IP). CONCLUSIONS: The inflammatory mediators didn’t show a characteristic pattern, there was higher elevation of AST in the group with IP. Neutrophilic infiltration was more common in liver biopsies with IP, however MPO did not show differences. This is an ongoing study, a larger population should be included before drawing definite conclusions on IP effects in OLT.

620 INFLUENCE OF DIFFERENT LABORATORY METHODS ON MELD CALCULATION IN THE BELGIAN LIVER TRANSPLANT CENTRES

Jeffrey Schouten1, Sven M. Francque1, Hans Van Vlierberghe2, Isabelle Collé2, Frederik Nevens3, Jean Delwaide4, Michael Adler2, Peter Stärkel5, Dirk Ysebaert6, Alain Gadisseur7, Peter P. Michielsen1; 1Hepatogastroenterology, University Hospital of Antwerp, Edegem, Belgium; 2Hepatogastroenterology, University Hospital of Ghent, Ghent, Belgium; 3Hepatogastroenterology, UZ Gasthuisberg Leuven, Leuven, Belgium; 4Hepatogastroenterology, U Liege, Liege, Belgium; 5Hepatogastroenterology, ULB Brussels, Brussels, Belgium; 6Hepatogastroenterology, Universite Catholique de Louvain Brussels, Brussels, Belgium; 7Hematology, University Hospital of Antwerp, Edegem, Belgium; 8Hepatobiliary surgery, University Hospital of Antwerp, Edegem, Belgium

Introduction: Liver allocation in Eurotransplant is based on the MELD score only including so called “objective” parameters (INR, bilirubin, creatinine). This score, theoretically, permits no
subjective centre dependent variation in priority for liver transplantation. It was recently shown that the laboratory methods, used to determine the MELD score may introduce significant and clinically relevant variation in this score between different laboratories. The aim of the study was to investigate whether significant differences in MELD score are obtained in patients with liver cirrhosis between the Belgian liver transplant centres. Patients and methods: Sixty five patients with biopsy proven cirrhosis (15 Child A, 25 Child B and 25 Child C) in 2 centres were enrolled. From each patient 6 aliquots were drawn, each aliquot containing samples for analysis of creatinine, bilirubin and INR. Analyses were performed in the 6 liver transplant centres. Control aliquots from 30 healthy volunteers and 30 patients receiving oral anticoagulants were collected for measurement of the same parameters at the same 6 centres. Multivariate analysis (within factor: 6 different centres and between factors: 5 different patient groups) was used to compare means, p<0.05 was considered statistically significant. Results: Significant differences (p<0.001) in MELD score were noted between the 6 centres as well for Child A (5.3 ± 1.1 - 10.1 ± 0.8), B (10.3 ± 0.8 -14.2 ± 1.0) and C (14.6 ± 1.5 -20.0 ± 1.3) patients. The highest difference in MELD score between centres was 4 points. In these centres INR and bilirubin values were significantly different, where as no differences were noted for creatinine. Differences in INR were also noted in normal controls and patients receiving oral anticoagulants in all 6 centres. Conlusion: Significant differences in MELD score were observed between the 6 Belgian liver transplant centres in patients with liver cirrhosis, mainly related to differences in INR and bilirubin values. These differences are explained by laboratory methodologies. The differences in MELD score might lead to significant differences in allocation priority on the waiting list for liver transplantation. We could demonstrate these differences not only in Child C patients, but for the first time also in Child A patients.

Disclosures: The following people have nothing to disclose: Jeffrey Schouten, Sven M. Francque, Hans Van Vlierberge, Isabelle Colle, Frederik Nevens, Jean DeWaele, Michael Adler, Peter Stäerkel, Dirk Ysebaert, Alain Gadisseur, Peter F. Michielsen compared to the 30 non-DCD LKT. RESULTS: In the LKT recipients 41.0% were diabetic, 48.7% required renal replacement therapy (RRT) pre-transplant and 33.3% required RRT post-operatively. None of the transplants utilized HBCAb-positive grafts and 1 non-DCD recipient received a HCVAb + graft. There was no significant difference in patient characteristics or transplant outcomes other than initial hospital length of stay (LOS). * The one-year patient survival for DCD LKT was 88.9% compared to 83.3% with non-DCD LKT. The one-year liver and kidney graft survival for the DCD group was 77.8% and 88.9%, respectively. Glomerular Filtration Rate at one year after LKT was 55.0 ± 30.4 and 46.8 ± 18.3 ml/min for non-DCD (n=20) and DCD (n=4) grafts, respectively. CONCLUSION: The use of DCD organs for solitary liver transplant or solitary kidney transplant is well described. The combination of the two has not been well defined. Despite the higher incidence of need for RRT and longer hospital stay the utilization of DCD donors provides comparable graft and patient survival and should be considered for patients requiring combined liver and kidney transplants.

622 PRIMARY LIVER RESECTION FOR CHILD-PUGH-A HCC WITHIN MILAN CRITERIA: FEASIBILITY OF RESECTION FOLLOWED BY SALVAGE TRANSPLANTATION

Takaaki Sugimoto, Junichi Yamanaka, Shinichi Saito, Tadamihiro Hirano, Toshiihiro Okada, Nobukazu Kuroda, Yui Imuro, Jiro Fujimoto, Surgery, Hyogo college of medicine, Nishinomiya, Japan

AIM: The 5-year survival after liver resection (LR) for Child-Pugh A HCC is comparable with that after liver transplantation (LT). But the recurrence rates of Child-Pugh A HCC after LR is high. The aim of this study is to investigate long-term survival and pattern of recurrence after LR in patients with preserved liver function, otherwise eligible for salvage transplantation. MATERIALS & METHODS: Curative liver resection was performed for HCC in 600 patients from 1984 to 2006. Retrospective data collection analysis was carried out on pattern of recurrence of these patients according to Milan criteria. Clinico-pathologic parameters at the time of the primary resection were analyzed to determine the factor(s), for which patients became ineligible for salvage transplantation. Treatments for recurrence and transplantable period were also analyzed. RESULTS: Overall 1, 3 and 5-year survival rates of the patients within Milan criteria after primary LR were 94, 74 and 56%. Child-Pugh A accounted for 88.6% of the patients, whose 1, 3 and 5-year survivals were 96, 77 and 60%. With a median follow up of 30 months, 66.7% developed tumor recurrence, of which 37.9% were within Milan criteria allowing salvage transplan-
tation. Microvascular invasion was the only significant factor for development of recurrence exceeding Milan criteria on univariate and multivariate analysis. Transplantable period after primary resection of the patients with microvascular invasion was 1511±1485 days and shorter than that (2088+1269 days) of the patients without microvascular invasion. CONCLUSIONS: Five-year survival after resection for Child-Pugh A HCC within Milan criteria was comparable with that after LT. Primary LR is ideal for Child-Pugh A HCC within Milan criteria. However, the patients with microvascular invasion are likely to exceed Milan criteria at the early stage after relapse. Therefore, their high-risk patients should have closer follow-up postoperatively to detect recurrence and receive salvage transplantation at earlier stage.

ASSESSMENT OF REPRODUCIBILITY OF CREATININE MEASUREMENT AND MELD SCORING IN FOUR LIVER TRANSPLANT UNITS IN THE UK

Carol Goulding1, Evangelos Cholongitas1, Devaki Nair1, Andrew Kerry1, Murat Akyol2, Simon Walker2, Derek Manus2, David McClure2, Neville Jamieison3, David Cartwright3, David Patch4, Andrew K. Burroughs3; 1Liver Transplant Unit, Royal Free Hospital, London, United Kingdom; 2Dept of Transplantation, Royal Infirmary of Edinburgh, Edinburgh, United Kingdom; 3HPB Surgery and Liver Transplant Unit, Freeman Hospital, Newcastle, United Kingdom; 4Liver Transplant Unit, Addenbrooke’s Hospital, Cambridge, United Kingdom

It has been proposed that the MELD scoring system be introduced in the UK and Ireland in order to improve equity of access to liver transplantation. Previous papers showed significant variation in creatinine results when different laboratory techniques were used, particularly in those with high bilirubin. This study aimed to evaluate the reproducibility of creatinine measurements and therefore MELD scores in four liver transplant units in the UK. Methods: Six transplant units in the UK and Ireland were invited to participate in the study. The centres were coded as centres ‘A-D’, and only the co-ordinator of the study knew the code. A total of 35 samples, up to 10 from each centre participated in the study. The participants were either on the liver transplant waiting list or undergoing assessment for transplant. In a pre-selected week 2x10ml of blood was collected in a lithium heparin tube from each of the participants, this was divided into 2ml aliquots. These 2ml aliquots were then sent to all of the participating centres, so creatinine and bilirubin were measured in every centre for every patient. All centres used measurement techniques based on the kinetic Jaffe technique except for centre C which used the Dade dimension technique. We then analysed these results for agreement between centres on creatinine values and MELD scores were significantly different between all centres (p<0.05) except for MELD A vs. MELD B and MELD B vs. MELD D. The difference between MELD score was 2 points in 15% of samples between MELD A vs. MELD C, and in 9% samples between MELD C vs. MELD D. Conclusion: This important study demonstrates lack of reproducibility in creatinine measurement and MELD scoring between 4 UK liver transplant centres. The fact that there was good agreement between creatinine values from centre B and C, but not in MELD score also suggests the impact of variation in bilirubin results between the centres. A difference in 2 MELD points could have significant impact on patient out-come and these factors will have to be addressed if a UK wide transplant list is to be initiated.

DOES HEALTH RELATED QUALITY OF LIFE CORRELATE WITH THE MODEL FOR END STAGE LIVER DISEASE SCORE BEFORE LIVER TRANSPLANTATION?

Eric T. Castaldo, Robert T. Russell, Irene D. Feurer, C Wright Pinson; Vanderbilt University Medical Center, Nashville, TN

Introduction: With minimal existing data our primary aim was to correlate the model for end-stage liver disease (MELD) score pretransplant and quality of life after liver transplantation (LT). Methods: A single institution prospective study of all patients undergoing first time LT over a 4-year period was conducted. Patients were given the SF-36 at 1, 3, 6, or 12 months post-LT. MELD was calculated the day of LT. Simultaneous multiple regression-based path analysis was used to test the effects of MELD, diabetes, diagnosis, length of stay (LOS), time post-LT, rejection, and the contemporaneous Karnofsky performance score (KPS), on the physical component (PCS) and mental component (MCS) summary scales of the SF-36. Results: There were 209 participants. Diabetes, LOS, and rejection were associated with worse KPS (p=0.02) whereas time post-LT was associated with an improved KPS (p=0.01). Factors influencing quality of life measured by PCS and MCS of the SF-36 are shown in the table. Conclusions: Increasing MELD score was associated with improvement in PCS, MELD did not affect MCS. Functional performance, measured by KPS, had the largest effects on post-LT quality of life. Since good quality of life can be expected even with higher MELD scores, they should not discourage transplantation.

SHOULD DONOR ORGANS AND RECIPIENTS BE MATCHED IN LIVER TRANSPLANTATION? AN ANALYSIS OF THE UNITED KINGDOM AND IRELAND LIVER TRANSPLANT DATABASE

Muhammad F. Dawwas1, David Collett2, Kerri M. Barber3, Christopher J. Watson4, James M. Neuberger2, Alexander E. Gimson2; 1Hepatology and Liver Transplant Unit, Addenbrooke’s Hospital, Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom; 2Liver Transplant, Bristol, United Kingdom

BACKGROUND The prevailing practice of matching liver transplant donors and recipients according to their respective risks of graft failure is predicated on the tacit assumption that the adverse effects of a high-risk graft are minimized in a low-risk recipient. The evidence-base supporting this practice is currently unclear. METHODS Using the UK and Ireland National Transplant Database, we examined the effect of the interaction between donor characteristics and recipient characteristics on the risk of graft loss (defined as graft failure or death whichever occurred first) among adult first single-organ liver transplant recipients in the two countries between 1 March 1994-31 October 2006 (n=6,658). Donors were categorised as high- or low-risk using the 75th centile of the UK and Ireland Donor Risk Index (UKDRI) as a threshold. Recipient risk was categorised as high, medium or low using the highest, middle two and lowest quartiles of the MELD score, respectively. Cox regression models including UKDRI and MELD with and without their interaction terms were fitted and compared using the likelihood-ratio test to determine whether the increased relative risk (RR) of graft loss for high-risk donors was consistent across the MELD categories. RR estimates by UKDRI in high, medium and low MELD categories were derived from Cox models including the interaction terms, stratified by transplant centre, with and without adjustment for other recipient risk factors and year of transplantation. RESULTS Recipients in the lowest MELD score quartile, respectively, of all recipient risk categories (table 1). The magnitude of the risk increase was similar in the first year but was modestly greater in high-risk recipients thereafter. CONCLUSIONS Both high- and low-risk recipients experience a significantly greater, albeit unequal, risk of graft loss when receiving high-risk organs. Given their substantially different mortality risks without transplantation, these results question the wisdom of the current practice of allocating high-risk organs to low-risk recipients in preference to high-risk recipients.

Aim: To provide a new prognostic score for refining the prediction of disease-free survival after LT for HCC, using variables assessable pre-operatively and to compare the prognostic value of this model with Milan criteria. Patients and Methods: The prognostic model was derived from the multivariate Cox model analysis of a series of 373 patients (training cohort (TC)) without portal thrombosis, transplanted for HCC (1998-1999) in 14 centers. 3 independent predictors were identified: maximal diameter (p<0.0001), tumor differentiation (p<0.0001) and number of nodules (p=0.001). Regression coefficients were estimated for each class of the variables, and a discrete prognostic score was derived. The score was subsequently simplified by linear transformation of the regression estimates. Two different prognostic groups were identified on the TC: group A < 3 points and group B > 4 points. The score was subsequently
Background: Hepatocellular carcinoma (HCC) is associated with a very high morbidity and mortality especially in the presence of portal hypertension. Our objectives were to characterize predictors of in-hospital mortality and to determine whether surgery at a liver transplant center (LTC) was associated with improved survival. Methods: We queried the Nationwide Inpatient Sample, the largest all-payer dataset of hospital discharges in the U.S., from 1998 to 2003, to identify patients who had undergone hepatectomy for a diagnosis of HCC using International Classification of Diseases, 9th Revision, Clinical Modification (ICD-9-CM) procedure and diagnosis codes. Multivariable logistic regression, accounting for survey design, was used to assess the independent effect of portal hypertension and surgery at a LTC while adjusting for demographic, clinical, and hospital factors. Results: There were an estimated 7,841 hepatectomies for HCC in the U.S. during the 6-year period. Since 2000, there has been an average 17% annual increase in the rate of HCC-related hepatectomies. The average age at surgery was 57 years, 63% were males, and 7% had clinical manifestations of portal hypertension. The overall in-hospital mortality was 8.2%. Patients with portal hypertension experienced higher mortality than those who did not (22% vs. 7%, p < 0.0001). Undergoing hepatectomy at a LTC compared to a non-transplant center was associated with lower mortality in both the portal hypertensive group (14% vs. 31%, p = 0.03) and non-portal hypertensive group (6% vs. 9%, p = 0.01). After multivariate adjustment, the odds ratio of in-hospital death for those with portal hypertension was 3.1 (95% CI: 1.9 – 5.1) and for those who underwent hepatectomy at a LTC was 0.61 (95% CI: 0.42 – 0.89). The median number of HCC-related hepatectomies performed at liver transplant and non-transplant centers was 50 and 6, respectively. The protective effect of hepatectomy at a LTC was eliminated after adjustment for hepatectomy volume (OR 0.93; 95% CI: 0.56 – 1.52). Mortality benefit from higher hepatectomy volumes plateaued at > 10 surgeries per year. Hepatectomies performed at centers that performed > 10 per year had 52% lower odds of death than those performed at centers with < 10 per year. The average length of stay was 2 days shorter at a LTC compared to non-LTC (9.3 days vs. 11.1 days, p = 0.003). Conclusions: Hepatectomy rates appear to be increasing as HCC incidence continues to rise. In-hospital mortality associated with hepatectomy is greatest in HCC patients with portal hypertension. Hepatectomy at a LTC confers survival benefit due to higher volumes of hepatic resection.

628 TREATMENT OUTCOMES OF TRANSCATHETER ARTERIAL CHEMOINFUSION (TACI) IN PATIENTS WITH UNRESECTABLE HEPATOCELLULAR CARCINOMA (HCC) PRIOR TO ORTHOTROPIC LIVER TRANSPLANTATION

Whitney de Luna, Bo Yoon Ha, Aijaz Ahmed, Daniel Sze, Emmet B. Keefe, Mindie H. Nguyen; Stanford University, Stanford, CA

Purpose: Transcatheter arterial chemoembolization (TACE) is a common therapy for unresectable HCC. While both TACE and TACI are generally well tolerated by patients with compensated liver disease, those with poor hepatic tend to have higher rates of complications. Compared to TACE, TACI without embolization may have similar efficacy with fewer side effects and may allow us to include patients with less hepatic reserve. Our purpose is to examine outcome of TACI in HCC patients awaiting orthotopic liver transplantation (OLT) and its efficacy as a bridge towards transplantation. Methods: We performed a retrospective study of 160 TACI cases in 82 HCC patients between 4/98 - 3/07 at single U.S medical center. We examined 30 and 90 day-morbidity following TACI. We also measured overall patient mortality while waiting on transplantation list. Results: Mean age was 55 ± 7, 84% were male, 44% were Asian and 41% were white. Most had cirrhosis (88.6%), and either chronic hepatitis C (62.0%) or B (32.9%). TNM staging of I, II, III and IV were 25%, 57%, 13% and 5%, respectively. Mean MELD score was 10.1 ± 4.1 and mean CTP score was 6.5 ± 1.7. Number of patients with Child A, B, C was 45, 25, 7, respectively. 40 patients underwent OLT. The average waiting period to OLT is 6 months. Among 42 patients on waiting list, 7 patients died. The cause of death for the seven patients include multigain failure, metastasis, recurrent hepatitis C and infection. Only one patient died in 90 days following TACI and the other 6 patients died in the one or two years following TACI. Among the remaining 35 patients, 23 patients are alive and remained on transplantation list and 12 patients are lost for follow up. Only 7 patients were hospitalized for > 24 hours (6.25% = 10/160 cases) The cause of hospitalization for > 24 hours include nausea, vomiting, fever, variceal bleeding and encephalopathy. One patient (0.63% = 1/160 cases) had worsening of liver function at the same day following first TACI procedure. Conclusion: TACI is an effective and safe treatment for unresectable HCC prior to OLT. Most of our patients required less than 24 hours of hospitalization, while patients undergoing TACE generally require longer hospitalization. Rate of worsening of liver function following was only 0.63%. Rate of mortality related to TACI was 1.43% (1/70). TACI may be used as an effective bridge towards transplantation.
629
INOS AND COX-2 SYNERGISTICALLY ENHANCE PGE2 PRODUCTION THROUGH S-NITROSYLATION OF CYTOSOLIC PHOSPHOLIPASE A2α IN HUMAN CHOLANGIOCARCINOMA CELLS
Lihong Xu, Chang Han, Kyu Lim, Tong Wu; Department of Pathology, University of Pittsburgh, School of Medicine, Pittsburgh, PA
Cyclooxygenase-2 (COX-2) and inducible nitric oxide synthase (iNOS) have recently been implicated in cholangiocarcinogenesis. The COX-2-mediated production of prostaglandin E2 (PGE2) requires concomitant activation of cPLA2α, which releases arachidonic acid (AA) from membrane phospholipids providing substrate for COX-2. This study describes a novel interplay among iNOS, cPLA2α and COX-2, which synergistically regulate the production of PGE2, a key lipid mediator perpetuating inflammation and driving carcinogenic process. Specifically, we show that iNOS-derived nitric oxide (NO) enhances PGE2 synthesis through S-nitrosylation of the cPLA2α enzyme in human cholangiocarcinoma cells and this effect is dramatically augmented by COX-2. Treatment of human cholangiocarcinoma cells (CCLP1 and SG231) with NO donor (GSNO) or transfection with iNOS adenoviral expression vectors in cholangiocarcinoma cells (CCLP1 and SG231) with NO donor (GSNO) or transfection with iNOS adenoviral expression vector induced S-nitrosylation of cPLA2α, resulting in a 2-3 fold increase of cPLA2 activity and AA release. These effects were blocked by the iNOS inhibitor, 1400W. Interestingly, iNOS overexpression in combination with COX-2 induction or overexpression induced a much more remarkable cPLA2α S-nitrosylation than either iNOS or COX-2 alone. Accordingly, overexpression of iNOS in combination with COX-2 induction or overexpression dramatically stimulated AA release by approximately 20 fold, whereas COX-2 induction alone caused only 1.5 fold increase of AA release. While COX-2 induction alone resulted in 20 fold increase of PGE2 production, combined COX-2 induction and iNOS overexpression enhanced PGE2 synthesis by approximately 100 fold. Furthermore, cPLA2α bound iNOS in human cholangiocarcinoma cells and their association was dramatically increased by overexpression of COX-2. Taken together, our data provide the first evidence that iNOS binds and S-nitrosylates cPLA2α and this effect is enhanced by COX-2 through formation of the iNOS-cPLA2α-COX-2 binding complex. The close proximity of these molecules in cell compartment provides a unique spatial advantage for iNOS-mediated S-nitrosylation and activation of cPLA2α, which cleaves AA for efficient PGE2 synthesis via COX-2. Therefore, therapy aimed at disrupting this interplay may represent a promising strategy to effectively inhibit PGE2 production and prevent cholangiocarcinogenesis.

ROLE OF IKKβ/NF-κB ACTIVATION FOR DEVELOPMENT OF LIVER METASTASIS
Shin Maeda1,2, Yoshi Hikiba1, Michael Karin2, Masao Omata2; 1Gastroenterology, Institute for adult diseases, Asahi Life Foundation, Tokyo, Japan; 2Pharmacology, University of California, San Diego, La Jolla, CA; 2Gastroenterology, University of Tokyo, Tokyo, Japan
Liver metastasis is one of critical factors for determination of prognosis in cancer patients. Activation of NF-κB plays an important role in regulation of innate immune responses, inflammation and oncogenesis. Intrasplenic administration of lung carcinoma cells, LLC, and melanoma cells, B16F10, activate NF-κB through IκB kinase (IKK)-dependent phosphorylation, induces metastasis in the liver. To explore the roles of IKKβ, which is the critical kinase for NF-κB activation in metastatic process, we administered cancer cells into two kinds of conditional IKKβ knockout mice, hepatocyte-specific (Δhep) and whole liver knockout (Δl+h), and control (F/F) mice. The Δl+h mice developed liver metastasis with significantly lower numbers of metastatic foci compared to the Δhep and F/F mice. The intrasplenic tumor injection induced mRNA expressions of IL-6, cyclooxygenase (COX)-2, and matrix metalloproteinase (MMP)-9 in Δhep and F/F mice, whereas in Δl+h mice these genes were poorly expressed. These observations indicate that IKKβ/NF-κB signals in non-parenchymal cells such as Kupffer cells play critical roles in liver metastasis. In IL-6 knockout mice, number of liver metastasis was marked decreased compared with controls. We also tested whether NEMO-binding domain (NBD) peptide, which was shown to block association of NEMO with IKKβ and inhibit NF-κB activity, reduces liver metastasis in mice. NBD peptide reduced tumor foci through downregulating proinflammatory cytokines such as IL-6. Collectively, these observations suggest the IKKβ/NF-κB signaling pathway is an attractive target for the development of anti-metastatic drugs.

A PROTECTIVE ROLE FOR ADIPONECTIN IN HUMAN HEPATOCELLULAR CARCINOMA: ACTIVATION OF AMPK INHIBITS HEPG2 PROLIFERATION IN VITRO AND STUNTS TUMOR GROWTH IN HEPG2-NUDE MICE XENOGRAFTS
Neeraj K. Saxena1, Xiaokun Ding1, Dipali Sharma2, Frank A. Anania1; 1Medicine, Division of Digestive Diseases, Emory University School of Medicine, Atlanta, GA; 2Haematology and Oncology, Winship Cancer Institute School of Medicine, Atlanta, GA
Adiponectin, secreted by white adipose tissue, has been proposed to possess therapeutic properties and is inversely correlated with obesity. Low levels of serum adiponectin are associated with a higher relative risk for cancer of the breast, endometrium, stomach, colorectum, pancreas, and hepatocellular carcinoma (HCC). The purpose of the present study was to elucidate the mechanism whereby adiponectin negatively modulates HCC growth. METHODS: mRNA transcripts and protein expression of adiponectin receptors, Adipor1 and Adipor2, were detected in the human HCC cell line HepG2 by RT-PCR and immunoblot analysis, respectively. Adiponectin dose and time studies were conducted to determine cell viability and cell proliferation by BrdU incorporation. Metastatic properties, including the effect of adiponectin on cell migration, were determined, by Electric Cell-substrate Impedance Sensing (ECIS). Adiponectin signal-transduction was assessed by immunoblot assay for phosphorylated S5-AMP-activated protein kinase (AMPK), PCNA, Cyclin-D1, p21/WAF, caspase-3 and cleaved caspase-3. Five-week old athymic nude-mice were injected with 5 x 10⁶ HepG2 cells into the right gluteal region. Two weeks later mice were subjected to either intraperitoneal saline injections or adiponectin (84µg/g/day) for four weeks. Tumor growth was monitored regularly by caliper measurements. RESULTS: Adipor1 and Adipor2 transcripts and respective proteins were identified in HepG2 cells. Optimization from dose and time course studies revealed that full-length
adiponectin treatment [10µg/ml] reduced HepG2 cell proliferation by 50% and increased apoptosis by six-fold as compared to serum-free (SF) treatment (p<0.01). Adiponectin significantly increased both phosphorylation of AMPK and cleaved caspase-3 production by three-fold (p<0.01). Adiponectin reduced PCNA expression and down-regulated cyclinD1 while up-regulating p27KIP2. Adiponectin decreased the rate of HepG2 cell migration in the wound-healing assay compared to SF conditions. None of the effects of adiponectin in HepG2 were observed in primary cultured hepatocytes. HepG2-xenograft-nude mice resulted in large tumors. Adiponectin treatment dramatically reduced the tumor burden as compared to saline-treated control mice. **CONCLUSIONS:** These data indicate that adiponectin has significant potential to inhibit malignant properties of HCC by decreasing cell proliferation and increasing apoptosis of HepG2 via AMPK activation. Taken together with the in vivo data, adiponectin may be an attractive therapy for human HCC.

**CANCER TARGETED AND TISSUE SPECIFIC GENE THERAPY OF IN VIVO HEPATOCELLULAR CARCINOMA MODEL BY HTERT-TARGETING TRANS-SPlicing RIBOZYMES AND LIVER SPECIFIC PROMOTER**

**Jin S. Jeong**, Sang Y. Han, Min S. Song, Seong W. Lee, In H. Kim, Dipali Sharma, Frank A. Anania

Hepatocellular carcinoma (HCC) is one of the most frequent human cancers worldwide. Effective treatment, surgical resection is available for only a small number of patients. Advanced HCC, multiple tumors, distant metastasis, recurrent tumors and even small HCC with impaired liver function have been required to develop new therapeutic modalities. In this study, we investigate a specific and efficient approach to HCC treatment that is based on a HCC-specific trans-splicing ribozyme. We constructed adenoviral vectors containing hTERT targeting trans-splicing ribozyme with downstream lacZ gene (Adv-PEPCK.Ribo.LacZ) or therapeutic suicide gene HSVtk (Adv-Ribo.Tk) under the control of liver-specific PEPCk or CMV promoter. We maintained hTERT(+)- Hep3B and HepG2 HCC cell lines, and hTERT(-) THLE3 non-tumorigenic normal liver cell line. For carcinoma peritonei model, we injected 2x 107 of Hep3B cells, intraperitoneally (i.p.) in BALB/C male nude mice and observed 95% of success rate within 21 days in the pilot work. For the specific transgenic expression, X-gal staining in removed abdominal organs and tumors in toto, and frozen tissue sections was done. For antitumor effect, we injected 1×109 pfu of Adv-PEPCK.Ribo.Tk (n=10), Adv-CMV.Ribo.Tk (n=10) and Ad-PEPCK-LacZ (n=10, as control) on 18th day, intraperitoneally, following injection of gancyclovir (50mg/kg), twice per day for 10 days. Eighteen days after virus injection, the total mass weights of removed tumors were measured. For the hTERT expression levels, RT-PCR and immunohistochemistry were performed. We observed tumor specific expression of B-galactosidase in Adv-PEPCK.Ribo.LacZ group and both liver and tumor in Adv-PEPCK.LacZ group. Twenty eight mice (no tumors in one mouse injected with Adv-PEPCK.Ribo.LacZ and Adv-PEPCK.LacZ, each) showed carcinoma peritonei. The mean tumor weights (mg) of control, Adv-PEPCK.Ribo.Tk and Adv-CMV.Ribo.Tk groups were 8.26±2.97, 3.91±1.66 and 2.36±1.39, showing significantly reduced tumor growth in treated groups, compared to control (Mann-Whitney [U] test, PEPCK; 0.0016, CMV; 0.0006). In addition to the hTERT-dependent therapeutic gene induction, significant reduction of the levels of hTERT RNA (> 75%) were observed in HCC mouse model by the specific ribozyme. These results showed that hTERT targeting TSR with PEPCk promoter represents a powerful dual targeting and dual efficacy agent for tumor targeted and liver specific gene therapy of HCC.

634 RELEVANCE OF IGF SIGNALING PATHWAY IN HUMAN HEPATOCELLULAR CARCINOMA, AND PRE-CLINICAL ASSESSMENT OF NOVEL TARGETED THERAPIES

Victoria Tovar1, Clara Alsinet1, Manel Sola1, Augusto Villanueva2, Derek Chiang3, Laira Cabellos3, Adriana Lázaro4, Myron Schwartz5, Vincenzo Mazzafarrella1, Jordi Bruix1, Josep M. Llovet1,2; 1Liver Unit and Pathology Department, IDIBAPS- Hospital Clinic, Barcelona, Spain; 2Mount Sinai Liver Cancer Program. Division of Liver Diseases, Mount Sinai School of Medicine, New York, NY; 3Cancer Program, Broad Institute of Harvard and MIT, Cambridge, Boston, MA; 4National Cancer Institute, Milan, Italy

BACKGROUND: Aberrant activation of IGF signaling has been involved in cell transformation, proliferation and survival in cell cultures and cancer mouse models, and has been implicated in human cancer. Targeted therapies abrogating this pathway have scarcely been tested in hepatocellular carcinoma (HCC).

AIMS: We aimed to explore the role of IGF signaling in a large cohort of HCV-induced HCC and to assess the impact of abrogating this pathway by blocking IGF-1R activity. METHODS: We evaluated the IGF pathway in 105 paired HCV-related HCC/non-tumoral cirrhotic liver and 10 healthy liver tissues assessing the activation status of six proteins (IGF-II, pIGF-1R, pIRS-1, pAkt, pERK, and pS6) by immunohistochemistry, and western blot, the expression levels of 7 genes (IGF-I, IGF-II, IGF-1R, IGFBP-3, IRS-1, IRS-2, IGFBP-3 and PTEN) by quantitative real-time PCR and the structural status using SNP-array (Affymetrix STY Mapping Array®). Liver cancer cell lines (Huh7, Hep3B and HepG2) were incubated with increasing concentrations of a monoclonal antibody against IGF-1R (A12, ImClone). We assessed cell viability (MTT assay), cell proliferation (3[H] Thymidine Incorporation Assay, FACS) for cell cycle analysis and immunoblot to evaluate protein expression. Experimental studies with HCC xenograft testing this molecular therapy were conducted. RESULTS: Activation of IGF signaling (defined by immunohistochemical analysis of pIGF-1R) was detected in 26% of cases, which significantly correlated with gene expression levels of IGF-II and IGFBP-3 (p=0.043 and p=0.038, respectively). Expression of IGF-II was up-regulated (>10 fold change) in 12% of HCCs in comparison to normal samples, whereas the tumor suppressors IGFBP-3 and PTEN were significantly down-regulated, >10 fold change in HCCs (both in 25% of cases). Increase copy number changes of IGFBP-3 by SNP array analysis was significantly associated with pIGF-1R (p=0.017). Abrogation of the IGF1R activation with the monoclonal antibody A12 [0.1 – 200 nM] decreased cell viability by 48h by 35%, and was able to decrease cell proliferation by 15-30% without inducing significant apoptosis, as revealed by flow citometry analysis. CONCLUSION: IGF pathway is dysregulated in a subgroup of HCCs patients, as a result of an increase of both IGFBP-3 ligand and IGFBP-3 copy number changes. Abrogation of IGF1R signaling in vitro reduces cell viability and proliferation. There is rationale for testing A12 monoclonal antibody against IGF-1R in experimental HCC models.

IFNγ IS CRITICALLY REQUIRED FOR IL-12-MEDIATED NK CELL ACTIVATION AND ANTI-TUMOR EFFECT IN THE LIVER
Aki Uemura, Tetsuo Takehara, Hayato Hikita, Akira Sasakiwara, Keisuke Kohga, Ryotaro Sakamori, Shinjiro Yamaguchi, Takuya Miyagi, Tomohide Tatsumi, Kazuyoshi Ohtawa, Tatsuya Kanto, Naoki Hiramatsu, Norio Hayashi; Dept. of Gastroenterology and Hepatology, Osaka Graduate School of Medicine, Suita, Japan

Background and Aim: The liver is the most common site of metastatic malignancy and the status of this organ is an important determinant of survival in patients with advanced disease. Since the liver contains an abundance of immune cells, the cytokine-mediated activation of these cells may be a promising approach toward this end. IL-12 is a pleiotropic cytokine and a strong inducer of IFNγ. IL-12 has been shown to elicit anti-tumor effects in various murine models of cancer. But the mechanisms have not been fully elucidated. The aim of this study was to examine the role of IFNγ in anti-tumor effect of IL-12 by using IFNγ knockout mice (GKO mice). Methods: We hydrodynamically injected naked plasmid DNA encoding IL-12 (pCMV-IL-12) into mice 2 days after intrasplenic injection of CT-26 cells. The serum IL-12 and IFNγ levels were measured using ELISA. The NK activity of mononuclear cells was assessed with standard 4-hour 51Cr-releasing assay using Yac1 cells as targets. Mononuclear spleen cells of wild type mice were injected via tail vein into GKO mice 1 days before hydrodynamic injection of plasmid DNA. Expression of phospho-STAT1 of whole cell lysate separated from mononuclear cells was analyzed by Western blotting. Results: Single injection of pCMV-IL-12 efficiently enhanced the NK activity of hepatic mononuclear cells, induced serum IFNγ elevation and led to complete rejection of tumors in the liver. All effects of pCMV-IL-12 were abolished in GKO mice. NK cells were critically required for IL-12-mediated rejection of hepatic metastasis, because their depletion by injecting anti-asialo GM1 antibody completely abolished the anti-metastatic effect. When wild-type splenocytes were adoptively transferred into GKO mice before pLl2 injection, anti-tumor effect and NK cytolysis were restored. Upon IL-12 stimulation splenocytes from wild-type mice showed enhanced NK activity and phosphorylation of STAT1, but those from GKO mice did not. When splenocytes from GKO mice cultured with recombinant IL-12 and recombinant IFNγ, NK cytolysis was restored and the expression of phospho-STAT1 was detected. Conclusion: NK cells play critical roles for IL-12-mediated initial rejection of hepatic metastasis of micro-disseminated tumors. The IFNγ production from mononuclear cells is significantly important for the NK activation and the anti-tumor effect of IL-12.

LIBRARY OF GENETIC ASSOCIATIONS: CONNECTING COMPLEX LIVER DISEASES AND GENETICS
Stefan Buchkremer, Jasmin Hendel, Markus Krupp, Arndt Weinmann, Kai Schlamp, Peter R. Galle, Andreas Teufel; Department of Medicine I, Johannes Gutenberg University, Mainz, Germany

A genetic basis has been established for almost all common liver diseases. However, the genetic basis of most of these diseases must be assumed to be rather due to a complex genetic interaction of multiple genes than to an individual, single gene. Thus, future efforts to unravel the genetic basis of common liver diseases will necessarily have to look into genetic networks and signaling pathways. However, at present no database is available providing a complete overview of genetic associations in common liver diseases. Therefore, we have established a Library of Genetic Associations providing these genetic informations for HCC, NASH, AIH, PBC, and PSC. In order to establish this database, the complete Pubmed database, currently containing more than 15 million publications, has initially been searched by means of MeSH terms and text mining algorithms. These tools suggested 57800 abstracts to provide evidence for genetic associations. Subsequently, these remaining publications were than individually and manually validated for genetic associations, leaving approximately 500 confirmed genetic associations for these diseases. Finally, validated informations were stored in a publicly available database (www.medicalgenomics.org/databases/LoGA). This database is searchable via a web interface by diseases, pathways or genes. Furthermore, the database output contains information on the genetic association and publications providing the respective genetic information. We are currently further extending this genetic resource to additional diseases such as viral hepatitis, fibrosis, and cirrhosis. Together, this novel database provides the complete current knowledge on genetic associations of HCC, NASH, AIH, PBC, and PSC. As it is publically and automated searchable, it will be a valuable resource for the analysis of complex genetic networks and clusters contributing to the development of chronic liver disease.

INHIBITION OF HEPATIC TUMOR ANGIogenesis WITH MET INHIBITORS
Piguet Anne-Christine1, Daniel Aebersold2-3, Willy Hofstetter4, Jean-Francois Dufour1, Yitzhak Zimmer2-3; 1Department of Clinical Pharmacology, University of Bern, Bern, Switzerland; 2Department of Radiation Oncology, Inselspital, University of Bern, Bern, Switzerland; 3Department of Clinical Reasearch, Radiation Oncology, University of Bern, Bern, Switzerland; 4Department of Clinical Research, Bone Biology, University of Bern, Bern, Switzerland

Background: Aberrant function of the tyrosine kinase Met receptor has been associated with numerous types of human cancers including hepatocellular carcinoma (Kaposi-Novak, JCI 2006). Met disregulated activity correlates with local invasion and metastasis. Met signalling stimulates VEGF production and promotes tumor angiogenesis. Therefore, we evaluated the potential of the Met inhibitors SU11274 and PHA665752 to prevent angiogenesis in an orthotopic liver tumor model.

Methods: NIH3T3 cells stably expressing Met constitutively activated mutated variant receptors, were injected subcutaneously into the liver of SCID mice. Two mutations were used, M1268T and Y1248H that exhibit respectively sensitivity and resistance towards the Met tyrosine kinase inhibitors PHA665752 and SU11274. One week after implantation, animals were randomized for PHA665752 (25mg/kg/day i.p.) or vehicle treatment. Following 7 days of treatment, tissues were harvested and tumor size was measured. Microvessel density was assessed by CD31 immunostaining. In vitro, the production of VEGF by M1268T (sensitive) and Y1248H (resistant) cells was determined by ELISA. The angiogenic effect of the media was assessed with the rat aortic ring assay. Means±standard deviations, Mann-Whitney test.

Results: M1268T (sensitive) tumors measured 716±164 mm³
PEGYLATED INTERFERON ATTENUATES WNT/β-CATENIN SIGNALING IN HEPATOCELLULAR CANCER

Michael D. Thompson, Gang Zeng, Ben Cieply, Satdarshan P. Monga; University of Pittsburgh, Pittsburgh, PA

Pegylated-Interferon (Peg-IFN) is used in patients with chronic Hepatitis C virus (HCV) infection. An observed consequence of such treatment is decreased occurrence of hepatocellular carcinoma (HCC). HCC remains the most common form of liver cancer, with poor prognosis. Wnt/β-catenin activation contributes to the development of a significant subset of HCC. Furthermore, activation of this pathway has been noted in many cases of HCV infection. We explored the possibility that anti-HCC activity of Peg-IFN might be through the inhibition of Wnt/β-catenin signaling. We treated two human hepatoma cell lines (HepG2 & Hep3B) with Peg-IFN or Ribavirin. Western blot and transcriptional activity of β-catenin was measured via the TOPFLASH luciferase reporter assay. Transgenic mice overexpressing a stabilized form of β-catenin (Serine-45-mutated) were exposed to Peg-IFN, which may be the mechanism of delayed HCC in treated HCV patients. In addition, this observation might have chemopreventive and chemotherapeutic implications in the scenario of aberrant canonical Wnt/β-catenin signaling.

EXPLOITING THE MULTIPLE MECHANISMS OF SORAFENIB: TUMOR GROWTH INHIBITION WITH A NOVEL COMBINATION OF SORAFENIB AND RAPAMYCIN TARGETING BOTH RAS AND MTOR PATHWAYS

Pippa Newell1, Augusto Villanueva1, Judit Peix1, Yingbei Chen1, Analisa Di Feo1, Stijn Van Laarhoven1, Eric R. Lemmer1, Maria Isabel Fiel1, Swan N. Thung1, Steven Yea1, Sasan Roayaie1, Myron Schwartz1, John A. Martignetti1, Scott L. Friedman1, Josep M. Llovet1,2; 1Liver Diseases, Mount Sinai School of Medicine, New York, NY; 2Liver Unit, Hospital Clinic, Barcelona, Spain

Background: Sorafenib has a proven survival benefit in advanced HCC. It is a potent inhibitor of Raf-1, a serine/threonine protein kinase, and has activity against several receptor tyrosine kinases, including VEGFR, PDGFR, and c-kit. Because of the heterogeneity of HCC, however, combination with other therapies targeting additional pathways may be more effective in these advanced tumors. Rapamycin is an mTOR inhibitor approved for immunosuppression post transplantation, with known anti-tumoral activity, whose efficacy in HCC is unknown. Aims: 1) To characterize Ras and mTOR pathway activation in human HCV-hepatocarcinogenesis, and 2) to assess the impact of their antagonism using Sorafenib in combination with Rapamycin, in culture and in a xenograft model. Methods. We investigated the expression of several key genes of the Ras pathway in 77 human HCC samples by qRT-PCR and used immunohistochemistry to localize expression of phosphorylated mTOR. Mutation analysis for k-Ras mutations was performed using direct sequencing. Liver cancer cell lines were incubated with increasing concentrations of ICG-001 to assess cell viability (MTT assay), proliferation (3[H] Thymidine Incorporation Assay), and apoptosis (flow cytometry). Xenograft nude mouse models were administered both agents alone and in combination. Immunoblotting was performed to demonstrate abrogation of downstream protein targets, including phosphorylated ERK and S6. Results: H-RAS was upregulated 4-fold in advanced HCC human samples compared to normal liver. Membranous staining of phospho-mTOR was lost in HCC (p<0.001). There was an additive effect of Sorafenib and Rapamycin in vitro, leading to decreased cell viability (p<0.001) and inhibition of proliferation (p<0.001). Flow cytometry confirmed apoptosis of HCC cell lines with Sorafenib alone and in combination with Rapamycin. Xenograft models are showing an early trend toward increased survival in all three treated groups compared to controls. Conclusions: Sorafenib and rapamycin synergize to inhibit tumor growth. Aberrant signaling through both the Raf/MEK/ERK pathways and the Akt/mTOR pathways has been demonstrated in human HCC, and this study provides compelling evidence that the combination of Sorafenib and Rapamycin merits consideration in human trials of HCC.

Disclosures:
The following people have nothing to disclose: Pippa Newell, Augusto Villanueva, Judit Peix, Yingbei Chen, Analisa Di Feo, Stijn Van Laarhoven, Eric R. Lemmer, Maria Isabel Fiel, Swan N. Thung, Steven Yea, Sasan Roayaie, Myron Schwartz, John A. Martignetti, Scott L. Friedman, Josep M. Llovet

in vehicle treated mice and 125±37 mm³ in PHA665752 treated mice (n=4, p<0.05). This was accompanied by a reduction by 35% of the microvessel density in the treated tumors. Y1248H (resistant) tumors measured respectively 178±52 mm³ and 346±227 mm³ (p>0.05) and microvessel density in drug treated tumors was increased by 47%. Treatment of M1268T (sensitive) cells with PHA665752 led to a 4 fold reduction in culture medium VEGF levels (p<0.05) whereas VEGF levels in medium of Y1248H (resistant) cells remained unchanged. In the rat aortic ring assay, vessels number was reduced by 44% after addition of medium from 2µM SU11274-treated cells compared to medium from untreated M1268T (sensitive) cells (p<0.05). Exposure to the medium of the Y1248H (resistant) cells treated with SU11274 or PHA665752 increased the number of vessels by 32% and 76% respectively. Conclusions: Tyrosine kinase inhibitors of Met receptor prevent Met-dependent VEGF production and hepatic tumoral angiogenesis in tumors expressing a drug sensitive receptor. In contrast, the same inhibitors seem to promote tumoral growth and angiogenesis in tumors expressing a drug-resistant receptor. These data emphasize the angiogenic role of Met signalling in hepatic tumor formation and stress the therapeutic importance to determine the nature of the Met receptor expressed.

641 ACTIVATION OF THE WNT/B-CATENIN PATHWAY IN HEPATOCELLULAR CARCINOMA, AND IN VITRO GROWTH INHIBITION WITH A NOVEL SMALL MOLECULE ICG-001

Pippa Newell,1 Augusto Villanueva,2 Derek Chiang,2 Judith Peix,2 Clara Alsina2, Stijn Van Laethoven,2 Swan N. Thung,2 Maria Isabel Fiel3, Steven Yea3, Myron Schwartz4, Michael Kahn3, Scott L. Friedman1, Josep M. Llovet1,2; 1Liver Diseases, Mount Sinai School of Medicine, New York, NY; 2Liver Unit, Hospital Clinic, Barcelona, Spain; 3Center for Stem Cell and Regenerative Medicine, University of Southern California, Los Angeles, CA; 4Dana-Farber Institute, MIT and Harvard University, Boston, MA

Background: Aberrant Wnt signaling has been implicated in the pathogenesis of HCC. There are no drugs approved that target this pathway in any tumors. ICG-001 is a small molecule which specifically inhibits the interaction between b-catenin and Cbp-binding protein (CSP), causing repression of a subset of TCF/b-catenin-mediated transcription. This small molecule has been shown to reduce growth in vitro of colon cancer but has not been evaluated in HCC. Aims: 1) To characterize Wnt pathway activation in hepatocarcinogenesis in a large cohort patients with HCV-related HCC; and 2) to test the effect of Wnt pathway abrogation with a novel small molecule inhibitor, ICG-001. Methods: Expression of Wnt pathway genes in 104 human HCV+ HCC samples was measured by qRT-PCR, and immunohistochemistry was used to localize b-catenin and E-cadherin. B-catenin gene mutations in exon 3 were assessed by direct sequencing (N=93 cases). Integrative genomic analysis of samples from the same cohort was performed using 250K SNP arrays and genome-wide microarrays (Affymetrix, Genechip Human Genome-U133 Plus 2.0). HCC cell lines were incubated with increasing concentrations of ICG-001 to assess cell viability (MTT), proliferation (3[H] Thymidine Incorporation), and apoptosis (flow cytometry). Luciferase reporter plasmids were used to measure TCF/b-catenin-mediated transcriptional activity. Results: Nuclear staining of B-catenin was observed in one-quarter of HCCs, but not in cirrhotic tissues, and was trendly correlated with tumor recurrence (p=0.09). Among 93 HCCs, point mutations in B-catenin were identified in 16 (17%), which correlated with recurrence (p=0.02). There was a significant correlation between B-catenin point mutations and nuclear staining (p=0.007). B-catenin was upregulated >2 fold in 34% of HCC samples across progressive stages of HCC. Interestingly, nuclear staining of B-catenin significantly correlated to lower levels of mRNA. ICG-001 decreased cell viability by 40-60% and proliferation by 80% in vitro in HCC cell lines, demonstrating a dose-dependent effect. ICG-001 also sensitized cells to apoptosis. Finally, ICG-001 reduced TCF/b-catenin-mediated transcriptional activity as measured by a luciferase reporter (p<0.00001). Conclusions: Wnt signaling is clearly activated in a subset of Hepatic C-induced HCCs, and correlates with tumor recurrence. The small molecule ICG-001 significantly decreased cell viability and proliferation by abrogating the Wnt pathway. These results provide the rationale for testing this compound in experimental models.

Disclosures: The following people have nothing to disclose: Pippa Newell, Augusto Villanueva, Derek Chiang, Judith Peix, Clara Alsina, Stijn Van Laethoven, Swan N. Thung, Maria Isabel Fiel, Steven Yea, Myron Schwartz, Michael Kahn, Scott L. Friedman, Josep M. Llovet

642 CLOSE RELATIONSHIP BETWEEN CYTOKERATIN 19 EXPRESSION AND SIDE POPULATION PHENOTYPE DURING HUMAN HEPATOCELLULAR CARCINOGENESIS

Yoh Zen1, Yasuni Nakanuma2; 1Pathology, Kanazawa University Hospital, Kanazawa, Japan; 2Human Pathology, Kanazawa University Graduate School of Medicine, Kanazawa, Japan

Aims: There is increasing evidence that stem cells might participate in the development of various tumors, including hepatocellular carcinoma (HCC). Cytokeratin 19 (CK19) expression is one of the most reliable phenotypic markers of hepatic stem/progenitor cells. The side population (SP) phenotype is a recently discovered functional marker of stem/progenitor cells. It is now believed that the SP phenotype is maintained by the expression of ATP-binding cassette transporter G2 (ABCG2) or multidrug resistance-1 (MDR-1). In this study, we examined relationships between CK19-positive cells and the SP phenotype during carcinogenesis of human HCC. Methods: We performed dual fluorescent immunostaining of CK19/ABCG2 and CK19/MDR-1 on pathological specimens (15 HCCs and 10 dysplastic nodules) and three HCC cell lines (HepG2, HuH7 and PLC5). Next, we tried to identify SP cells in each cell line, and sort into SP and non-SP fractions. Expressions of CK19, ABCG2 and MDR-1 in SP and non-SP fractions were examined by RT-PCR and dual fluorescent immunostaining. Results: In the non-neoplastic livers, expressions of CK19, ABCG2 and MDR-1 were closely co-localized in bile ducts, bile ductules and parenchymal oval cells. In dysplastic nodules, small dysplastic cells around entrapped portal tracts were positive for these three molecules. In addition, carcinoma cells dual positive for CK19/ABCG2 and CK19/MDR-1 were also identified in histological specimens of HCCs. We could isolate and sort into SP and non-SP cells from HuH7 and PLC5, but not HepG2. SP cells of HuH7 and PLC5 could generate SP and non-SP progenies, whereas non-SP cells generated only non-SP in sustained culture. This result suggested that tumor cells with SP phenotype are located at the higher level of tumor-cell hierarchy, and cancer stem cells might exist in SP cells. SP cells more intensely expressed CK19 than non-SP, and CK19 expression in SP cells decreased time-dependently during sustained culture. In addition, ABCG2 and MDR-1 were commonly expressed in CK19-positive cells in SP fractions. Conclusion: This study revealed that CK19-positive cells were closely related to expressions of ABCG2 and MDR-1 during carcinogenesis of human HCC in vivo. In addition, in vitro studies revealed that carcinoma cells double positive for CK19/ABCG2 or CK19/MDR-1 were enriched in SP fractions of human HCC cell lines. This study suggested that CK19 expression and SP phenotype might be closely related during carcinogenesis of human HCC.

643 THE INTRONIC P53 BINDING SITE IS ESSENTIAL FOR ACTIVATION OF THE CD95 GENE BY THE P53 FAMILY NETWORK

Elisa Schulze Schleithoff1, Astrid Kairat1, Andreas Koch1, Tobias Schilling2, Min Li-Weber2, Peter H. Krammer2, Martina Müller1; 1Internal Medicine IV, University of Heidelberg, Heidelberg, Germany; 2Internal Medicine I, University of Heidelberg, Heidelberg, Germany

Introduction: p53 is a key regulator of cell-cycle control, apoptosis and genomic stability. The p53 family members p63 and...
p73 give rise to proteins that have p53-agonistic as well as p53-antagonistic functions. However, like p53, they possess the ability to induce apoptosis after DNA damage. p63 and p73 express two main classes of isoforms: isoforms which contain the transactivation domain (TaP73 and TaP63) executing transcrip tional activity and dominant negative isoforms which are truncated at the NH2-terminus (DeltaNp63 and DeltaNp73) acting as operant inhibitors of TaP73, TaP63 and wild-type p53, and thus containing oncogenic potential. Aim: The aim of our study has been to provide insight into the molecular mechanisms of the regulation and transactivation of the CD95 gene. Methods: 1. Identification of the p53 binding site in intron 1 and three p53 binding sites in the promoter of the CD95 gene by immunoselection assay and computer analyses. 2. Establishment of CD95-Luciferase constructs with mutations and deletions of the p53 binding sites of the CD95 gene. 3. Performance of chromatin immunoprecipitation (ChIP) to show the ability of wt p53, TaP63 and TaP73 protein to bind directly the p53 binding site in the first intron of the CD95 gene. 4. Assessment of the p53/TaP63/TaP73-dependent transactivation of the CD95 gene, using different established CD95-Luciferase constructs. Results: Wt p53, TaP63 and TaP73 transactivate the CD95 gene via binding to the p53 binding site of intron 1 and three p53 binding sites in the promoter of the CD95 gene. Transcriptional activation of the CD95 gene by all p53 family members involves cooperation between the p53 binding sites of the CD95 promoter and the intronic p53 binding site. By mutational analyses, we can clearly identify the intrinsic p53 response element as the most important binding site for the transactivation of the CD95 gene by wt p53, TaP63 and TaP73. The oncogenic potential of the dominant negative isoforms of p63 and p73 is evidenced by the fact that deltaNp63 and deltaNp73 dramatically inhibit the wt p53-, TaP63- and TaP73-mediated transactivation of the CD95 gene. Discussion: Deregulated dominant negative p63 and p73 isoforms play an oncogenic role in human cancer and contribute to chemoresistance. Here we show the molecular mechanisms of the regulation of the CD95 gene by the full-length TA isoforms of p63 and p73. Furthermore, we show the inhibition of the transactivation of the CD95 gene by deltaNp63 and deltaNp73. This leads to resistance towards apoptosis. Interfering with the expression of deltaNp63 and/or deltaNp73 in tumor cells may render such tumors more responsive to therapy.

EXPRESSION OF MULTIDRUG RESISTANCE-ASSOCIATED PROTEIN 1 IN HEPATOCELLULAR CARCINOMA IS ASSOCIATED WITH AGGRESSIVE TUMOR PHENOTYPE AND CAN REFLECT PROGENITOR CELL ORIGIN

Sara Vander Borght1, Louis Libbrecht1, Mina Komuta1, Jacques Pirene2, Frederik Nevens3, Snorri S. Thorgerisson3, Chris Verslype1, Tania Roskams1, 1Morphology and Molecular Pathology, University Hospitals Leuven, Leuven, Belgium, 2Abdominal Surgery, University Hospitals Leuven, Leuven, Belgium, 3Hepatology, University Hospitals Leuven, Leuven, Belgium.

Patients with hepatocellular carcinoma (HCC) often have poor response to treatment with chemotherapy due to intrinsic or acquired multidrug resistance (MDR). This MDR can be caused by over-expression of ATP-binding cassette transporters in the tumor cells. The transcriptional profile of ABC transporter genes was assessed in a series of 65 solitary untreated HCCs that were earlier subjected to global gene expression analysis. The multidrug resistance-associated protein 1 (MRP1, ABCC1) appeared as the only ABC transporter whose expression level was significantly up-regulated in HCCs in comparison with surrounding normal tissue and its expression level is well associated with a more aggressive phenotype. Recent studies showed that HCC could be of progenitor cell origin. In view of the specific expression of MRP1 in hepatic progenitor cells (HPCs) and not in hepatocytes, expression of this transporter in HCC can be a reflection of progenitor cell origin and provide the tumor cells with a MDR phenotype. To confirm this micro-array data we performed real-time RT-PCR and immunohistochemistry for MRP1 (ABCC1), MRP3 (ABCC3), MDR1 (ABCB1), BCRP (ABCG2) and biliary/ progenitor cell markers cytokeratin 7 (CK7) and CK19 on an independent set of 23 primary untreated hepatocellular carcinomas and surrounding non-tumoral liver (available in 11 cases). Data were correlated with clinical pathological data of the HCCs. In 11 of 23 HCCs we observed a basolateral staining pattern of MRP1 in the tumor cells. In 9 of the HCCs, we observed MRP1 positivity in more than 30% of tumor cells. MRP1 protein expression is associated with differentiation grade, tumor diameter and microvascular invasion. Expression of CK7 and/or CK19 in more than 5% of tumor cells was seen in 9 of 23 patients (34%). Expression of CK19 only was seen in 5 of 23 patients (22%) of which 4 were MRP1 positive in the same areas of the tumor. MRP1 mRNA levels were significantly up-regulated in HCCs in comparison with surrounding non-tumoral liver and associated with invasion, differentiation grade and tumor diameter. All other transporters, including MDR1 showed a trend towards decreased protein and mRNA expression probably as a sign of dedifferentiation. The strong basolateral MRP1 expression can result in more growth potential and a more aggressive phenotype of the tumor by pumping toxic substances out of the tumor cells and can be the reflection of a progenitor cell origin. Given the existence of specific MRP1 inhibitors, this finding may be of therapeutic relevance. (1) Lee JS et al. Nature Medicine 12(4): 410; (2) Durnez A et al. Histopathology 49(2):138

SELECTIVE HOMING OF ENDOTHELIAL PROGENITOR CELLS WITH CYTOSINE DEAMINASE CDNA TO TUMOR TISSUES SUPPRESSES GROWTH OF HEPATOCELLULAR CARCINOMA BY 5-FLUOROURACIL SECRETION

Takji Toriumi1,2, Takata Ueno2, Kinya Inoue1,2, Eitaro Taniguchi1,3, Toru Nakamura1,2, Osamu Hashimoto1,2, Hironori Koga1,2, Hirohisa Yano2,3, Masamichi Kojio1,2, Michio Sata1,2; 1Medicine, division of Gastroenterology, Kurume university, Kurume city, Japan; 2Research Center for Innovative Cancer Therapy and Center of the 21st Century COE Program for Medical Science, Kurume university, Kurume city, Japan; 3Pathology, Kurume university, Kurume city, Japan

Background/Aim: Cytosine deaminase (CD) is the enzyme that transforms nontoxic 5-fluorocytosine (5-FC) into the highly toxic 5-fluorouracil (5-FU). Recently, it has been proved that endothelial progenitor cells (EPC) are selectively recruited into tumor tissues. Stromal cell-derived factor-1 (SDF-1) and its receptor CXCR4 interactions tightly regulate the homing of stem and progenitor cells. In the present study, we investigated the anti-tumor effect of a CD/5-FU system with CD cDNA transfected EPC for hepatocellular carcinoma (HCC).

Methods: Human hepatoma cell line (HuH-7) and rat EPC cell line (TR-BME) were

524A AASLD ABSTRACTS HEPATOLOGY, October 2007

HEPATOLOGY, October 2007
used. In vitro; E. coli CD cDNA was transfected into TR-BME with a retroviral system (CD-TR-BME). The expression of CXCR4 on CD-TR-BME was assessed by RT-PCR. The inhibitory effect of 5-FU secreted by CD-TR-BME with 5-FC on the proliferation of co-cultured HuH-7 was evaluated by a tetrazolium-based assay. In vivo; Nude mice received subcutaneous injection of HuH-7 (5 x 10^6). After tumor formation, the mice received CD-TR-BME (5 x 10^7) injection via tail vein for 5 days and then received intraperitoneal injection of 5-FC (500 mg/Kg body weight) for 10 days. During the course of experiment, tumor volume was measured every 3 days. SDF-1 expression in tumor tissue was evaluated by RT-PCR. The localization of CD-TR-BME in tumor tissues was investigated. Serum and tumor tissue S-FU levels were measured. Results; In vitro; Transfection of CD cDNA in TR-BME was confirmed by RT-PCR. CD-TR-BME expressed CXCR4. CD-TR-BME secreted 5-FU and inhibited the proliferation of HuH-7 in a dose dependent manner of 5-FC addition. In vivo; Tumor tissues expressed SDF-1. CD-TR-BMEs were selectively recruited into the tumor tissues and incorporated into endothelial cells of tumor vessels. Tumor growth was significantly suppressed in the period of 5-FC administration. 5-FU level in tumor tissue was 26.4 ± 11.3 ng/g tissue weight. However, 5-FU was not detected in the mouse serum. Body weight loss and bone marrow suppression were not observed. Conclusion; These results suggest that the new CD/S-FU system with CD cDNA transfected EPC will be an effective and safe strategy to suppress the growth of HCC. Selective homing of endothelial progenitor cells with cytokine deaminase cDNA to tumor tissue suppresses the growth of hepatocellular carcinoma by 5-fluorouracil secretion.

MAPK7 IDENTIFIED AS A PROBABLE TARGET FOR AMPLIFICATION AT 17P11 IN HEPATOCELLULAR CARCINOMA

Keiko Zen1, Kohichiroh Yasui1, Tomoaki Nakajima1, Yoshikazu Inagaki2, Shoji Mitsufuji1, Shinji Tanaka1, Masahito Minami1, Yoshihito Itoh1, Shigeki Arii2, Takeshi Okanoue2

(Background and aims) Amplification of chromosomal DNA is one mechanism capable of activating genes whose over-expression contributes to the development and progression of cancer. The recent introduction of high-density single nucleotide polymorphism (SNP) arrays enable high-resolution and genome-wide identification of DNA copy-number aberrations in cancer. The aim of the present study is to detect novel amplification in HCC cell lines using SNP arrays that have been missed in a conventional analysis, such as via comparative genomic hybridization (CGH), and to investigate the role of the target gene within the amplicon in HCC cells. (Methods) The GeneChip Mapping 100K array set and GeneChip Mapping 250K Sty array (Affymetrix) were used in this study. Genomic DNA and mRNA of MAPK7 were quantified using real-time PCR. MAPK7 expression was down-regulated by small interfering RNA (siRNA). Cell viability was determined by MTT assay. (Results) Two of the twenty HCC cell lines exhibited amplification at chromosomal region 17p11 via SNP array analysis. We were able to define the smallest commonly affected region in the 17p11 amplicon. This region includes seven known or predicted protein-coding genes, GRAP, EPN2, EPPB9, MAPK7, MFAp4, ZNF179, and FLJ10847. Of all seven genes including the region, we found that mitogen-activated protein kinase 7 (MAPK7), which encodes extracellular-regulated protein kinase 5 (ERK5), was over-expressed in cell lines in which the gene was amplified. ERK5 is a member of the mitogen-activated protein kinase (MAPK) subfamilies that transmit extracellular signals from cell surface receptors to specific targets within cells. Several lines of evidence have suggested that ERK5 is implicated in tumorgenesis. In our studies, copy-number gain for MAPK7 was observed in 35 of the 66 primary HCC tumors (53%). We next investigated the effects of MAPK7 over-expression on HCC cells. PD98059, an inhibitor of the MEK5/ERK5 and MEK1/ERK1/2 pathways, caused concentration-dependent growth inhibition of a HCC cell line with the most remarkable amplification and over-expression of MAPK7. Because we were not able to find a specific chemical inhibitor of the MEK5/ERK5 pathway, we knocked down MAPK7 expression via RNAi. siRNA-mediated down-regulation of MAPK7 suppressed growth of the HCC cells. (Conclusion) Our results suggest that MAPK7 is likely to be a target of 17p11 amplification and may play a role in the growth of HCC cells and thus, that the ERK5 protein product of the MAPK7 gene may be an optimal target for development of novel therapies for this widespread type of cancer.

NEIGHBOR OF PUNC E11 (NOPE): A NOVEL MARKER FOR MURINE HEPATOCELLULAR CARCINOMA

Dirk Nierhoff1, Jens Marquardt1, Maria J. Quasdorff1, Gisela Holz1, Bernd Arnold2, Ulrike Pratzer4, Tobias Goesser1; 1Department of Gastroenterology and Hepatology, University Hospital Cologne, Cologne, Germany; 2Molecular Infectiology at the Center for Molecular Medicine, University of Cologne, Cologne, Germany; 3German Cancer Research Center, Heidelberg, Germany

Hepatocellular carcinoma (HCC) is the 5th common malignancy worldwide and the incidence has almost doubled within the last 40 years. As established markers fail to detect up to one third of HCC, the identification of new markers is particularly relevant. We have recently identified Neighbor of Punc E11 (Nope) as a surface marker of murine fetal liver stem cells. In analogy to established HCC markers like α-Fetoprotein (AfP) and Glypican-3 (Gpc-3), we here investigate Nope as a potential onco-fetal marker of HCC and its expression during hepatocarcinogenesis. Methods: We induced HCC in 8 to 12 week old, Cre-inducible SV40 T-antigen transgenic mice (Alb-SV40TAgind). Animals were sacrificed at different time points after tumor induction to obtain specimens from all stages of HCC development. RNA and protein fractions were extracted. Expression levels of Nope, AfP and Gpc-3 were analyzed by quantitative RT-PCR using Gapdh and β-Actin as internal controls. Western blot studies were performed to analyze protein expression of Nope and AfP with β-Actin as internal control. Sections from different stages of tumor development were stained with hematoxylin/eosin, and cryosections were costained for Nope and AfP or E-cadherin for identification of epithelial tumor cells. Results: In livers of our mice, hyperplastic nodules develop at 2 weeks and diffuse cellular dysplasia was detected at 3 weeks after tumor induction. HCC start to develop at 8 weeks after tumor induction. We detected expression of Nope neither in the normal liver nor at early stages of HCC development by quantitative RTPCR. In contrast, we found a significant increase in the expression of Nope at 8 weeks after...
tumor induction and at all later time points when HCC were identified. All samples were negative for Afp, but expression of Gpc-3 closely correlated with Nope expression. Results were confirmed on protein level in Western Blot studies. In immunohistochemistry, Nope was specifically detected in HCC as phenotypically diagnosed in H/E stainings and all Nope positive cells coexpressed E-cadherin. Conclusion: We identified Nope as a novel surface marker for murine HCC by quantitative RTPCR, Western Blot and immunohistochemistry. Nope was specifically expressed by epithelial tumor cells of HCC but not in normal liver or at earlier stages of tumor development. Further investigations will concentrate on the functional and prognostic significance of Nope as a novel marker of murine and human HCC.

648 HSP90 INHIBITION ABROGATES HUMAN HCC GROWTH THROUGH CDC2-MEDIATED G2/M CELL CYCLE ARREST
Robin D. Kim, Go Watanabe, Kevin E. Behrns; Surgery, University of Florida School of Medicine, Gainesville, FL
Heat shock protein 90 (Hsp90) is a molecular chaperone which can promote human cancer growth by stabilizing client proteins. 17-(demethoxy), 17-allylamino geldanamycin (17-AAG), the specific inhibitor of Hsp90, can decrease growth in some cancers. We examined 1) the potential effects of 17-AAG-mediated Hsp90 inhibition on human HCC growth, and 2) the possible mechanisms of these effects. HepG2, Hep3B and HuH7 cells were exposed to 17-AAG or DMSO (control) for different time periods and compared. (1) Hsp90 expression was detected by Western blots; (2) Viabilities were measured by MTT assays and IC50 values were calculated. (3) Cell death (necrosis and apoptosis) were determined by fluorescence microscopy of Hoechst 33342/PI-stained cells. (4) Cell cycles were analyzed by flow cytometry of PI-stained cells. (5) The G2/M cell cycle checkpoints Cdc2 (total and phosphorylated Tyr15)) and Cyclin B1 were examined by Western blots. Each of the three HCC cell lines showed the presence of Hsp90 by Western blot. Compared to their respective controls, each HCC cell line treated with 17-AAG showed (1) decreased relative viability at 24, 48 and 72 hours (1.0 vs 0.2, P<0.05), (2) increased apoptosis and necrosis (28% vs 4%, and 5% vs 1%, P<0.05) and decreased total cell numbers (1 x 105 vs 1.3 x 106 cells/well), (3) increased G2/M cell cycle arrest at 24 h (39.2±14.2% vs 26.0±5.0%), and (4) decreased total and phosphorylated Cdc2 at 24, 48 and 72 hours. 17-AAG-mediated inhibition of Hsp90 abrogates human HCC cell growth in part through Cdc2-mediated G2/M cell cycle arrest. Although further studies using physiologic models are needed to delineate the mechanisms of Hsp90's effects, these data suggest a potential therapeutic strategy against human HCC growth.

649 LIVER SPECIFIC LDB1 DELETION RESULTS IN ENHANCED LIVER CANCER DEVELOPMENT
Andreas Teufel1, Heiner Westphal2, Yangu Zhao2, Stephan Kanzler1, Peter R. Galle1; 1 Department of Medicine I, Johannes Gutenberg University, Mainz, Germany; 2 National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD
Ldb1 has been demonstrated to be essential to embryonic development in diverse tissues as the constitutive Ldb1 knock out in mouse lead to an embryonic lethal and pleiotropic phenotype with impaired development of multiple organs, such as the heart, head and posterior axis as well as severe defects in mesoderm-derived extraembryonic structures, including the allantois, blood islands, and primordial germ cells. Ldb1 was demonstrated to be a ubiquitously expressed LIM- and Homeodomain binding protein. Some of these have already been demonstrated to be involved in cancer development. Furthermore, we suggested earlier, that Ldb1 induced functions through regulating the Wnt signaling pathway. Wnt signaling has also been repeatedly demonstrated to be involved in cancer development. We now analysed the influence of Ldb1 on liver cancer development. Therefore, conditional Ldb1 knock out mice containing a loxP flanked genomic stretch of the exons 1 – 9 were crossed to mice expressing Cre recombinase liver specifically under the control of the albumin promoter. Subsequently, liver cancer development was induced by DEN injection at the age of 10 days followed by continuous phenobarbital administration. Analysing the mice 9 months after cancer induction, Ldb1 deleted mice exhibited an average 10-fold higher rate of liver cancer nodules. We currently furthermore investigate a role of differential Wnt signaling in these tumors. Together, we demonstrate that deletion of Ldb1 results in enhanced liver cancer development and expand the current picture on the genetic basis of HCC development by adding yet another key regulatory gene, Ldb1.

TARGETING HISTONE DEACETYLATION FOR TREATMENT OF HEPATOCELLULAR CARCINOMA

Yun-Han Lee1, Hyun Goo Woo1, Izhak Avital1,2, Adam D. Judge3, Marian Durkin1, Anita Ton1, Ju-Seog Lee4, Elizabeth A. Conner1, Valentina Factor1, Ian MacLachlan5, Snorri S. Thorgeirsson1; 1Lab of Experimental Carcinogenesis, National Cancer Institute, NIH, Bethesda, MD; 2Surgery Branch, National Cancer Institute, NIH, Bethesda, MD; 3Proativa Biotherapeutics, Inc., Burnaby, BC, Canada; 4Department of Systems Biology, UT MD Anderson Cancer Center, Houston, TX

Post-translational modification of histones resulting in chromatin remodelling plays a key role in the regulation of gene expression. Also, it is well established that global hypoacetylation of histone H4 is a common hallmark of human tumors and changes in H4 acetylation may occur early in the tumorigenic process (Gallinari et al., Cell Research 2007) We have recently identified an elevated expression of histone deacetylase 2 (HDAC2) gene in primary human hepatocellular carcinoma (HCC) and HCC derived cell lines (Lee et al., Hepatology 2004). In this study we have examined the effects of HDAC2 gene knockdown on cell growth and apoptosis in human HCC cell lines. For silencing HDAC2 gene expression, Huh7 and HepG2 cells were treated with 5 – 20 nM of three different siRNAs (HDAC2-1, HDAC2-2 and HDAC2-3) directed against HDAC2. Cell growth was then analyzed by MTT and apoptosis was analyzed by ELISA for detection of ssDNA and caspase activation. The expression of HDAC2 target gene was determined by quantitative real-time RTPCR. Among the three tested siRNA molecules, the HDAC2-1 siRNA was the most effective in inhibiting HCC cell growth when compared to control treatments (untreated and treated with a negative control siRNA). Huh7 and HepG2 cells transfected with 15 nM of HDAC2-1siRNA for 4 days showed 68% and 71% growth inhibition, respectively, associated with decreased G2/M cell populations. Inhibition of liver cancer cell growth was due to increased rate of apoptotic cell death which was about 1.9-fold higher than in control cells. The increased level of apoptosis directly correlated with activation of caspase-3 and reduction of target mRNA level. Taken together, these results show that HDAC2 is an important regulator of HCC cell growth and survival, and therefore may represent a potential target for human HCC treatment.

DECREASED INTRAHEPATIC CD8 TRAPPING IS ASSOCIATED WITH SUPPRESSION OF HEPATOCELLULAR CARCINOMA: A ROLE FOR THE BETA GLYCOLIPID ACYL CHAIN LENGTH
Gadi Lalazar, Ami Ben Ya’acov, Menachem Hareati, Yaron Ilan; Liver Unit, Hadassah Hebrew University Medical Center, Jerusalem, Israel

Different immune-escape mechanisms are associated with tumor progression. Redistribution of lymphocyte subsets is a possible counter-measure to overcome this phenomenon. It has been suggested that the glycolipid acyl-chain may be important in determining the affinity to the CD1 groove in tumor-antigen presenting cells affecting CD8 and NKT activation. Aims: To determine the effect of beta-glycolipids with different acyl chains on CD8 redistribution and hepatocellular carcinoma progression. Methods: Athymic Balb/c mice (n=8/group) were sublethally irradiated and transplanted with 1x106 human Hep3B HCC, followed by daily intraperitoneal injections of beta-glucosylceramide (GC), or beta-lactosylceramide (LC), with 8 or 12 carbons in the acyl chain (GC8, GC12, LC8, and LC12, respectively. 1.5µg in 100µl PBS/dose) or PBS for 42 days. The effect of the acyl chain length on CD8 redistribution was assessed by FACs analysis of intrahepatic and intrasplenic lymphocytes in CD8, CD4 and NKT, markers. The anti-tumor effect of lymphocyte redistribution was assessed by follow up of tumor volume and alpha-feto-protein (AFP) levels. Results: The beta-glycolipids GC12 and LC8 exerted a profound effect on CD8 lymphocyte distribution, manifested by decreased intrahepatic CD8 T lymphocyte trapping (spleen/liver CD4/CD8 lymphocyte ratio 3, 0.39 vs. 4.68 for GC12, LC8 vs. PBS, respectively). NKT lymphocyte distribution was also affected, shown by an increase in intrahepatic NKT lymphocytes (liver/spleen NKT lymphocyte ratio 2.6, 0.97 vs. 0.35 for GC12, LC8 vs. PBS, respectively, p<0.05). Administration of GC12 and LC8 markedly suppressed HCC growth. Maximal tumor volume was significantly lower for GC12 and LC8 compared with GC8 and LC12, respectively (0.63, 0.19 vs. 1.22, 2.72 mm3, respectively, p<0.05). Conclusions: Length of the beta-glycolipid acyl chain was essential in determining the magnitude of CD8 redistribution, breaking immune tolerance towards tumor antigens, leading to marked suppression of HCC growth. Alteration of the numbers of carbons in beta-glycolipids may serve as an important tool for modulation of CD8 lymphocyte function in anti-tumor immune surveillance.

SUPPRESSION OF ALPHA-1,6 FUCOSYLTRANSFERASE INHIBITS INVASIVENESS OF HUMAN HEPATOCELLULAR CARCINOMA CELLS
Takayuki Kagure, Yoshiyuki Ueno, Osamu Kimura, Tooru Shimosegawa; Division of Gastroenterology, Tohoku University Graduate School of Medicine, Sendai, Japan

Background: The proportion of alpha-1,6 fucosylated alpha-fetoprotein (AFP), which is also called the percentage of Lens culinaris agglutinin (LCA)-reactive AFP (AFP-L3), is a useful diagnostic marker for hepatocellular carcinoma (HCC). Furthermore, AFP-L3 is considered as a poor prognostic factor of HCC. The mechanism by which AFP-L3 is related to the malignant potential has not yet been clarified. The factors that participate in the mechanism of increasing the malignant potential may be a promising treatment target. Alpha-1,6 fucosylated glycoproteins (FGPs) are synthesized by alpha-1,6 fucosyltransferase (FucT). We aimed to clarify the role of FucT in the cell proliferation and invasiveness of HCC cells in an in vitro model. Method: HCC cell line, HepG2 was used. (1) For the assay of fluorescence staining to detect FGPs, cells were plated on the chamber slide and treated with FITC-labeled LCA, which recognizes FGP, and analyzed by a confocal laser microscope. To evaluate FGPs quantitatively, lectin blot using HRP-labeled LCA was performed. (2) Short interfering RNA targeted to FucT (FUT8 siRNA, Ambion®) was used to knock down FucT mRNA. After 48 h of FUT8 siRNA transfection, FucT mRNA was measured by real-time PCR. The alteration of the expression of FGP was examined by fluorescence staining and lectin blot. (3) Cells were plated on 96-well plates at 1x104 cells/well after transfection of FUT8 siRNA and cell proliferation was evaluated with the time course. (4) Cells were plated on an 8 µm pore-sized migration chamber coated with or without Matrigel® after transfection of FUT8 siRNA. The numbers of the cells migrated through the membrane were counted. Results: (1) FGP were detected on the cell surface and in the cytoplasm. The bands of lectin blot were quantified by densitometry. (2) After 48 h of FUT8 siRNA transfection, FucT mRNA decreased 85.7 ± 4.2 % compared with the negative control (scramble sequence). The expression of FGP was decreased 54.6 ± 2.2 % by lectin blot. (3) The numbers of proliferated cells after FUT8 siRNA transfection (x104 cells/well vs negative control) were as follows: 24 h, 1.81 ± 0.24 vs 1.89 ± 0.21; 48 h, 2.46 ± 0.18 vs 2.29 ± 0.25; 72h, 3.25 ± 0.11 vs 3.46 ± 0.24. There was no significant difference between them. (4) Cell migration through the membrane and Matrigel® coated membrane was decreased 48.6 ± 2.1 % and 42.6 ± 1.6 % by FUT8 siRNA transfection (p<0.05). Conclusion: Suppression of FucT by siRNA reduced the expression of FGP and inhibited the invasiveness of HCC cells. These results provide the rationale of the mechanism by which AFP-L3 is related to the malignant potential in HCC patients.

INDUCTION OF HEPATOMA-SPECIFIC IMMUNITY BY SUICIDE GENE THERAPY IN CC CHEMOKINE RECEPTOR (CCR) 1- OR CCR5-DEPENDENT MANNER

Noriho Iida1, Yasunari Nakamoto1, Kaheita Kakinoki1, Shuichi Kaneko1, Naofumi Mukaida2; 1Department of Disease Control and Homeostasis, Graduate School of Medical Science, Kanazawa University, Kanazawa, Japan; 2Division of Molecular Bioregulation, Cancer Research Institute, Kanazawa University, Kanazawa, Japan

BACKGROUND: Immunomodulatory agents including chemokines are believed to enhance the antitumor effects of tumor cell apoptosis induced by suicide gene therapy. We recently found that suicide gene therapy, together with delivery of a chemokine, eradicated hepatoma cells and exerted prolonged antitumor effects by activating innate immune responses (J. Immunol. 178:574, 2007). Inflammatory chemokine receptors such as CCR1 and CCR5 expressed by immature dendritic cells (DCs) are presumed to regulate their migration into inflammatory sites. In order to clarify the roles of these receptors in tumor immunity, we evaluated immune responses during suicide gene therapy, in mice deficient in these chemokine receptors, in comparison with wild-type mice. METHODS: Wild-type (WT), CCR1-/-, CCR5-/-, and CCL3-/- mice received ganciclovir (GCV), after they were injected with a murine hepatoma cell line, BNL 1ME A.7R.1 (BNL) transfected with herpes simplex virus-thymidine kinase gene. We examined tumor-infiltrating lymphocytes and mRNA expression of chemokine in the tumor after GCV treatment. Moreover, we examined cell population of lymphocytes in the draining lymph nodes after GCV treatment. Furthermore, we determined cytotoxicity of lymphocytes in draining lymph nodes against BNL cells. Finally, we re-challenged parental BNL cells into the mice after GCV treatment, to determine tumor growth rates. RESULTS: GCV treatment increased the numbers of DCs, CD4+ T and augmented mRNA expression of CCL3 in the tumor. Moreover, CCR1-, CCR5-, or CCL3-deficient mice, intratumoral and intranodal DC infiltration and subsequent cytotoxicity generation were impaired in these mice. When parental cells were injected again after complete eradication of primary tumors by GCV treatment, wild-type mice completely rejected the re-challenged cells, but these deficient mice exhibited impairment in rejection. CONCLUSIONS: CCR1, CCR5, and their ligand, CCL3, may have a crucial role in regulation of DC accumulation into hepatoma tissues and subsequent establishment of tumor-specific immunity after suicide gene therapy.

MOLECULAR COMBINED THERAPY IN HEPATOCELLULAR CARCINOMA (HCC) WITH AEE788 (EGFR/HER2/VEGFR INHIBITOR) AND RAD001, EVEROLIMUS (mTOR INHIBITOR): ANTINEOPLASTIC ACTIVITY IN A XENOGRAFT MODEL OF HCC

Augusto Villanueva1, Philippa Newell1, Judit Peix2, Analisa Di Feo2, Stijn Van Laarhoven1, Swan Thung3, Fiel Isabel3, Steven Yea1, Sasan Roayaie2, Myron Schwartz2, John Martignetti2, Scott L. Friedman2,3; 1Liver Diseases, Mount Sinai School of Medicine, New York, NY; 2Human Genetics, Mount Sinai School of Medicine, New York, NY; 3Pathology, Mount Sinai School of Medicine, New York, NY; 4Surgical Oncology, Mount Sinai School of Medicine, New York, NY; 5BCLC Group. Liver Unit, IDIBAPS. Hospital Clinic, Barcelona, Spain

Background: The knowledge of the signaling pathways involved in HCC provides the rationale for using new targeted molecular therapies. Aim: To study the effect in vivo of a combined dual-level selective pathway blockade in HCC: EGFR/VEGFR (AEE788, Novartis-Pharma, Basel) and mTOR signalling (RAD001, everolimus, Novartis-Pharma). Methods: We used a xenograft model by injecting 5x10^6 HuH-7 cells subcutaneously in athymic mice. Mice were randomized in 4 groups: placebo (n=9), AEE788 [25 mg/kg 3 times per week] (n=9), RAD001 [5 mg/kg 3 times per week] (n=7), and combination of AEE788+RAD001 (n=9). We assessed tumor growth and animal weight every 48 hours. Distressed mice were euthanized according to IACUC protocol. Tumors were collected for immunohistochemistry analysis. We studied tumoral cell proliferation (Ki-67 staining, Proliferation index: percentage of positive nuclei in 10 high-power fields), and apoptosis (TUNEL staining, Apoptotic index: number of positive nuclei in 10 high-power fields). In order to evaluate the effect of both drugs on their molecular targets, we studied the staining status of phosphorylated EGFR and phosphorylated S6. Results: AEE788 and RAD001 delayed tumor growth: 2-week mean volume in control, AEE788, RAD001 and combination were 2396, 1395, 1039 and 784 cc (p<0.05) respectively. There was also a significant increase in median survival: 15, 20.8, 23.1, and 34 days, respectively (p<0.05). Benefits in survival were significantly higher in combination therapy when compared with both drugs separately. Proliferation index was significantly reduced in tumors from mice treated with RAD001 alone and in combination (52.6% and 57.3% vs 80% in control, p<0.05). Apoptotic index was significantly higher in tumors from mice treated with AEE788 alone and in combination (18 and 16 respectively vs 8 in control, p<0.05). There was 1 partial response in the AEE788 group and 1 complete response in the combination group. Drugs were well tolerated at the doses applied. AEE788 and RAD001 decreased p-EGFR and p-S6 staining, respectively. Conclusions: Blockade of EGFR/VEGFR and mTOR signaling with AEE788 and RAD001 significantly reduce proliferation, increase apoptosis, decrease tumor growth and improve survival in an animal model of HCC. These results establish a rationale to test these drugs in clinical trials in HCC.

We adopted an integrated genomics approach to characterize molecular alterations in hepatocellular carcinomas that arose in patients with chronic hepatitis C virus infection. METHODS: Genomic copy number alterations were measured with Affymetrix 238K Sry arrays in 102 tumor samples obtained at the time of surgical resection or transplantation. For 81 samples obtained from resection, gene expression changes were also profiled with Affymetrix U133 Plus 2.0 arrays. DNA was extracted from tumor and uninvolved cirrhotic tissue samples paired from the same patients. For each sample, 250 ng of genomic DNA was processed according to Affymetrix protocols, and gene expression estimates were obtained for each sample with the RMA algorithm. RESULTS: Among 81 resected patients, the mean age was 65.1 years, 67% were male, 58% had microscopic vascular invasion, and the mean tumor diameter was 4.4 cm with a standard deviation of 3.1 cm. The most frequent copy number alterations included gains of chromosome arms 1q, 5, 6p, 7, 8q, and 17q, as well as losses of 4q, 6q, 8p, 13q, 16, and 17p. We noted recurrent high-level amplifications at cytoband 6p21 in 4% of samples, as well as 11q13 amplifications in 7% of samples. Significant increases in RNA expression of VEGFA and TMEM63B were found among tumor samples with 6p21 amplification. Significantly overexpressed genes among samples with 11q13 amplification included ORAOV1, CCND1 and FGFR19. Comparison of gene expression profiles with previously published studies supported at least two distinct molecular classes that were significantly associated with copy number alterations. We confirmed that poor differentiation and high AFP levels were associated with a high fraction of alveolocytic type, especially in chromosomes 13q, 14 and 16q. Notably, we found that another molecular class could be distinguished by gains of chromosomes 5 and 7, both of which were strongly associated with recurrence after resection. CONCLUSIONS: We identified candidate oncogenes in regions of high-level copy number amplifications and determined that certain chromosomal gains and losses segregated with independently validated gene expression classes.

EXPRESSION AND ROLE OF STEAROYL COENZYME A DESATURASE (SCD) IN HUMAN HCC

Samiksha Bansal2,1, Michael Berk2,1, Ariel E. Feldstein2,1

Hepatocellular carcinoma (HCC), the third most important cause of cancer death worldwide, is highly resistant to currently available chemotherapy. Alterations in lipid metabolism have been recently linked to HCC pathogenesis. However the expression and role of stearoyl coenzyme A desaturase (SCD), the rate limiting enzyme in the biosynthesis of monounsaturated fats, in human HCC remains completely unknown. Thus, the AIMS of our study were to determine the expression of SCD in human HCC and to examine the role of SCD in modulating HCC survival and resistance to chemotherapy. METHODS: SCD expression was assessed by immunoblot analysis and immunohistochemistry in three different human HCC cell lines (HepG2, Hep3B, PLC/PRF5), HCC liver tissues (n = 20) and normal liver (n = 10). Cells were incubated in the absence or presence of different chemotherapeutic agents commonly used for HCC treatment (Staurosporine-STS, 5-FU, Doxorubicin) and a time course of SCD expression, caspase 3 activation and apoptosis was assessed by immunoblot, Apo-1 caspase-3 assay, and cell titer blue assay, respectively. Finally, SCD activity was suppressed using a siRNA approach. RESULTS: SCD was strongly expressed in all three hepatoma cell lines as well as in all 20 surgically resected human HCC tissues. The three HCC cell lines showed low sensitivity to chemotherapy induced apoptosis with levels below 15% at 24 hours for all three drugs (STS, 1µM, 5-FU, 10µg/ml and doxorubicin, 1µg/ml). Exposure of HCC cell lines to this panel of drugs resulted in a similar time-dependent upregulation of SCD expression which parallel the degree of resistance to drug-induced apoptosis despite the presence of significant caspase 3 activation. Finally, SCD-specific siRNA to knock down SCD expression resulted in a significant increase sensitivity to chemotherapy induced apoptosis (% apoptosis at 24 hrs: STS from 15% to 50%, p<0.001; 5-FU, from 5% to 25%, p<0.01). CONCLUSIONS: Our data suggest that increased SCD expression may play an important role in HCC development and resistance to chemotherapy induced apoptosis. These results may have important implications in the understanding of HCC pathogenesis as well as in designing novel therapeutic strategies.

KNOCKDOWN OF MIRNAS ENCODED BY THE POLY-CISTRON, MIr-17-92, CAUSES A PARTIAL REVERSION OF THE MALIGNANT PHENOTYPE OF HEPG2 CELLS

Erin Connolly, Tatiana Tchaikovskaya, Leslie E. Rogler, Charles E. Rogler; Medicine, Albert Einstein College of Medicine, Bronx, NY

Erin Connolly, Tatiana Tchaikovskaya, Leslie E. Rogler, and Charles E. Rogler. Liver Research Center, Department of Medicine, Albert Einstein College of Medicine, Bronx, NY, MicroRNAs (miRNAs) have emerged as a general regulator of tissue specific gene expression and differentiation. Certain miRNAs have been implicated in oncogenesis including the miRNA encoded by the microRNA polycistron mir-17-92, which includes six miRNAs (mir-17-5p, mir-17-3p, mir-18a, mir-19a, mir-20a, mir-19b-1 and mir-92). mir-17-92 is regulated by c-myc and last year we reported that the mir-17-92 cluster was over expressed in 100% of primary woodchuck HCCs and 95% of
human primary HCCs tested. This year we have carried out functional testing to determine the effect of knocking down the levels of miR-17-92 miRNAs on the malignant characteristics of HepG2 hepatoma cells in culture. We have used a transfection approach with 2′O-methyl antisense oligonucleotides against the six miRNA in the miR-17-92 polycistron. Transfection of HepG2 cells with the 2′O-methyl mix led to a loss of miR-17-92 miRNAs as assayed by quantitative RT/PCR. FACs analysis of HepG2 cells 48 hours after 2′O-methyl transfection revealed a significant increase in cells in G1 compared to a scrambled control, suggesting a block in cell cycle progression. An apoptosis assay that measures the levels of Caspases 3 and 9, showed no increase in apoptosis in cells subjected to the 2′O-methyl transfection. HepG2 cells transfected with 2′O-methyl mix were planted on soft agar and the extent of colony formation measured five days later. A significant reduction in colony growth was observed down to the level of 5 nM per 2′O-methyl. Additional experiments with individual miRNAs from the miR-17-92 cluster are ongoing. In summary, these data are the first of their kind to link over expression of miR-17-92 miRNAs with the maintenance of the malignant phenotype of HCC cells.

HEPATOCELLULAR PROLIFERATIVE RESPONSE TO PARTIAL HEPATECTOMY IS MARKEDLY IMPAIRED IN TIRAP KNOCKOUT MICE
Hongdan Sun1, Romi Ghose2, Saul J. Karpen1, Sundararajah Thevamanther1, 1Pediatrics-Gastroenterology, Hepatology & Nutrition, Texas Children's Liver Center, Baylor College of Medicine, Houston, TX; 2Department of Pharmaceutical and Pharmacological Sciences, University of Houston, Houston, TX

Introduction. Partial hepatectomy induces a well-orchestrated cascade of signaling events necessary for the cell cycle progression and proliferation of hepatocytes which culminates in liver regeneration. Proinflammatory cytokines and innate immune system play important roles in the initiation of liver regeneration, yet individual roles of distinct members of the Toll-like receptor (TLR) signaling pathways remains to be fully identified. TIRAP (Toll/IL-1 receptor domain containing adaptor protein) is an adaptor protein that mediates intracellular signaling from TLRs 2 and 4 and plays important roles in the induction of cytokine response during inflammation. However, it is unknown if TIRAP-mediated signaling plays any role in the induction of cytokine response and influence hepatocyte proliferation during liver regeneration. Therefore, the purpose of this study was to test the hypothesis that TIRAP plays a key role in the induction of hepatocyte proliferation in response to partial hepatectomy. Methods. To test our hypothesis, 70% partial hepatectomy (PH) was performed on adult (12 weeks) male wide-type (WT) and TIRAP knock-out mice (KO). Resected lobes and remnant livers obtained after PH (1, 3 hrs) were analyzed by TaqMan real-time PCR for the expression of cytokines and the activation of cytokine-mediated signaling pathways by electromobility shift assays, and western blotting. Mice subjected to PH were injected with BrdU (50 mg/kg) 2 hrs prior to the harvest of remnant livers (24, 45, 72 hrs PH) and the hepatocyte proliferative response was analyzed by immunohistochemistry for the incorporation of BrdU and Ki67 expression, established markers of cell proliferation. Results and discussion. The early proliferative response was analyzed by immunohistochemistry for the incorporation of BrdU and Ki67 expression, established markers of cell proliferation. Results and discussion. The early proliferative response was analyzed by immunohistochemistry for the incorporation of BrdU and Ki67 expression, established markers of cell proliferation. Results and discussion. The early proliferative response was analyzed by immunohistochemistry for the incorporation of BrdU and Ki67 expression, established markers of cell proliferation. INTRACELLULAR INTERLEUKIN-2 IN CYTOTOXIC CD8+ T-LYMPHOCYTES CORRELATES TO THE BANFF SCORE DURING ACUTE ORGAN REJECTION IN LIVER TRANSPLANT RECIPIENTS

Bora Akoglu1,2, Susanne Kriener3, Stefan Zeuzem1, Dominik Faust2,1; 1Hepatology, University Hospital Frankfurt, Frankfurt, Germany; 2Gastroenterology, Asklepios Clinic, Langen, Germany; 3Senckenberg Institute for Pathology, University Hospital Frankfurt, Frankfurt, Germany

Liver transplantation is a highly effective treatment for end-stage liver disease. Acute liver rejection is a rare complication compared to other organ systems in transplantation medicine. Therefore a noninvasive method to detect this complication could be beneficial in long term aftercare. The aim of our study is to compare the histological grading of acute organ rejection according to the Banff score compared to the noninvasive detection of intracellular IL-2 in cytotoxic CD8+ T-Cells from blood samples. Methods: 95 Patients were included into this study from march 2005 until december 2006. (66 liver transplant recipients and 29 healthy controls). The blood samples of liver transplant recipients were collected beside routine lab testing or in case of suspected organ rejection by elevated liver enzymes. Immediate liver biopsy in Menghini technique was arranged within 36h including confirmation from our pathologist. For cytometry the blood samples were collected in our outpatient clinic and prepared for the Flow Cytometer (FACSscalibur). After Isolation of white blood cells, the cells were stained with fluorochromes for CD3+(FITC), CD8+(PE-Cy5) and intracellular IL-2(PE). The cells were double-gated (CD3+ and CD8+) for analysis of percentage for intracellular IL-2. Results: The average Banff score in patients during acute organ rejection was 5.8±1.8. The percentage of cells with detectable intracellular IL-2 was significantly increased in patients with acute rejection (p<0.001, ANOVA) compared to recipients without rejection or healthy individuals. The mean detectable intracellular IL-2 percentage (%±SEM) was in rejection patients (7.7±0.91), in stable liver transplant recipients (2.1±0.32) and healthy controls (1.5±3.12). There is a good correlation in rejection patients for intracellular IL-2 and the Banff score (Spearman's rho=0.81, two tailed p<0.05). This cytometric method shows a good sensitivity (71%) and an excellent specificity (95%) for histological proven organ rejection. Conclusion: This flow cytometric method correlates very well to the histological grading according to the Banff score and shows a good sensitivity and excellent specificity. Preparation and analysis is fast, non invasive and cost effective.

INCREASED MORTALITY IN MMP-9 KNOCKOUT MICE FOLLOWING 75-PERCENT PARTIAL HEPATECTOMY

Norifumi Ohashi, Naoki Shimojima, Justin H. Nguyen; Division of Transplant Surgery, Mayo Clinic College of Medicine, Jacksonville, Fl.

Partial hepatectomy (PH) is routinely performed for liver tumors or for transplantation. Mediators of liver regeneration following PH are poorly understood. Recent data suggest that MMP-9 plays an important role in liver regeneration. We hypothesized that MMP-9 is critical for the survival of small liver remnant following massive PH. Method: We performed 75-percent PH in MMP-9 gene knockout mice with C57BL/6 background by removing right and left posterior and anterior lobes of the liver. The age-matched wild-type (WT) C57BL/6 mice were purchased from Jackson laboratory. Following PH, the mice were recovered in heated-support beddings. The extent of PH was estimated by the ratio of the weight of resected liver lobes to the estimated liver weight (ELW). From 10 WT mice, ELW was correlated to the body weight (BW): LW=0.077*BW - 0.7977, with a correlation coefficient of 0.918. Results: 9 MMP-9 KO and 10 WT mice had PH of 70.9±7.6 percent versus 76.4+/−6.5 percent, respectively (p=0.11). As shown in the Figure, only 1 of 9 MMP-9 KO mice survived by 3 days after PH. In contrast, 5 of 10 WT survived more than 3 days after PH. The mortality at 24 hours after PH was 10% versus 70% in WT versus MMP-9 KO mice, respectively (p=0.023). Conclusion: These results corroborate that MMP-9 plays an important role in posthepatectomy liver regeneration and survival.

DOWN-REGULATION BY 1,25 DIHYDROXYVITAMIN D3 OF CD40L-INDUCED IMMUNOREGULATORY CYTOKINES PRODUCTION AND CO-STIMULATORY ACTIVITY IN MONOCYTE-MACROPHAGES FROM LIVER TRANSPLANT RECIPIENTS

Cristiana Almerighi1, Alberto Bergamini2, Raffaella Lionetti1, Anna Sinistra2, Simona Francioso1, Giuseppe Tisone3, Maria Angelico1; 1Hepatology Unit, Tor Vergata University, Rome, Italy; 2Infectious Disease, Tor Vergata University, Rome, Italy; 3Transplant Surgery, Tor Vergata University, Rome, Italy

Background. In transplant, rejection depends on proper T cell arm activation of the immune system. In turn, T cell activation relies on the CD40L-induced co-stimulatory effect of antigen presenting cells (APC) such as monocyte-macrophages. 1,25 dihydroxyvitamin D3 (VitD3) has been previously shown to affect several functions of APC. In search for new non-toxic, anti-rejection compounds, we examined whether VitD3 may interfere with the ability of CD40L to induce co-stimulatory activity in monocyte-macrophages from liver transplant recipients. Patients and Methods. Twelve consecutive patients transplanted >2 years earlier for end-stage liver disease (8 males; median age 58 years, range 46 to 65) were investigated. Peripheral blood mononuclear cells were obtained by centrifugation over Ficoll-Hypaque density gradient solution. The effect of VitD3 (10nM) to affect the ability of CD40L to induce co-stimulatory activity in monocyte-macrophages from liver transplant recipients. The age-matched wild-type (WT) C57BL/6 mice were purchased from Jackson laboratory. Following PH, the mice were recovered in heated-support beddings. The extent of PH was estimated by the ratio of the weight of resected liver lobes to the estimated liver weight (ELW). From 10 WT mice, ELW was correlated to the body weight (BW): LW=0.077*BW - 0.7977, with a correlation coefficient of 0.918. Results: 9 MMP-9 KO and 10 WT mice had PH of 70.9±7.6 percent versus 76.4+/−6.5 percent, respectively (p=0.11). As shown in the Figure, only 1 of 9 MMP-9 KO mice survived by 3 days after PH. In contrast, 5 of 10 WT survived more than 3 days after PH. The mortality at 24 hours after PH was 10% versus 70% in WT versus MMP-9 KO mice, respectively (p=0.023). Conclusion: These results corroborate that MMP-9 plays an important role in posthepatectomy liver regeneration and survival.

AASLD ABSTRACTS
HEPATOLOGY, October 2007
labeled by immobilized anti-CD3. Surface markers expression and cytokine production was evaluated by FACS. Data were analyzed using Student’s test (paired two tailed) and results are means±SD. Results: VitD3 strongly reduced the production of IL-12 (4.4±5.3% vs 1.1±1.6%, p<0.05) and TNF-α (5.2±3.8% vs 1.0±1.2%, p<0.05) by CD40L-stimulated monocyte-macrophages. VitD3 also significantly reduced the expression of CD80 (74.9±13.1% vs 31±27.2%, p<0.05) but not that of CD40 (14.5±7.4% vs 14.6±7.4%, p>0.05). Finally, the addition of VitD3 to T lymphocytes cultured in the presence of immobilized anti-CD3 plus autologous CD40L-stimulated macrophages resulted in a marked decrease in the production of IFN-γ (6,9±7,1% vs 2,9±2,8 %, p<0.05). Conclusion. VitD3 interferes with the co-stimulatory activity of macrophages and cytokines production induced by CD40L. Therefore this compound has a potential role in controlling rejection in liver transplanted patients.

665 PERIPHERAL BLOOD MONONUCLEAR CELLS GZB POSITIVE INCREASE AFTER THE FIRST WEEK FROM LIVER TX IN PATIENTS EXPERIENCING HCV RECURRENCE

Alessandro Perrella, Giuseppe Arenga, Oreste Cuomo; Department of Laparoscopic, Hepatic Surgery and Liver Transplant Unit, AORN, A. Cardarelli Hospital, Naples, Italy, Naples, Italy

Background: It has been demonstrated that the Granzyme B (GZB) ELISPOT assay might be used as an alternative marker for the cytotoxic T-lymphocyte (CTL). It has also been demonstrated that GZB plays a role during HCV infection as marker of CD8+ activation to clear the virus. We aimed to verify whether GZB could be used as marker to early predict HCV recurrence after liver transplantation. Material and Methods: We enrolled 26 patients (pts) undergoing LTx for end stage liver disease HCV related. On this subset of subjects we assayed the GZB spot forming clonies (SFCs) on PBMCs by means of ELISPOT assay stimulated with tethanic toxoid (TT), before (T0) and one week after liver TX (T1). Furthermore, we also performed a GZB ELISPOT assay when HCV clinical recurrence was diagnosed (high HCV-RNA viral load and histological evidence). All patients underwent the same immunosuppressive treatment schedule (Calcineurin Inhibitors + Steroids +Myophenonol) and were divided in two groups on the basis of HCV recurrence: (Group A – 16 pts with HCV recurrence; Group B 10 pts – no HCV recurrence) statistical analysis (U Mann whitney Test) has been managed once the two groups were settled. Results: A T0 we had 132 ± 42 GZB SFCs in group A and 118 ± 36 GZB SFCs in group B without any statistical significant difference. At T1 we had 270 ± 89 SFCs in Group A; and 120 ± 58 SFCs in Group B, with statistical significant increase in group A respect Group B (U Mann-Whitney Test, p < .0001). Moreover, at the onset of HCV clinical recurrence ( 4th month in mean), GZB SFCs were 256 ±68 in group A, without any statistical significant difference respect to T1. Conclusion: Granzyme B, markers of CTL activation during viral infection, has been found increased one week after OLTx in those patients who experienced a HCV recurrence and to remain triggered at the onset of HCV clinical recurrence. These results would suggest GZB ELISPOT assay as an useful tool to assess the early HCV recurrence and to candidate those patients to a pre-emptive interferon plus ribavirin treatment.

666 HEPATITIS C VIRUS COULD BE ERADICATED WITH STRONG IMMUNE RESPONSES AFTER WITHDRAWING INTERFERON TREATMENT POST LIVING DONOR LIVER TRANSPLANTATION

Akinobu Takaki1, Takahito Yagi2, Yoshiaki Iwasaki1, Hiroshi Sadamori2, Kazuko Koike1, Masashi Tatsukawa1, Haruhiko Kobashi1, Kohsaku Sakaguchi1; 1Gastroenterology, Okayama University, Okayama, Japan; 2Gastroenterological surgery, transplant and surgical oncology, Okayama University, Okayama, Japan

Background and aim: Hepatitis C virus (HCV) specific immune response is believed to control hepatitis activity and clinical course. Recently several reports revealed that strong HCV specific immune response was seen in recurrent hepatitis C patients with mild hepatitis activity after liver transplantation. These data were mostly in patients who underwent cadaveric liver transplantation. The cadaveric liver and living donor transplanted liver are different since living donor partial liver shows aggressive proliferation of hepatocytes after transplantation. The immune response might also be different in these two different conditions. To investigate the HCV specific immune responses after living donor liver transplantation, we examined the HCV specific interferon (IFN) gamma production by ELISPOT assay using CD4 positive T cells with in vitro established dendritic cells (DC) coculture systems. Methods: Subjects comprised 20 patients with hepatitis C virus (HCV)-related end-stage liver cirrhosis who underwent living donor liver transplantation (LDLT) and survived longer than 6 months. Seven of the HCV-related patients received IFN treatment. Peripheral blood mononuclear cells (PBMC) of 10 of these patients were separated and CD14 positive cells were enriched using CD14 microbeads. These CD14 positive cells were cultured with media containing GM-CSF and IL-4. On day 5, the cells, proved to be immature DC were harvested and pulsed with 5 recombinant HCV proteins (core, NS3, NS4, NS5A, and NS5B). These HCV treated iDC were matured with lipopolysaccharide (LPS). After maturation, mature DC and CD4 positive T cells were mixed and IFN gamma ELISPOT assay was performed. Results: In all patients, the spots were very small amount after one month of LDLT. The amount of the spots in all HCV proteins was 19.2 in average. The amount of the spots of 7 patients who showed active hepatitis was reduced to 12.4 during 3 months to 12 months after LDLT. However, the amount of the spots of 3 patients who showed normal ALT levels increased to 36.3. One patient received one year interferon therapy with unsuccessful outcome. However, 2 months after cessation of interferon the patient showed HCV RNA negative and the interferon gamma spots amount increased to 34 from 13 before interferon administration. Conclusion: In LDLT patients, IFN gamma production increased in patients with no signs of active hepatitis or patients who eradicated the virus after cessation of interferon, although active hepatitis patients showed reduced HCV specific IFN gamma production 6 months after operation.

ISCHEMIC PRECONDITIONING INCREASES MN-SUPEROXIDE DISMUTASE AND PREVENTS FREE RADICAL-DEPENDENT MITOCHONDRIAL DEPOLARIZATION IN SMALL-FOR-SIZE LIVER GRAFTS

Hasibur Rehman\(^1\), Henry D. Conner\(^2\), Venkat K. Ramshesh\(^1\), Tom Theruvath\(^1\), Ronald P. Mason\(^3\), John J. Lemasters\(^1,2\), Zhi Zong\(^4\),

\(^1\)Pharmaceutical Sciences, Medical University of South Carolina, Charleston, SC; \(^2\)Biochemistry & Molecular Biology, Medical University of South Carolina, Charleston, SC; \(^3\)Laboratory of Pharmacology and Chemistry, NIEHS, RTP, NC

**Background:** Our previous studies showed that small-for-size liver transplantation causes a free radical-dependent mitochondrial permeability transition. Ischemic preconditioning (IP) renders tissues more tolerant to subsequent longer episodes of ischemia. Therefore, the **Aim** of this study was to test if IP attenuates injury of small-for-size liver grafts by preventing free radical production and mitochondrial dysfunction.

**Methods:** IP was induced by clamping the portal vein and hepatic artery for 9 min. Livers were harvested from donor rats 5 minutes after releasing the clamp. Half-size livers were implanted into recipients of about twice the donor weight, resulting in quarter-size liver grafts. Mitochondrial polarization and cell death were assessed by intravital confocal and multiphoton microscopy of liver grafts. Mitochondrial polarization and cell death were assessed by intravital confocal and multiphoton microscopy of liver grafts. Mitochondrial polarization and cell death were assessed by intravital confocal and multiphoton microscopy of liver grafts. Mitochondrial polarization and cell death were assessed by intravital confocal and multiphoton microscopy of liver grafts.

**Results:** After quarter-size liver transplantation, alanine aminotransferase, serum bilirubin and necrosis all increased. IP blocked these increases by >58%. Brdu labeling and graft weight increases were only ~3% and 0.2% in quarter-size grafts without IP, respectively, but increased to 32% and 60% after IP, indicating better liver regeneration. Eighteen hours after implantation, viable cells with depolarized mitochondria in quarter-size grafts detected by intravital confocal microscopy were 15 per high power field (hpf), and non-viable cells were <1/hpf, indicating that depolarization preceded necrosis. IP blocked mitochondrial depolarization by 66%. Hsp10, Hsp27, Hsp32, Hsp60, Hsp70, Hsp72, Hsp75 and cytosolic Cu/Zn-SOD (SOD1) before and after transplantation of quarter-size liver grafts but enhanced the expression of Hsp90, a chaperone that facilitates protein import into mitochondria, and increased Mn-SOD (SOD2), a mitochondrial antioxidant enzyme that is synthesized in the cytosol and then imported into mitochondria. A 6-line ESR free radical adduct signal was detected from bile after implantation of quarter-size grafts detected by intravital confocal microscopy.

**Conclusion:** Taken together, IP decreases injury and improves regeneration of small-for-size liver grafts, most likely by increasing mitochondrial SOD2, thus protecting against free radical-dependent mitochondrial dysfunction (NIDDK).

ADENOVIRAL GENE DELIVERY OF INTERLEUKIN-10 REDUCES HEPATIC ISCHEMIA-REPERFUSION INJURY IN RATS THRU INHIBITION OF KUPFFER CELL ACTIVATION

Matthias Froh, Peter Walbrun, Susanne Natter, Reiner Wiest, Jürgen Schoelmerich, Claus Hellerbrand; Internal Medicine I, University of Regensburg, Regensburg, Germany

**Background and aims:** Ischemia-reperfusion injury to the liver occurs in trauma, hemorrhagic shock, and after hepatic surgery, including tumor resection and transplantation. Reactive oxygen species, produced by activated macrophages (in particular Kupffer cells) and neutrophils, play a critical role in the injury caused by ischemia-reperfusion. The multifunctional cytokine Interleukin-10 (IL-10) is known for its ability to inhibit activation and effector function of T cells, monocytes, and macrophages. Therefore, the aim of this study was to investigate the effect of adeno viral gene delivery of IL-10 in an acute model of hepatic oxidative stress. **Methods:** Kupffer cells (KC) were isolated from Sprague Dawley rats and infected with adenoviral vectors expressing (human) Interleukin-10 (Ad5.IL-10) applying different multiplicities of infection (moi: 0.1-1000 pfu/cell). Adenoviral vectors expressing beta-Galactosidase (Ad5.LacZ) served as control. In some experiments KC were stimulated with LPS (10 µg/ml) and cytokine release was analyzed with IL-10, IL-6, and TNFα ELISAs, respectively. Oxidative stress was established using a warm ischemia-reperfusion model. Three days prior to the experiments, animals were infected i.v. with 3 x 10⁹ plaque-forming units (PFU) of Ad5.IL-10 or Ad5.EGFP. IL-10 expression was analyzed using quantitative PCR analysis and ELISA. **Results:** Transduction of isolated KC with Ad5.IL-10 resulted in a dose-dependent induction of IL-10 secretion with a maximum at moi = 50 pfu/cell. In functional assays, transduction of KC with Ad5.IL10 blunted LPS-induced IL-6 and TNFα secretion as compared to Ad5.LacZ-infected and control cells. In vivo infection with Ad5.IL-10 caused a significant increase of hepatic IL-10 mRNA expression and IL-10 serum levels as compared to Ad5.EGFP-treated control animals. The increase of serum transaminases (ALT, AST) observed after hepatic ischemia-reperfusion was significantly reduced compared to controls. Furthermore, histopathological hepatic changes as focal necrosis and leukocyte infiltration seen in control animals were almost completely absent in Ad5.IL10 infected animals. **Conclusions:** Increased hepatic IL-10 expression can effectively reduce hepatic oxidative stress caused by hepatic ischemia-reperfusion. These data support the hypothesis that increased IL-10 secretion plays an important antiinflammatory role in liver disease and suggest that KC-targeted therapeutic approaches may be a promising strategy affecting hepatic inflammation.

URIDINE-5’-TRIPHOSPHATE (UTP) PROTECTS AGAINST HEPATIC ISCHEMIC INJURY IN MICE

Ziv Ben-Ari\(^1\), Orit Pappo\(^2\), Smadar Yitzhaki\(^3\), Yelena Cheporko\(^4\), Asher Shainberg\(^3\), Eytan Mor\(^5\), Edith Hochhausser\(^4\); \(^1\)Liver Institute, Rabin Medical Center, Petah-Tiqva, Israel; \(^2\)Department of Histopathology, Rabin Medical Center, Petah-Tiqva, Israel; \(^3\)Faculty of Life Sciences, Bar-Ilan University, Ramat Gan, Israel; \(^4\)Cardiac and Liver Research Laboratory, Felsenthal Medical Research Center, Petah-Tiqva, Israel; \(^5\)Department of Transplantation, Rabin Medical Center, Petah-Tiqva, Israel

Warm ischemia occurs in liver transplantation, trauma, shock and during partial hepatectomy. Liver failure is the most com-
mon cause of mortality. Adenosine 5' triphosphate (ATP)-depletion from hepatic tissue following warm ischemia causes necrotic and apoptotic cell death. Uridine 5'-triphosphate (UTP) significantly reduced cardiomyocyte death induced by hypoxia via activating P2Y receptors. The role of pyrimidine nucleotides in the hypoxic liver has not been explored. The aim of this study was to investigate the role of UTP on the hepatic injury induced by ischemia in isolated mouse livers. Isolated mouse livers were randomly divided into five groups: (1) control group, perfused for the whole study period (120 minutes); (2) 30-minute perfusion followed by 90 minutes of ischemia; (3) like group 2, but with the perfusion of UTP (1 µM), for 30 minutes before ischemia; (4) like group 2, but with the perfusion of suramin (200 µM), a P2Y antagonist, for 30 minutes before ischemia (5) like group 3 but with the simultaneous perfusion of suramin. Effluent enzyme levels, intrahepatic ATP content and caspase-3 activity were measured. Apoptotic cells were identified by morphological criteria, the terminal deoxynucleotidyl trans-ferase-mediated dUTP nick-end labeling (TUNEL) fluorometric assay and immunohistochemistry for caspase-3. Results: Post-ischemia, there was a statistically significant reduction in liver enzyme levels in the animals pretreated with UTP (p<0.05), the infrahepatic caspase-3 activity was significantly decreased (p<0.05) and the infrahepatic ATP content increased (p<0.05) compared to group 2 (ischemic untreated). The reduction in postischemic apoptotic hepatic injury in the UTP-treated groups was confirmed morphologically, by the significantly fewer apoptotic hepatocytes detected (p<0.05); immunohistochemically, by the significantly weaker activation of caspase-3 compared to the ischemic untreated group 2 (p<0.05); and by the TUNEL assay (p<0.05). The administration of suramin (group 4) aggravated the apoptotic ischemic injury while the simultaneous perfusion of UTP and suramin induced ischemic changes in group 2. Conclusion: The administration of UTP before induction of ischemia can attenuate the postischemic hepatic apoptosis and thereby minimize liver damage. Apoptotic hepatic injury seems to be mediated through caspase-3 activity. Inhibition of endogenous release of UTP aggravates the ischemic hepatic injury. These findings have important implications for the potential use of UTP in ischemic hepatic injury.

671 INTERMITTENT REPERFUSION STRESS ACCELERATES LIVER REGENERATION BY INDUCING ENTRY AND PROGRESSION IN CELL CYCLE OF HEPATOCYTES

Sasse-Fanie Mbatchi1, Hélène Duval1, Stéphane Grandadam1,2, Catherine Ribault1, Claire Piquet-Pellorce1, Pascal Loyer1, Christine Guuguen-Guilhouzou1, Anne Corlu1, Karim Boudjema1,2, INSERM U522, INSERM, Rennes, France; 2Département de Chirurgie Viscèreale, Hôpital Pontchaillou, Rennes, France

Massive blood loss during liver resection can be prevented by temporary vascular inflow occlusion, consequently leading to ischemia and reperfusion injury in the remnant liver. It has been shown that intermittent clamping was less deleterious than continuous clamping. Our goal was to evaluate the effects of intermittent ischemia-reperfusion stresses on regenerative capacity of the liver. For this purpose, we developed an original rat model of selective lobe occlusion to isolate reperfusion stress from ischemia injury followed by 70% partial hepatectomy. Four animal groups were distinguished: the "reperfusion group", median and left lateral lobes were subjected to selective intermittent clamping before resection so that the remnant liver (caudal and right lobes) did not suffer from ischemia injury but was exposed to the reperfusion effects of resected lobes. In the "control group", simple exteriorisation of median and left lateral liver lobes was performed before resection. These two groups were compared to "standard group" subjected to immediate partial hepatectomy and to "sham group" subjected to laparotomy only. Higher levels of serum transaminases and increased numbers of apoptotic figures were detected in the reperfusion group compared to other groups, demonstrating a transient and greater cellular damage induced by the reperfusion stress. This cellular damage appeared not impairing liver regeneration since DNA synthesis and mitotic index were similar in both reperfusion and control groups. However, cell cycle progression was speeded up in these two groups when compared to the standard hepatectomy group, as DNA synthesis and mitotic index peaked at least 6 hrs earlier. Further analysis of Cyclin D1, CDK1 and Cyclin A expression kinetics evidenced an earlier cross-over of the mitogen-dependent restriction point and G1/S transition in both groups. In addition, we perfusate were analysed. Results: Six livers showed serum biochemical evidence of initial poor function (IF). These livers had significantly more staining for C4d of both lobular and periportal hepatocytes. C4d positive hepatocytes were also found in the liver during cold storage (3/15). These periportal hepatocytes also showed evidence of necrosis and were found to have intracellular neutrophils. Hepatocyte rounding in zone III, necrosis and C4d staining in recipient were also significantly correlated with the degree of lactic acidosis during this phase. Intrahepatic lactic acidosis at all time points was significantly associated with sinusoidal endothelial cell (SEC) injury post-reperfusion. There were no correlations between glucose, pyruvate and glycerol levels and histopathological changes in the liver. Discussion: In the patients studied the degree of C4d staining correlated with IF and was associated with intrahepatic lactic acidosis in the donor, during cold storage and post-reperfusion. Complement activity in the liver during cold storage may be as a result of in situ activation. Intrahepatic lactic acidosis is associated with SEC and hepatocyte injury. The presence of intrahepatic neutrophils is likely to be in response to cell necrosis. Disclosures: The following people have nothing to disclose: Michael A. Silva, Darius F. Mirza, Nick Murphy, Douglas A. Richards, Stephen J. Wigmore, John A. Buckels, Desley A. Neil

670 INTRAHEPATIC COMPLEMENT ACTIVATION, SINUSOIDAL ENDOTHELIAL INJURY AND LACTIC ACIDOSIS IS ASSOCIATED WITH INITIAL POOR FUNCTION OF THE LIVER POST TRANSPLANTATION

Michael A. Silva, Darius F. Mirza, Nick Murphy, Douglas A. Richards, Stephen J. Wigmore, John A. Buckels, Desley A. Neil; The Liver Unit, University Hospital Birmingham NHS Trust - Queen Elizabeth, Birmingham, United Kingdom

Background: We recently described changes in glucose metabolism in the liver during transplant procurement, storage and post-reperfusion using microdialysis. We now aim to correlate these findings with histopathological, immunohistochemical and ultrastructural changes in liver during pre-harvest, post-storage and post-reperfusion. Methods: Microdialysis catheters were inserted into 15 human livers to monitor metabolic changes that took place during procurement, backtable preparation, and post-reperfusion in the recipient. At each stage menhingi needle biopsies were also taken. Each biopsy was studied using light microscopy and electron microscopy. The microdialysis cannula was perfused with isotonic solution and samples of

HEPATOLOGY, Vol. 46, No. 4, Suppl. 1, 2007 AASLD ABSTRACTS 535A
showed that in the reperfusion group, c-fos and IL-6 mRNA were expressed before hepatectomy suggesting that G0/G1 transition occurred before resection in this group. In conclusion, our study provides evidence that the surgical exteriorisation step itself induces cell cycle progression. Moreover it shows that the transient cellular damage related to the reperfusion process might trigger greater cell defence mechanisms and signalling pathways that contribute to liver regeneration acceleration. These observations strongly argue for a positive effect of reperfusion stress on liver regeneration which should be beneficial to clinical practice.

Disclosures: The following people have nothing to disclose: Sasse-Fanie Mbatici, Hélène Duval, Stéphane Grandadam, Catherine Ribault, Claire Piquet-Pellorce, Pascal Loyer, Christiane Guguen-Guilhouzo, Anne Corlu, Karim Boudjema

672
OXIDATIVE DAMAGE TO MITOCHONDRIAL DNA AND PROTEINS IN SMALL-FOR-SIZE LIVER GRAFTS
Zhi Zhong1, Hasibur Rehman1, Tom Theruvath1, John J. Lemasters1,2,1 Pharmaceutical Sciences, Medical University of South Carolina, Charleston, SC; 2Biochemistry & Molecular Biology, Medical University of South Carolina, Charleston, SC

Background: Small-for-size liver transplantation compromises energy supply. Mitochondrial dysfunction probably plays an important role in graft injury and suppression of regeneration after transplantation of small-for-size liver grafts. The Aim of this study was to investigate mitochondrial injury in small-for-size liver grafts. Methods: After harvest, liver grafts were reduced in size to ~50% ex vivo, stored in UW solution at 0-1°C for 6 h and then implanted into recipients of similar or greater body weight, resulting in a relative graft weight of 50% (half-size) or 25% (quarter-size). Results: Serum transaminase was 3-fold higher after transplantation of quarter-size than of full-size grafts. Cell proliferation detected by BrdU incorporation increased from ~1% in full-size to 17% in half-size grafts but did not increase in quarter-size grafts. ATP content in livers was not significantly altered after transplantation of full-size grafts but decreased to 30% of normal in quarter-size liver grafts. Mitochondrial DNA (mtDNA) contains genes which encode proteins critical for oxidative phosphorylation, and an adequate copy number of mtDNA per cell is required for respiration and oxidative phosphorylation. The ratio of mtDNA/nuclear DNA detected by native gel Southern blotting was not altered at 5 h after transplantation of quarter-size relative to full-size grafts (p<0.05), indicating double-strand DNA damage. Alkaline gel Southern blotting also showed that mitochondrial DNA underwent single-strand damage in quarter-size liver grafts. 8-Oxyguanosine, an indicator of DNA oxidation, increased in both nuclei and mitochondria, but more markedly in mitochondria. Subunit III of respiratory chain Complex I, a protein that is encoded by mitochondrial DNA, decreased substantially in quarter-size grafts. COX IV and ATP synthase-β, mitochondrial proteins encoded by nuclear DNA, also decreased in quarter-size grafts. C. sinenesis polyphenols (20 µg/mL), potent scavengers of reactive oxygen and nitrogen species, prevented mitochondrial DNA damage, blunted decreases of mitochondrial respiration chain components and restored ATP levels to 75%. In Conclusion, small-for-size liver transplantation increases free radical formation which causes mitochondrial and nuclear DNA damage and a decrease of mitochondrial respiratory chain proteins. These alterations may contribute, at least in part, to compromised energetic status and graft failure after small-for-size liver transplantation. These effects can be effectively prevented by free radical scavengers (NIDDK).

ALTERNATIVE PRECONDITIONING WITH DEATH LIGANDS TNF-α & FASL PROTECTS THE CIRRHOTIC MOUSE LIVER AGAINST ISCHEMIC INJURY
Jae-Hwi Jang, Wolfgang Moritz, Rolf Graf, Pierre A. Clavien; Visceral and Transplantation Surgery, University Hospital Zürich, Zürich, Switzerland

Background and Aims: Ischemic preconditioning is the pre-emptive proven strategy to reduce ischemic injury in the liver, but it can be harmful in the elderly or patients with liver diseases. Patients who have underlying liver diseases are increasing, but the chance of transplantation which might be the last choice for the patients is rare. Thus, alternative ways to protect the livers are required. Ischemic preconditioning induces cyto-protective effects via activation of oxidative stress. Low dose application of Fas ligand or tumour necrosis factor can induce a similar response by inducing limited hepatic injury. Therefore, we tested if death ligands could mimic ischemic preconditioning. Methods: Ischemia was performed for 60 minutes in carbon tetra chloride induced cirrhotic mice. The optimal dose of preconditioning was found in a pilot study in cirrhotic animals. Death ligands were given 40 minutes before ischemia by intraperitoneal injection. Ischemic injury was assessed by histology, and biochemical assays after 1, 4, and 24 hours of reperfusion. To elucidate the mechanism of protection, we used zinc-protoporphyrin, an inhibitor of heme oxygenase-1 (HO-1) and gadolinium chloride, an inhibitor of Kupffer cell activation. Results: Compared to the non-treated control group, death ligand preconditioning strongly reduced all markers of injury: serum transaminase levels were reduced; the area of necrosis and the extent of apoptosis were significantly ameliorated. Death ligand preconditioning mimicked the effect of ischemic preconditioning in terms of HO-1 up-regulation, predominantly in macrophages. When zinc-protoporphyrin or gadolinium chloride was applied prior to preconditioning, the beneficial effect of preconditioning was lost. Additionally, death ligand preconditioning induced anti-inflammatory (IL-1 receptor antagonist) and pro-inflammatory (IL-1beta, CXCL2) cytokines prior to ischemia, which are known to be produced by macrophages. Conclusion: These results demonstrate that ischemic preconditioning can be replaced by death ligand preconditioning in the cirrhotic liver to prevent ischemic injury. The protective mechanism is depending on HO-1 induction in macrophages. These results open new doors for novel hepatoprotection strategies in cirrhotic liver surgery.

P66SHC, AN AGEING PROTEIN, PLAYS A PIVOTAL ROLE IN POST-HEPATECTOMIZED LIVER REGENERATION IN AGED MICE
Michitaka Ozaki1, Sanae Haga2, Tadahiro Osada2, Yoko Oikawa1, Hiroyuki Furukawa1, Kaikobad Irani2, Satoru Todo3,1 Department of Molecular Surgery, Hokkaido University SOM, Sapporo, Japan; 2Department of Surgery, Hokkaido University SOM, Sapporo, Japan; 3Department of Organ Transplantation and Regenerative Medicine, Hokkaido University SOM, Sapporo, Japan; 4Cardiovascular Institute, University of Pittsburgh Medical Center, Pittsburgh, PA

Liver regeneration is composed of a series of complicated processes, which are affected by various patho-physiological...
conditions. The present study was designed to investigate the influence of ageing on liver regeneration following partial hepatectomy (PH) in mice. [Materials & Methods] Male C57BL/6j mice (8-10 wks and 13/20 mo old), fed by low fat/protein CR-LPF chow for long breeding (Oriental Yeast Co. Japan), were used as young and aged mice models, respectively. These mice were subjected to simple 70% PH. Adenoviral vectors were introduced intravenously 3 days prior to the experiment (5 x 10^8) pfu/body. The mice were sacrificed and liver specimens were collected and applied for the assays before and after hepatectomy, and the recovery of liver mass was also examined until 14 days post-PH. [Results] Post-PH liver regeneration was significantly impaired following to age (Fig.). Nevertheless, reactive liver cell proliferation after PH was not impaired at all even in 20 mo old mice after PH, assessed by mitotic index and PCNA positivity. Instead, liver cell apoptosis was markedly increased in the aged mice after PH. Many apoptotic cells were observed immediately after PH and continued until 14 days post-PH in the aged mice, though much less apoptosis was observed in the young mice. In support of this observation, serum levels of AST/ALT were also increased until 3 days post-PH in the aged mice. By western blot analysis, signal proteins responsible for cell proliferation (MAPK, STAT3) were expressed and activated after PH in the aged mice liver, equally or even more strongly than the young mice. However, Akt was less activated though its protein was expressed enough in the aged liver tissue. Interestingly, p66Shc, ageing protein known to control 1) cellular redox states, 2) Akt-mediated 'survival' pathway and 3) apoptosis, was expressed moderately in the aged mice, and strongly phosphorylated at Serine36. To examine the effect of p66Shc on liver regeneration in the aged mice, p66Shc was knocked down by introducing adenoviral vector coding p66Shc-siRNA. By the knocking down of p66Shc, liver regeneration was significantly improved in the aged mice, compared to the LacZ-control mice, mainly by suppressing apoptotic cell death in the post-PH liver. [Conclusions] p66Shc may play a pivotal role in liver regeneration in the aged mice, by increasing vulnerability to the stresses such as hepatocyte and/or oxidative stress. Further study must be performed to examine the underlying mechanisms in the impaired liver regeneration in the aged mice. However, this may provide a clue to understand the processes of liver regeneration especially in the aged.

** 675 METHOXYPOXYETHYLENE GLYCOL MODIFIED-ALBUMIN (PEG-ALB) ENHANCED THE COLD PRESERVATION PROPERTIES OF UW SOLUTION IN RAT LIVER GRAFTS**

Rime Abbas1, David Dingam2, Deepak Malhotra2, Henry Brunengraber2, Juan R. Sanabria1,1 Education and Research Centre, St Vincent's University Hospital, Dublin, Ireland; 2Liver Unit, St Vincent's University Hospital, Dublin, Ireland; 3Conway Institute Biomedical and Biomolecular Sciences, St Vincent's University Hospital, Dublin, Ireland; 4Pathology, St Vincent's University Hospital, Dublin, Ireland

Liver grafts preserved in cold undergo changes mainly manifested by morphological changes of the sinusoidal endothelium. Swollen and fragmented cytoplasm translates into poor portal blood flow, increase release of liver enzymes and low bile production upon liver reperfusion. Studies were performed to determine if the addition of higher molecular weight polyethylene glycol modified albumin to the University of Wisconsin (UW) preservation solution ameliorates the cold preservation injury of liver grafts. Methoxyxypolyethylene glycol 5000 activated with cyanuric chloride was covalently coupled to human albumin (Peg-Alb) at multiple sites. The isolated Perfused Rat Liver model was used (IPRL). Human and Rat hepatocytes cell lines were preserved in cold under similar preservation solutions. Effects were studied after rewarming of cells on Glutathione turn over by mass spectrometry. Apoptosis of SLC's on liver tissue and cell lines were evaluated by Tunel assay and flowcymeter techniques. Preliminary results showed Glutathione turnover was significantly decreased in all groups compared to negative controls. In contrast, apoptosis of SLC was similar in the PEG-Alb group when compared to the negative control group but significantly decreased in the PEG-Alb group when compared to other groups. Conclusions: The addition of high molecular albumin to UW preservation solution appears to ameliorate endothelial injury of cold preserved liver grafts as judged by better portal vein blood flow, increased bile production and decreased SLC apoptosis. PEG-Alb appears to have no effect on hepatocytes preservation.

**IPRL results of grafts preserved with UW solution and UW solution plus PEG- Alb. Values are given after 60 minutes of perfusion with a sanguineous perfusate.**

Ischemia reperfusion (IR) leads to generation of reactive oxygen species (ROS), which, as well as causing tissue damage, also activate mechanisms of cytoprotection. The ROS sensitive transcription factor Nrf2 induces tissue repair mechanisms through transcriptional activation of phase II antioxidant pathways. Here, for the first time, we correlate Nrf2 in human liver with histological, immunological and biochemical markers of injury and inflammation post liver transplantation (LT). Paired biopsies were acquired from donor livers (n = 17) prior to and following the IR phase of LT. Each biopsy was assessed using the Modified Suzuki Scoring system (histological grading of degree of IR injury) and the polymorphonuclear infiltrate quantified. Nrf2 protein levels were measured using Western blots. Oxidised and reduced glutathione levels were measured using the Glutathione assay kit (Cayman Chemical Co.) and IL-8 was measured by ELISA. The data was analyzed using the SPSS statistical package. All reperfusion biopsies showed evidence of IR injury with significantly increased Suzuki scores and polymorphonuclear infiltration. (P<0.05). GSH levels decreased following IR as did the GSH: GSSG (redox ratio). Median GSH in donor...
and reperfusion biopsies was 146.88 µM/g (25.52-307.94) and 75.80 µM/g (7.18-180.15) respectively. Nrf2 protein levels post-IR were decreased as compared to pre-IR (P<0.01). IL-8 levels in post-IR biopsies were decreased as compared to pre-IR (P<0.01). IL-8 levels increased in post-IR biopsies (median donor and 75.80 µM/g (25.52-307.94) respectively). Nrf2 protein levels in donor liver post-IR may be cytoprotective as they correlate with Nrf2 levels. Recipients of donor organs with high Nrf2 could induce the trans-differentiation of ADSC into hepatic lineage cells. ADSC could be a source of hepatic lineage cell transplantation.

MURINE ADIPOSE TISSUE DERIVED STROMAL CELLS TRANS-DIFFERENTIATE INTO HEPATIC LINEAGE CELLS BY BASIC FIBROBLAST GROWTH FACTOR

Yoshihiro Kamada, Shinji Tamura, Yukiko Saji, Yuichi Yoshida, Shinichi Kiso, Norio Hayashi; Gastroenterology and Hepatology, Osaka University, Suita, Japan

Background and Aims: During the past few years, multiple studies have revealed that bone marrow-derived mesenchymal stromal cells (BMSC) can be trans-differentiated into various cell types under proper conditions. Recently, mesenchymal stromal cells (MSC) are also reported to exist in adipose tissue. Compared with BMSC, adipose tissue derived stromal cells (ADSC) can be easily and repeatedly harvested from patients by a simple, minimally invasive method. ADSC also have a potential to differentiate into various cell types, including hepatic lineage cells. However, the molecular mechanism underlying this phenomenon has remained unclear. To address this issue, we investigated effective differentiation method to differentiated ADSC into hepatic lineage cells. Methods: (1) ADSC was isolated from the subcutaneous adipose tissue of 12-week-old male C57Bl6/J mice. ADSC was cultured in 3 dimensional culture system (3D) of collagen gel with or without 20ng/ml of the growth factors (bFGF, HGF, OSM, HGF+OSM+0.1% of DMSO) or on plastic dishes (2 dimensional culture system; 2D) with or without bFGF (20ng/ml) for 2 or 4 weeks. To investigate the effect of these growth factors, the gene expressions of AFP, albumin, CK18, CK19, PEPC, G6Pase, Cytp2b9, and transthyretin (TTR) were examined by RTPCR. (2) Albumin secretion into the media by ADSC (2D) was evaluated by ELISA.

(3) Glycogen synthesis, urea production, and low-density lipoprotein (LDL) uptake, were confirmed by periodic acid-Schiff staining, a colorimetric assay, and an LDL uptake assay, respectively in ADSC (2D). (4) ADSC was cultured with bFGF (20ng/ml) (2D or 3D) for 4 weeks. We assessed the expressions of albumin and CK18 proteins of ADSC by immunohistochemistry. Results: (1) Albumin was induced in ADSC (3D) cultured with bFGF, OSM, and HGF+OSM+DMSO. ADSC cultured with bFGF for 4 weeks induced hepatocyte markers gene expression most effectively, and revealed the gene expressions of albumin, CK18, PEPC, G6Pase, Cytp2b9 and TTR. ADSC (2D) cultured with bFGF for 4 weeks expressed albumin, CK18, PEPC, G6Pase, and TTR. (2) Albumin secretion by ADSC (2D, 3D) cultured with bFGF was significantly higher than control. The bFGF treated ADSC showed the ability to uptake LDL. (4) ADSC (2D, 3D) was stained for both albumin and CK18. Conclusions: Basic fibroblast growth factor could induce the trans-differentiation of ADSC into hepatic lineage cells. ADSC could be a source of hepatic lineage cell transplantation.

DO INJECTED AUTOLOGOUS BONE MARROW CELLS WORK IN PATIENTS WITH ADVANCED LIVER CIRRHOSIS?

Ja Kyung Kim1,2, Young Nyun Park3,2, Mee Sook Park4,7, Myeong-Jin Kim4,7, Hyun Ok Kim2, Jin Seok Kim1, Kyung Sik Kim4,7, Sang Hoon Ahn1,2, Dong Han Pak1,2, Do Young Kim1,2, Chae Yoon Chon1,2, Kwan Sik Lee1,2, Byung Soo Moon1,2, Young Myoung Moon1,2, Kwang-Hyub Han1,2; 1Dept. of Internal Medicine, Yonsei University College of Medicine, Seoul, South Korea; 2Liver Cirrhosis Clinical Research Center, Seoul, South Korea; 3Dept. of Pathology, Yonsei University College of Medicine, Seoul, South Korea; 4Dept. of Diagnostic Radiology, Yonsei University College of Medicine, Seoul, South Korea; 5Dept. of Laboratory Medicine, Yonsei University College of Medicine, Seoul, South Korea; 6Dept. of Surgery, Yonsei University College of Medicine, Seoul, South Korea; 7Yonsei Institute of Gastroenterology, Seoul, South Korea

Background/Aims: Liver cirrhosis (LC) is the end stage of chronic liver disease and is extremely difficult to treat. Although recent studies examining the role of bone marrow cells (BMCs) in regeneration or fibrosis using liver fibrosis/cirrhosis animal models have given conflicting results, human clinical trials of BMC infusion for cirrhotic patients have had positive results. In this study, we evaluated the safety and effect of autologous BMC infusion (ABMI) on the liver in patients with advanced LC. Methods: Six patients (three males) aged between 18 and 75 years with a clinical diagnosis of advanced LC (Child-Pugh class B or C), with a total bilirubin less than 3.0 mg/dl, a platelet count exceeding 50,000/uL, and no viable hepatocellular carcinoma on magnetic resonance imaging (MRI) were enrolled. Autologous BMCs were harvested from the ilium under general anesthesia and infused into a peripheral vein after RBC depletion and mononuclear cell concentration. Serologic tests, MRI, and biopsy were performed before and 1, 3, and 6 months after the procedure. The quality of life of the patients was surveyed using a questionnaire. Results: The mean patient age was 57 years (range 47–64 years), and the mean number of infused mononuclear cells was 6.83 x 10^9. The serum albumin and cholesterol level increased and the prothrombin time was shortened. The ascites of the patients improved or disappeared after stopping oral diuretics or reducing their requirement. All patients showed improved symptoms and quality of life. The fibrosis index measured using MRI indicated reduction of fibrosis in some patients. The liver volume measured using MRI had increased in some patients. In serial biopsies, a significant increment in the progenitor cell compartment, including the ductular reaction and intermediate hepatocytes, was consistently noted. No serious adverse events occurred. Conclusions: Autologous BMC infusion for advanced LC resulted in improved liver function and subjective symptoms with progenitor cell compartment activation. ABMI can be used as a bridging modality in select patients with decompensated LC.

N-ACETYLCYSTEINE IMPROVES THE METABOLIC AND SYNTHETIC FUNCTION OF HUMAN HEPATOCYTES ISOLATED FROM SEVERELY STEATOTIC DONOR LIVERS

Filippos Sagias1, Ragai Mity1, Robin Hughes2, Sharon Lehec1, Ameet Patel1, Giorgina Mieli-Vergani2, Mohamed Rela1, Nigel Heaton1, Anil Dhawan1

The availability of good quality hepatocytes has limited progress in the development of human hepatocyte transplantation. Marginal donors are the main source of tissue available for cell isolation, but the isolated hepatocytes obtained are of low viability and are usually not suitable for clinical use. The most common source is livers rejected on the grounds of steatosis. The aim of this study was to evaluate the effects of addition of the antioxidant N-acetylcysteine (NAC) during isolation of human hepatocytes from severely steatotic donor livers. Methods: Human hepatocytes were isolated from 10 donor livers (7M, 3F) rejected for transplantation on the grounds of being severely steatotic (>60%). The median donor age was 55y (range 44-76y) and cold ischaemia time 19h (range 11-29h). The left lateral segment of the liver was dissected into two pieces, which were cannulated and randomised to control and NAC. A standard collagenase liver digestion technique was used with and without NAC (5mM) added to the first perfusion buffer. The hepatocytes obtained were plated and cultured for 24h and then assays performed: SRB staining for hepatocyte attachment, MTT for cell metabolic activity, [14C]-leucine incorporation, albumin ELISA and urea production. Results: A significantly higher cell viability and cell yield were obtained from tissues perfused with NAC (median 82%; range 72-91 and 2.6x10^6 cells/g; 0.5-5.5) compared to control (71%; 38-82, p=0.005 and 1.1x10^6 cells/g; 0.3-3.6, p=0.005). Cell attachment (median 1.19 OD unit; range 0.08-2.46 vs. 0.59 OD unit; 0.07-2.06, p=0.017) and overall cell metabolic activity (median 0.22 OD unit; range 0.12-0.28 vs. 0.10 OD unit; 0.09-0.19, p=0.005) were both significantly higher in cells from tissues perfused with NAC. Protein synthesis from [14C]-leucine incorporation (median 857 cpm/well; range 275-1938 vs. 795 cpm/well; 238-1560, p=0.012) and albumin content (median 339 ng/mg protein/well; range 180-1227 vs. 197 ng/mg protein/well; 124-1144, p=0.012) in hepatocytes from tissues perfused with NAC were significantly higher than control. Urea production was not significantly affected by NAC. Preliminary experiments suggested that N-acetylcysteine decreased hepatocyte iNOS expression. Conclusions: This study demonstrates that addition of NAC during isolation of hepatocytes from steatotic donor liver tissue, significantly improves the metabolic and synthetic function of the isolated cells. Incorporation of NAC in the hepatocyte isolation protocol should make better use of rejected steatotic livers and thus increase the availability of hepatocytes for clinical cell transplantation.

PURIFICATION OF A SPECIFIC CELL POPULATION CONTAINING ALL OF THE REPOPULATION POTENTIAL OF FETAL LIVER STEM CELLS FOR THE NORMAL ADULT RAT LIVER

Michael Oertel1, Anuradha Menthen1, Yuan-Qing Chen1, Borge Teisner2, Charlotte Harken Jensen2, David A. Shafritz1
1Marion Bessin Liver Research Center, Albert Einstein College of Medicine, Bronx, NY; 2University of Southern Denmark, Odense C, Denmark

Cell transplantation is a promising alternative to liver transplantation. Previously, we showed a high level of long-term liver replacement after transplantation of unfractionated embryonic day (ED)14 fetal liver stem/progenitor cells (FLSPC). However, hematopoietic stem cells, a major component in unfractionated fetal liver cell preparations engraft in other organs, e.g. bone marrow, spleen and lung, and may cause undesirable side effects or complications. Therefore, for most clinical applications, cell isolates need to be highly enriched before cell transplantation. Dlk-1, a member of the delta-like family of transmembrane proteins, is highly expressed in human and rodent fetal livers. We therefore isolated Dlk-1+ cells from ED14 fetal liver and examined their hepatic gene expression profile and characteristics in vitro and proliferative and differentiation potential after transplantation into the normal adult rat liver in comparison to Dlk-1- fetal liver cells. Methods & Results: We have purified rat ED14 FLSPC to 95% homogeneity using immunomagnetic microbeads (MACS). Dlk-1-enriched fetal liver cells are AFP+/CK-19. Anti-Dlk-1 selected rat fetal liver cells exhibit all the cell culture and gene expression characteristics expected for hepatic stem/progenitor cells. Compared to Dlk-1- cells, Dlk-1+ cells preferentially express AFP, Alb, CK-19, G6-Pase, CPS-1, TAT, TRPO, OSMR, Hex, HNF-3β, HNF-4α, CYP3A1 and E-Cadherin, all of which are related to hepatocytic or hepatic progenitor cell functions. After transplantation of Dlk-1+ fetal liver cells (0.4 to 1.9x10^6 cells), these cells engrafted in the liver, proliferated and differentiated into both mature hepatocytes and bile duct structures. These cells express unique hepatocyte-specific proteins and are structurally and functionally indistinguishable from host hepatocytes throughout the entire hepatic lobules. The level of repopulation exceeded 15% at 6 months after cell transplantation. In selected areas, liver repopulation reached 50% and transplanted cell clusters became confluent and generated complete new liver lobules. In contrast, Dlk-1- fetal liver cells do not repopulate the normal adult rat liver, however, they engraft in other organs. Conclusions: This is the first study showing a method to separate a highly enriched hepatic cell fraction that contains all the hepatic fetal liver stem/progenitor cell types identified to date and all of the normal liver repopulation potential found in the fetal liver. This approach is a major step forward in the development of protocols that will be essential for future clinical applications.

A CRITICAL ROLE OF FAS (CD95) IN ALLOREJECTION OF TRANSPLANTED HEPATOCYTES

RituPalma Moitra, Elena Mashalova, Xia Wang, Jinlan Jiang, Laibin Liu, Yong Chen, Chandan Guha, Jayanta Roy-Chowdhury, Namita Roy-Chowdhury; Albert Einstein College of Medicine, Bronx, NY

BACKGROUND: As with whole organ transplantation, allograft rejection is a major problem in hepatocyte transplantation,
requiring long-term immunosuppression. Death receptors such as Fas (CD95) are highly expressed at hepatocyte cell surface. Fas-mediated apoptosis has been implicated as an important mechanism of liver injury and liver transplant rejection. We showed previously that expression of genes of the E3 domain of the adenoviral genome (AdE3) in donor rat hepatocytes prevented their rejection after transplantation into allogeneic recipients. AIM and HYPOTHESIS: Our objective is to determine the mechanism of hepatocyte allorejection with the ultimate goal of modifying donor cells to prevent immune rejection. Since AdE3 gene expression did not downregulate cell surface MHC class I in the donor cells, but markedly reduced cell surface Fas, we hypothesized that abrogation of Fas-FasL signaling by host alloreactive CTLs was critical in preventing allorejection. METHODS: We tested this hypothesis in two steps. First, we injected C57Bl6 mice with 109 pfu of an adenovector Ad-RIDβ-expressing the receptor internalization and degradation complex (RIDβ) which degrades cell surface "death receptors" including Fas. Control mice received an adenovector expressing an irrelevant gene (Ad-UGT1A1). Two days later the mice were challenged with an agonistic anti-Fas mAb (Jo2). Liver injury and hepatocyte apoptosis were assessed by serum ALT measurement and TUNEL staining of liver sections, respectively. Second, we transplanted hepatocytes from Fas-deficient lpr mice or congenic wildtype C57Bl6 mice, genetically marked by transduction with LacZ into fully allogeneic BalbC recipients. RESULTS: Hepatic expression of AdE3 proteins resulted in marked reduction of Fas-mediated apoptosis and abrogation of liver injury as assessed by serum ALT levels. LacZ-marked hepatocytes from lpr mice survived in allogeneic BalbC mice, whereas hepatocytes from wildtype C57Bl6 mice were rejected within 10 days. CONCLUSION: Down-regulation of cell-surface Fas on donor hepatocytes prevented Fas-mediated apoptosis. Lack of Fas expression in hepatocytes is sufficient to prevent their rejection after transplantation into allogeneic recipients.

MECHANISMS REGULATING SURVIVAL OF DONOR CELLS IN THE NON-HEART BEATING RAT LIVER

Yuta Enami1, Brigid Joseph1, Sriram Bandi1, Juan Lin2, Sanjeev Gupta2; 1College of Medicine, Bronx, NY; 2Department of Epidemiology & Population Health, Albert Einstein College of Medicine, Bronx, NY

The shortage of donor organs poses a major restriction for cell therapy programs. To determine whether additional sources of cells could be developed, we examined non-heart-beating (NHB) donors. F344 donor animals were killed with i.v. KCl and maintained at 4 degrees C with instillation of hepwarin in portal vein to avoid thrombosis for cell isolation. Tissue analysis from NHB donors during 15 min to 40 h period after death showed normal lobular architecture, morphological integrity and absence of significant hepatic apoptosis or necrosis. TUNEL indicated that despite onset of hepatic apoptosis in NHB donors after 30 h, its extent was limited and DNA ladder analysis verified the findings. To demonstrate regulation of global gene expression, we analyzed whole NHB liver and normal liver RNAs with Affymetrix 230 2.0 Arrays (30K genes). Data analysis showed that >2-fold differential gene expression was limited in NHB donors after 4 h to a single metabolic gene; after 16 h to 95 genes; and after 30 h to 372 genes. Ontological groupings showed representation of multiple biochemical processes, including those affected by hypoxia, although genes in apoptosis, death signaling, DNA damage, ATM or NF-kb pathways were not represented, indicating significant integrity at the genetic level. Next, we isolated hepatocytes from a series of NHB donors and found that capacity to exclude trypan blue declined within 15 min after death without change subsequently from donors after up to 4 h (50-55% viable). By contrast, viability of hepatocytes from donors beyond 6 h declined, although viability of cells from donors after 6, 16 or 24 h was similar (20-30%). To enhance viability of NHB donor cells, we studied whether donor pretreatment to perturb adrenergic (labetalol, phentolamine), calcium channel (verapamil) or KATP channel (diazoxide) will be helpful. However, these treatments did not improve cell viability from NHB donors 3, 6, 16 or 24 h after death. Finally, we examined the capacity of F344 NHB donor cells to engraft in DPP4-rats after intrasplenic transplantation. After 7 d, survival and engraftment of transplanted cells from NHB donors up to 4 h after death resembled that of cells from live donors with integration in the liver parenchyma. However, cells from NHB donors between 6-24 h after death engrafted rarely. Conclusions: The NHB donor liver remains intact for prolonged periods and can offer healthy hepatocytes capable of engrafting in the liver. As perturbations in the NHB donor liver were limited, this suggests that damage to hepatocytes likely emanated from reperfusion during cell isolation, which should be amenable to manipulations.

HUMAN HEPATOCYTE GROWTH FACTOR EXPRESSION IN ENDOTHELIAL PROGENITOR CELLS ENHANCES REGENERATIVE PROPERTIES IN RAT CIRRHOTIC LIVER

Toru Nakamura1,2, Takuji Torimura1,2, Masaharu Sakamoto1,2, Eitaro Taniguchi1,2, Osamu Hashimoto1,2, Ryuichiro Sakata1,2, Takato Ueno2, Michio Sata1; 1Department of Medicine, Kurume University School of Medicine, Division of Gastroenterology, Kurume, Japan; 2Kurume University, Research Center for Innovative Cancer Therapy and Center of the 21st Century COE Program for Medical Science, Kurume, Japan

Background: Previously we reported that endothelial progenitor cell (EPC) transplantation could reduce established liver fibrosis and promote hepatic regeneration in a cirrhotic liver rat model. In the present study, we investigated the hypothesis that gene transfer can be used to achieve phenotypic modulation of EPCs. Especially, we investigated the effect on regenerative properties of human hepatocyte growth factor (hHGF)-transduced EPCs in rat cirrhotic liver. Methods: Rat EPCs were isolated from rat bone marrow cells. In vitro, rat EPCs cultured for 7 days were transduced an adenovirus encoding hHGF gene (AdhHGF) or bacterial beta-galactosidase gene (AdlacZ) as a control. In vivo, recipient rats were injected i.p. with carbon tetrachloride (CCl4) twice weekly for six weeks before initial administration of EPCs. CCl4 was then re-administered twice weekly for more four weeks, and LacZ-transduced EPCs (Td/L-EPCs) or hHGF-transduced EPC (Td/H-EPCs) transplantation were carried out for these same four weeks. Examination items were as follows. 1) the measurement of rat HGF concentration in plasma and in liver tissues by ELISA, 2) the morphometry of fibrotic areas by Azan-Mallory staining, 3) immunohistochemistry using anti-collagen-type I, fibronectin, TGF-β, α-SMA, and Ki67 antibodies, and 4) blood chemistry. Results: Rat HGF plasma levels of rats transplanted with Td/H-EPCs disclosed significantly higher than those of rats transplanted with Td/L-EPCs after CCl4 treatment.
for 10 weeks (48.0 ± 27.9 versus 34.5 ± 15.2 ng/mL). In the AdhHGF-transduced group, the degree of liver fibrosis was suppressed compared to those in the AdLacZ-transduced group (4.29 ± 1.4 versus 5.25 ± 1.0 %), and the expression of type-I collagen, fibronectin, TGF-β and α-SMA was diminished after CCl₄ treatment for 10 weeks although insignificantly. Ki67-positive hepatocytes in the AdhHGF-transduced group were significantly increased (13.3 ± 1.1 versus 10.5 ± 1.8 %; p<0.05). Moreover, serum total protein and albumin levels were significantly higher in the AdhHGF-transduced group than those in the AdLacZ-transduced group. Conclusions: This enhanced regenerative acceleration of transplanted EPCs by HGF transfer will provide novel therapeutic strategy for hepatic regeneration in patients with severe cirrhosis.

684 INITIAL CLEARANCE OF TRANSPLANTED CELLS FROM THE LIVER IS REGULATED IN PART BY COX-1-MEDIATED INFLAMMATORY MECHANISMS AND COX-INHIBITION IMPROVES CELL ENGRAFTMENT

Yuta Enami, Brigid Joseph, Sanjeev Gupta; Marion Bessin Liver Research Center, Albert Einstein College of Medicine, Bronx, NY

To develop robust applications of hepatocyte transplantation, insights into cell engraftment mechanisms will be helpful. Cell transplantation leads to activation of both beneficial and deleterious events in the liver, including Kupffer cells, phagocytes, hepatic stellate cells, and endothelial cells, that affects cell engraftment. In particular, release of inflammatory mediators, e.g., cytokines, impairs transplanted cell engraftment. Here, to establish whether Cox-1 and Cox-2-dependent mechanisms serve roles in clearing transplanted cells, we studied groups of DPPIV-F344 rats that were subjected to intrasplenic transplantation of 10-20 million freshly isolated F344 rat hepatocytes. Analysis of cell transplantation-induced perturbations included hepatic expression of Cox-1 and Cox-2, Kupffer cell activation, onset of cytokine-dependent liver inflammation through hepatic biliary excretion of 99m-Tc-mebrofenin and changes in cell engraftment. RT-PCR and immunostaining showed that Cox-1 but not Cox-2 was expressed in the liver of DPPIV- rats even without cell transplantation. After cell transplantation, hepatic Cox-1 expression increased within 6 h and persisted throughout the 7 d period of the study, whereas Cox-2 was not expressed. Similarly, cell transplantation was associated with rapid activation of Kupffer cells as shown by increased carbon incorporation. Moreover, hepatobiliary excretion of 99m-Tc-mebrofenin, which is perturbed by the release of TNF-alpha and IL-6, was abolished after cell transplantation. To demonstrate whether perturbation of Cox-1 activation by prior treatment of animals with Naproxen, a non-specific Cox inhibitor, will benefit cell engraftment, we performed dose-ranging studies in DPPIV-rats. Administration of Naproxen 2 h before cell transplantation decreased systemic inflammation, as indicated by normalization of 99m-Tc-mebrofenin excretion. Furthermore, morphometric analysis of transplanted cell numbers in Naproxen-treated rats and untreated control rats showed significant increases in transplanted cell engraftment after Cox-inhibition. Conclusions: The inflammatory response activated by cell transplantation extends to Cox-1-mediated processes in the liver leading to impairment of transplanted cell engraftment. As interference with Cox activation improved cell engraftment, these findings establish further roles for intrinsic inflammatory mechanisms in clearance of transplanted cells, as well as the possibility of thwarting these deleterious consequences with pharmacological approaches. The findings will be helpful in optimizing clinical strategies for cell transplantation.

Although several groups have described autoreactive T cells in primary biliary cirrhosis (PBC), there remains a major intellectual gap in understanding loss of tolerance. This loss of tolerance is critical for developing the hallmark of PBC, the multi-lineage anti-mitochondrial response. To address this issue, we developed 8 unique T cell clones (TCC) specific for the major mitochondrial antigen, the E2 component of pyruvate dehydrogenase. The qualitative and quantitative characteristics of these TCCs were studied and mapped in detail with respect to their selective activation by co-stimulatory signals. Importantly, using readouts of not only cytokine production, but also stimulation with putative mimics of PDC-E2, we found that, in patients with PBC, silencing in the periphery rather than clonal deletion, maintains tolerance. In particular, we studied the ability of these TCC specific clones for PDC-E2 163-176 to proliferate or become anergic in the presence of co-stimulation signals. TCC were stimulated with either human PDC-E2 163-176, an E coli 2-oxoglutarate dehydrogenase mimic (OGDC-E2 34-47), or analogs with amino acid substitutions using HLA-matched allogeneic PBMC or mouse LDR53 fibroblasts as APC. Based on their differential responses to these peptides in the different APC systems, TCC were classified as co-stimulation-dependent or -independent. Only co-stimulation dependent TCC could become anergic. TCC with co-stimulation dependent responses to OGDC-E2 become anergic to PDC-E2 when preincubated with mimic, even if co-stimulation independent for PDC-E2 163-176. Anergic TCC produced IL-10. One selected TCC could not become anergic after preincubation with PDC-E2 163-176 pulsed LDR53 but became anergic using LDR53 pulsed with PDC-E2 peptide analogs with a substitution at a critical TCR binding site. TCC that only respond to peptide-pulsed PBMC, but not LDR53, proliferate with peptide-pulsed CD80/CD86 transfected LDR53; however, anergy was not induced with peptide-pulsed LDR53 transfected with only CD80 or CD86. These data highlight that co-stimulation plays a dominant role in maintaining peripheral tolerance to PBC-specific antigens. They further suggest that, under specific circumstances, molecular mimicry of an autoantigen may restore rather than break peripheral tolerance. Furthermore, based on
686 PRIMARY SCLEROSING CHOLANGITIS IS AN INDEPENDENT PREDICTOR OF EARLY HEPATIC ARTERY THROMBOSIS FOLLOWING PRIMARY LIVER TRANSPLANTATION: A COHORT MULTI-CENTRE STUDY

Muhammad F. Dawwas, Christopher J. Watson, Alexander E. Gimson; Hepatobiliary and Liver Transplant Unit, Addenbrooke’s Hospital, Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom

BACKGROUND Primary sclerosing cholangitis (PSC) is an uncommon relentlessly progressive disease leading to liver failure for which liver transplantation is the only established long-term treatment. Controversy exists however as to whether PSC increases the risk of early hepatic artery thrombosis (HAT), a catastrophic complication of liver transplantation. The objective of this multi-centre cohort study is to examine this hypothesis in a large risk-adjusted analysis.

PATIENTS AND METHODS

We examined the impact of PSC on the risk of early (<3 months) HAT and thrombotic graft loss among 6,297 adult first single-organ liver transplant recipients in the UK and Ireland during the period 1 March 1994-31 March 2006, adjusting for recipient, donor and graft characteristics. Independent verification of our findings was sought by undertaking a risk-adjusted analysis of the impact of PSC on the time to thrombotic graft loss among 58,034 such recipients reported to the OPTN/UNOS database in the US between 1 October 1987-31 March 2006. Multiple logistic and Cox regression models were used in the analysis as appropriate.

RESULTS The incidence of early HAT among patients transplanted for PSC in the UK and Ireland (n=571) was significantly higher than that among those transplanted for other liver diseases (OR 1.63 95%CI 1.10-2.40). This association persisted even after adjustment for other risk factors (OR 1.86 95%CI 1.24-2.81). Among those who ultimately lost their graft in the first year (n=1,254), the incidence of early HAT was even higher among PSC recipients compared to those transplanted for other diseases (unadjusted OR 1.97 95%CI 1.24-3.12, adjusted OR 2.19 95%CI 1.33-3.61). Similarly, the risk of thrombotic graft loss within the first year among PSC recipients in the US (n=4,150) was significantly higher than those transplanted for other diseases, both with and without risk-adjustment (unadjusted HR 1.81 95%CI 1.53-2.13, adjusted HR 1.67 95%CI 1.41-1.97). In both cohorts, the incidence of thrombotic graft loss after the first post-transplant year was similar in PSC and non-PSC recipients. PSC recipients who had developed early HAT had a significantly higher risk-adjusted graft loss than those who had not (HR 12.73 95%CI 6.54-24.80).

CONCLUSIONS PSC is an independent predictor of early HAT following primary liver transplantation, leading to substantially greater recipient morbidity and futility of a scarce resource. Our results suggest the need for detailed pre-operative screening for underlying thrombophilia, increased postoperative surveillance for early HAT and consideration of appropriate prophylactic antithrombotic therapy in this patient population.

687 IMPAIRMENT OF THE INDOLEAMINE 2,3-DIOXYGENASE PATHWAY IN PRIMARY BILIARY CIRRHOSIS

Sabine Oertelt-Prigione1,3, Tin K. Mao1, Carlo Selmi1,2, Koichi Tsuneyama4, Aftab A. Ansari5, Ross L. Coppel6, Pietro Invernizzi1,3, Mauro Poddà1, M. Eric Gershwin1,1; Internal Medicine, University of California, Davis, Davis, CA; 2Clinical Sciences Luigi Sacco”, University of Milan, Milan, Italy; 3San Paolo hospital School of Medicine, University of Milan, Milan, Italy; 4Pathology, Tumato Medical and Pharmaceutical University, Toyama, Japan; 5Pathology, Emory University, Atlanta, GA; 6Microbiology, Monash University, Clayton, VIC, Australia

The immunomodulatory effects of the tryptophan-catabolizing enzyme indoleamine-2,3-dioxygenase (IDO) have been elucidated at a cellular level and implicated in the pathogenesis of several complex diseases. Defects within the regulatory T cell compartment are one of the characteristics of primary biliary cirrhosis (PBC), an autoimmune chronic cholestatic liver disease, a phenotype that has also been shown in disease-mimicking animal models of this disease. In fact, human PBC manifests a quantitative decrease in the T regulatory lymphocyte compartment while three murine models mimicking several features of the disease are associated with specific dysfunctions of T cell proliferation. Since IDO constitutes an inducible control mechanism of T lymphocyte proliferation, we hypothesized that IDO dysregulation could lead to altered frequency and/or function of T cells at the level of antigen processing/presentation ultimately contributing to tolerance breakdown. We investigated (i) the IDO induction profile and function in peripheral blood monocytes in 30 women with PBC and 20 controls using RTFPCR and HPLC methods, (ii) the IDO expression in 5 PBC and 14 control liver tissues by immunohistochemistry and, (iii) the association of a TGF-beta gene promoter polymorphism in 120 PBC and 120 control DNAs. Results demonstrate that (i) both IDO expression and activation manifest an impaired IFN-γ response in peripheral monocytes. After stimulation, IDO transcription was significantly lower in monocytes from patients with PBC compared to healthy controls (0.1143 ± 0.019 vs 0.051 ± 0.013, P<0.007), patients also manifested lower rates of trp to kyn transformation when compared to healthy controls (0.4621 ± 0.222 vs 0.0867 ± 0.03, P<0.005). (ii) A peculiar IDO expression profile in intrahepatic bile duct cells characterized early stage PBC with a typical apical pattern observed if the enzyme was expressed in the cholangiocyte. Further, we observed significantly different gain-of-function -509 T allele frequencies within the TGF-beta promoter region in the two populations (0.600 in PBC vs. 0.504 in controls, P=0.035). In conclusion, we submit that an impaired IDO induction might represent a contributing factor in PBC pathogenesis in association with several specific defects in the target tissue and a susceptible genetic background.

INDUCTION OF PRIMARY BILIARY CIRRHOSIS IN GUINEA PIGS USING CHEMICAL XENOBIOTIC IMMUNIZATION: IMPLICATIONS FOR TOLERANCE AND THE ETIOLOGY OF HUMAN PBC

Patrick S. Leung1, Ogyi Park1, Koichi Tsuneyama2, Mark J. Kurth3, Kit S. Lam4, Afzab A. Ansari5, Ross L. Coppel6, M. Eric Gershwin1; 1Internal Medicine, University of California at Davis, Davis, CA; 2Department of Pathology and 21st Century COE Program, Toyama Medical and Pharmaceutical University, Toyama, Japan; 3Department of Chemistry, University of California at Davis, Davis, CA; 4Division of Hematology and Oncology, University of California at Davis, Sacramento, CA; 5Department of Pathology and 21st Century COE Program, Emory University School of Medicine, Atlanta, GA; 6Department of Microbiology, Monash University, Melbourne, VIC, Australia

Although significant advances have been made in dissecting the effector mechanisms in autoimmunity, the major stumbling block remains defining the etiological events that precede disease. Primary biliary cirrhosis (PBC) illustrates this paradigm because of its high degree of heritability, its female predominance and its extraordinarily specific and defined immune response and target destruction. In PBC, the major autoantigens belong to E2 components of the 2-oxo-acid dehydrogenase family of mitochondrially-located enzymes which share a lipoylated peptide sequence that is the immunodominant target. Using rigorous combinatorial chemistry, our previous work demonstrated that synthetic mimics of the lipopeptide molecule such as 6-bromohexanoate (6-BH) react intensely with PBC sera but not controls. This observation prompted us to immunize guinea pigs with 6-BH conjugated to BSA and to follow them for 2 years. Herein, we provide serologic and immunohistochemical evidence that such immunized guinea pigs not only develop antimitochondrial autoantibody responses similar to human PBC, but also develop autoimmune cholangitis after 18 months. Firstly, 6BHBSA-immunized guinea pigs produced antibodies to PDC-E2, BCOADC-E2, and OGD-E2 as early as 4 wk after the initial immunization, and 100% of animals were AMA positive by 12 weeks. Most importantly, at 18 months post-immunization, guinea pigs demonstrated significant lymphoid cell infiltrates surrounding damaged bile ducts and mild to moderate infiltration of lympho-plasmacytes and vacuolated histiocytes in portal areas where interlobular bile ducts were surrounded by variably swollen lympho-plasmacytes with a vacuolated cytoplasm and an irregular luminal border, or showed an eosinophilic shrunken appearance with pyknotic nuclei. Portal inflammation was distributed heterogeneously within the liver and in some portal areas, interlobular bile ducts were not clearly observed as in bile duct loss. In contrast to the pathological changes of interlobular bile ducts, septal to large bile ducts did not show any significant pathological changes. Mild piecemeal necrosis (interface hepatitis) was observed in the affected portal tracts. In summary, the observed histology was similar to the chronic non-suppressive destrucitve cholangitis that characterizes PBC. In conclusion, these data reflect the likelihood that in PBC, the multi-lineage anti-mitochondrial response is a pathogenic mechanism and that loss of tolerance and subsequent development of biliary lesions depends on either modification of the host mitochondrial antigen or a similar breakdown due to molecular mimicry.

RISK OF CARDIOVASCULAR AND CEREBROVASCULAR EVENTS IN PRIMARY BILIARY CIRRHOSIS: A POPULATION-BASED COHORT STUDY

Masoud Solaymani-Dodaran1, Guruprasad P. Aithal2, Tim Card1, Joe West1; 1Epidemiology and Public Health, The University of Nottingham, Nottingham, United Kingdom; 2Wolfson Digestive Diseases Centre, Nottingham University Hospitals, Nottingham, United Kingdom

Background: Patients with primary biliary cirrhosis (PBC) have a 2.7 fold increase in death compared with general population the cause of which is unclear. Risk factors such as smoking and hyperlipidemia have been associated with PBC. Therefore, patients with PBC may have higher risk of major vascular events. Methods: We compared the risk of developing Myocardial Infarction (MI), Stroke and Transient Ischaemic Attack (TIA) in a cohort of PBC patients and a general population control cohort. Subjects were selected from General Practice Research Database (GPRD). For each case, 10 controls were chosen from the same general practice matched on age and sex. Hazard ratios and 95% confidence intervals were calculated. Results: There were 930 patients (88% female) in our PBC cohort that were compared with 9202 controls. There were similar proportions of smokers, and subjects with hypertension in PBC and control groups. However, PBC patients had lower Body Mass Index (BMI) [Chi-square=11.4, df=4, P=0.02] and higher frequency of diabetes [Chi-square=16.3, df=1, P<0.001]. Less than 5% of subjects in each group received lipid lowering agents. During a total of about 43000 person years of follow-up, 244 MI's, 591 Stroke's and 221 TIA's were identified. Incidence rates per 1000 person years for MI, stroke, and TIA during the study period were 6.0 (3.9-9.1), 13.9 (10.5-18.3) and 3.3 (2.0-6.0) for PBC cohorts and 5.6 (5.0-6.4), 14.1 (13.0-15.3), and 5.3 (4.6-6.0) for control cohorts respectively. Hazard ratios for vascular events in PBC cohort compared to control cohort were 1.04 (0.67-1.62), 0.98 (0.73-1.31), 0.66 (0.38-1.16) for MI, Stroke and TIA respectively. Hazard ratio for any vascular event was 0.99 (0.77-1.27). Adjustment for confounders did not change the results. Conclusions: PBC is not associated with an increased risk of myocardial infarction, stroke or TIA. Major vascular events are unlikely to account for the increased mortality in PBC patients. Nor is there excess morbidity from these conditions. Hypercholesterolemia related to PBC may not require treatment with lipid lowering agents.

... be the key to successful immunotherapy. Response to PDC-E2 will be the effector mechanism for biliary antigenic driver of this disease. Finally, we submit that these imply that PDC-E2 is a major autoantigen and likely to be of NOD.2445 mice as a model of human PBC, but also further NOD.2445 mice. These data highlight not only the relevance splenic CD4 T cells specific to PDC-E2 (0.04 to 0.1%) in C57BL/6 mice when either BSA or PDC-E2 were used flow cytometry. Importantly, there was no detection of reactive stimulated T cells was examined by ELISpot and intracellular medium alone. Two days later, IFN-γ production of the antigen-stimulated T cells was examined by ELISpot and intracellular flow cytometry. Importantly, there was no detection of reactive T cells in C57BL/6 mice when either BSA or PDC-E2 were used as antigens. Furthermore, the NOD.2445 mice had a similar frequency of reactive T cells to BSA as control C57BL/6 mice. However, there was an extraordinarily high frequency of splenic CD4 T cells specific to PDC-E2 (0.04 to 0.1%) in NOD.2445 mice. These data highlight not only the relevance of NOD.2445 mice as a model of human PBC, but also further imply that PDC-E2 is a major autoantigen and likely to be the antigenic driver of this disease. Finally, we submit that these data provide further evidence that the multi-lineage, multi-cell response to PDC-E2 will be the effector mechanism for biliary damage in humans with PBC. Manipulation of this pathway will be the key to successful immunotherapy.

691 GENETIC POLYMORPHISM OF HLA-DR AND CYTOKINE GENES IN JAPANESE PATIENTS WITH PRIMARY BILIARY CIRRHOSIS (PBC) – HLA-DRB1*0405 CONFFERS SUSCEPTIBILITY TO GP210-TYPE PROGRESSION OF PBC–

Minoru Nakamura1, Hisayoshi Kondo2, Yoshihiro Aiba1, Atsumasa Komori1, Mutsumi Matsuyma2, Masahiro Ito1, Kiyoshi Migita1, Hiroshi Yatsuhashi1, Takeo Saashiro3, Michiaki Kaga4, Yukio Watanabe5, Hideki Hayashi6, Naohiko Masaki2, Hideo Morimoto5, Masakazu Kobayashi3, Koichi Honda6, Hiroki Oishi4, Kazuhiro Tsukamoto4, Michio Kikuchi3, Michio Yasunami7, Hiromi Ishibashi1; 1Clinical Research Center, NHO Nagasaki Medical Center, Omura, Japan; 2Atomic Bomb Disease Institute, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan; 3Institute for Tropical Medicine, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan; 4Institute of Immunology, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan; 5Pharmacotherapeutics, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan; 6NHO Study Group for Liver Disease in Japan, National Hospital Organization (NHO), Omura, Japan

Background/Aims: Anti-gp210 and anti-centromere antibodies are different risk factors for hepatic failure-type (gp210-type) and portal hypertension-type (centromere-type) progression, respectively, in primary biliary cirrhosis (PBC). To study the underlying immunogenetic mechanisms for each type of disease-progression, we examined the HLA-DR and cytokine gene polymorphism in 150 well-characterized PBC patients who have been registered to National Hospital Organization Study Group for Liver disease in Japan (NHOSLJ). Methods: Serum antibodies to gp210 and centromere were measured by EUISA over periods extending from 2-289 (median 59) months of observation. HLA-DRB1 genotype was determined by sequence-based typing (SBT) of group-specific PCR products. Genetic polymorphism in the cytokines TNF-α, IFN-γ, TGF-β1, IL-10, IL-6 and MDXR were analyzed by polymerase chain reaction-sequence specific primers (SSP). Results: HLA-DRB1*0803 confers susceptibility to PBC development in Japanese population [OR=1.93, 95% CI: 1.17, 3.18] and is a risk factor for positive anti-centromere antibodies [OR=2.24, 95% CI: 0.93, 5.33], HLA-DRB1*0405 is a significant risk factor for positive anti-gp210 antibodies [OR=2.10, 95% CI: 1.10, 4.45] and is a significant negative risk factor for positive anti-centromere antibodies [OR=0.27, 95% CI: 0.09, 0.71]. In addition, IFN-γ intron +874 (T/T + T/A) genotype was a risk factor for anti-gp210 antibodies: production [OR=2.38, 95%CI: 0.97, 5.96] with reference to IFN-γ (A/A) genotype. While HLA-DRB1*0803 nor HLA-DRB1*0405 per se were not risk factors for disease-progression, HLA-DRB1*0405 carriers who progressed to advanced stage were all positive for anti-gp210 antibodies, indicating that the development of anti-gp210 antibodies is an essential step for the progression of PBC in HLA-DRB1*0405 carriers. In addition, we found a novel haplotype of MDXR gene polymorphism (Hap*2) which determines the development of jaundice in gp210 positive PBC patients. Conclusions: While HLA-DRB1*0803-linked genetic factor confers a susceptibility to PBC development and anti-centromere antibodies-production, HLA-DRB1*0405-linked genetic factor confers a susceptibility to anti-gp210 antibodies-production and gp210-type progression of PBC in Japanese population. Furthermore, genetic polymorphism of MDXR gene (Hap*2) confers a susceptibility to the development of jaundice resulting in end-stage hepatic failure in gp210-positive PBC patients. These results indicate that multiple different genetic factors are involved at multiple steps of disease-progression in PBC.

A CRITICAL ROLE OF INVARIANT NKT CELLS IN EXACERBATING THE BILIARY LESIONS IN A TGF-β RECEPTOR II DOMINANT-NEGATIVE MOUSE MODEL OF PRIMARY BILIARY CIRRHOSIS

Ya-Hui Chuang1, Zhe-Xiong A. Lian1, Guo-Xiang Yang1, Shang-An Shu1, Yuki Moritoki1, William M. Ridgway2, Altaf A. Ansari3, Mitchell Kronenberg2, Richard A. Flavell4, Bin Gao5, M. Eric Gershwin1

1Internal Medicine, University of California, Davis, Davis, CA; 2Division of Rheumatology and Immunology, University of Pittsburgh School of Medicine, Pittsburgh, PA; 3Department of Pathology, Emory University School of Medicine, Atlanta, GA; 4La Jolla Institute of Allergy and Immunology, La Jolla, CA; 5Section of Immunobiology, Howard Hughes Medical Institute, New Haven, CT

A key question in human PBC revolves around the mechanisms involved in destruction of small intrahepatic bile ducts. Autoreactive T cells are induced by CD83+ dendritic cells (DCs) leading to the generation of autoantibodies against the E2 subunit of the pyruvate dehydrogenase enzyme complex (PDC-E2). Innate immunity has also been postulated to play a key role in the exacerbation of liver injury. For example, natural killer (NK) cells are increased in number in the liver of PBC patients and recruited more efficiently, resulting in exacerbated hepatic damage which is hypothesized to be due to their higher cytotoxic ability. While CD1d expression and the frequency of invariant NKT (iNKT) cells are both increased in PBC liver, the involvement of such iNKT cells in the pathogenesis of PBC is not clear. It is important to note that whereas there is an increase in hepatic presence of iNKT cells in PBC patients as compared to controls, there is in fact a concomitant decrease in the hepatic presence of iNKT cells activated by α-galactosylceramide (α-GalCer) in young but not older δTGFβRII mice, suggested an age dependent role of iNKT cells. These data demonstrate that iNKT cells in δTGFβRII mice are a critical factor in liver injury.

Disclosures: The following people have nothing to disclose: Ya-Hui Chuang, Zhe-Xiong A. Lian, Guo-Xiang Yang, Shang-An Shu, Yuki Moritoki, William M. Ridgway, Altaf A. Ansari, Mitchell Kronenberg, Richard A. Flavell, Bin Gao, M. Eric Gershwin.
ment should ideally be targeted to patients with low bone mass because of limited availability of BMD technology in some communities and cost considerations. We aimed at comparing the performance of several risk score indices to identify PBC patients who are more likely to have low bone mass who should be referred for BMD measurements. METHODS: We studied 363 patients with PBC. BMD of lumbar spine and femoral neck was measured. BMD values were converted into T-score separating patients with normal BMD (T>-1), osteopenia (T-1 to -2.5), and osteoporosis (T<-2.5). We included a subcategory of "low-BMD" for patients with T<-2 of either lumbar spine or femoral neck to detect those pre-osteoporotic patients that should be referred for BMD measurements. Four risk score indices that were created and validated in postmenopausal women from the general population were calculated in our PBC patients. Those indices are the Osteoporosis Self-assessment Tool (OST) which is based only on age and weight, and three other risk tools including the Osteoporosis Risk Assessment Instrument (ORAI), the Simple Calculated Osteoporosis Risk Estimation (SCORE), and the Osteoporosis Index of Risk (OSIRIS) which are based on age and weight in combination with up to four additional variables such as race, and history of estrogens use, rheumatoid arthritis, and non-traumatic fractures. ROC analyzes and the AUC were computed for each index to evaluate their discriminatory performance and accuracy. Additionally, three risk categories (low, moderate, and high) were used for each score index according to the developer’s recommendation for DXA referral. RESULTS: The AUC was consistently high for the four indices indicating good test performance (Table). OST, SCORE, ORAI, and OSIRIS identified respectively 90%, 89%, 88%, and 94% of the patients at high risk for low-BMD (T<-2) who subsequently should have been recommended for densitometry; and 84%, 65%, 60%, and 84% of patients at low risk for low-BMD who subsequently should not have been recommended for densitometry. CONCLUSIONS: Simple risk score indices are effective and efficient tools to help target high-risk patients with BMD for measurements. As the OST index is the simplest and quickest to calculate, OST may be used as a first-line prescreening tool in PBC patients.

**AUTONOMIC DYSFUNCTION IN PRIMARY BILIARY CIRRHOSIS IS ASSOCIATED WITH STRUCTURAL BRAIN ABNORMALITIES, PARTICULARLY IN THE GLOBUS PALIDUS**

Kieren Hollingsworth¹, David E. Jones², Ahmed El-Sharkawy¹,², Zia Khan¹,², Roy Taylor¹, Andrew Blamire¹, Julia L. Newton²; ¹MR Centre, Newcastle University, Newcastle, United Kingdom; ²Institute for Cellular Medicine, Newcastle University, Newcastle, United Kingdom

Autonomic dysfunction (AD) (assessed using symptom assessment tools, heart rate variability (HRV), baroreflex sensitivity (BRS) and dynamic testing in the context of the Valsalva manoeuvre and tilt testing) is a frequent finding in the autoimmune liver disease primary biliary cirrhosis (PBC). Recent studies from our group have confirmed that the degree of AD seen in individual patients is unrelated to the severity of their liver disease, with AD being a frequent finding even in patients with confirmed early stage disease. Although the consequences of AD, such as the symptom of fatigue, have been a focus of recent work, the underlying mechanisms that lead to AD in PBC have received less attention. The aim of this study was to examine structural brain lesions in early stage PBC and to determine whether their presence and position associated with AD. Par-
ticular attention was paid to deep white matter lesions (DWML) which have been linked with AD and associated cognitive impairment development in the dementia literature. 29 female subjects with early stage PBC were included. BRS was assessed using the sequence method and HRV using spectral analysis using the continuous beat-to-beat Taskforce system (CNSystems; Austria). High-resolution T2w images (TR/TE = 2000/60ms, 0.49x0.49mm, 3mm thick) were acquired with a Philips 3T Intera Achieva with a dedicated head coil. DWML load was assessed by two independent observers according to the Scheltens classification criteria. A consensus score regarding total lesion load (TLL) was reached. DWML were found to be present in all 29 PBC subjects suggesting that the presence of organic brain change is universal in PBC. BRS showed a significant correlation with Total Lesion Load (TLL). When individual brain areas were considered the lesion load in the Globus Pallidus (GP) inversely correlated (non-parametric) with impaired BRS (p=0.03; r=-0.4). In conclusion, AD in PBC is associated with the presence of structural brain abnormalities when assessed using MR techniques. These abnormalities are particularly in those brain areas that are associated with autonomic nervous system function. Dynamic and longitudinal studies are needed to determine the nature of the association between AD and structural brain lesions in PBC.

RESULTS OF THE FRENCH STUDY OF RISK FACTORS FOR PRIMARY BILIARY CIRRHOSIS

Christophe Corpechot, Yves Chrétien, Olivier Chazouilleres, Raoul Poupon; Service d'Hépatologie, Centre de référence des maladies inflammatoires des voies biliaires, Hopital Saint-Antoine, Paris, France

BACKGROUND AND AIM: Primary biliary cirrhosis (PBC) is a complex disease thought to result from combination of genetic and environmental factors. Elucidating these factors are critical for understanding the pathophysiology of the disease and developing new therapeutic approaches. A large case-control study recently performed in the US has identified several environmental risk factors associated with PBC, namely urinary tract infections (UTI), tobacco smoking, cosmetics use and hormone replacement therapy (HRT). Accordingly, our study was carried out in a large scale in France to determine whether these results could be confirmed and considered as paradigm of risk factors for PBC. METHODS: Patients with PBC and unrelated controls matched for sex, age and geographical location were subjected to a standardized questionnaire regarding demographic characteristics, lifestyle, personal and familial medical history and reproductive history. Comparisons between cases and controls were performed using the Wilcoxon test for continuous variables and the Fisher exact test for categorical variables. Multiple logistic regression models were used for multivariate analysis. RESULTS: 222 patients with PBC (89% female; mean age, 51 years) and 509 controls were enrolled in the study. Data analysis indicated that having a first-degree relative with PBC (adjusted odds ratio [AOR] 6.82, 95% confidence interval 1.16 – 32.93) or with autoimmune thyroid disease (AOR 5.30, 95%CI 1.38 – 28.07), a personal history of UTI (AOR 1.89, 95%CI 1.26 – 2.84), or a past history of active or passive smoking (AOR 3.12, 95%CI 1.95 – 5.00) were significantly associated with increased risk of PBC. The frequent use of hair dye was not shown to confer disease susceptibility. A history of use of HRT was not more frequent in women with PBC, however the past use of oral contraceptives was found to be significantly associated with a decreased risk of the disease (AOR 0.64, 95%CI 0.43 – 0.95). The age at first pregnancy was significantly lower in PBC than in control women (24.0 ± 4.8 years vs. 25.0 ± 4.5; p=0.0096) while the mean number of pregnancies in the two groups was similar. CONCLUSION: The present data: (a) confirm the major genetic predisposition to autoimmune disorders and PBC; (b) reinforce the strong association between UTI, tobacco smoking and risk of PBC development; (c) suggest that exogenous estrogens may confer protection against PBC.

PRIMARY BILIARY CIRRHOSIS (PBC) WITH INITIAL NORMAL BILIRUBIN CONCENTRATION: TREATMENT WITH URSEDOXYCHOLIC ACID (UDCA) DOES NOT AFFECT LIVER-RELATED SURVIVAL

Cristina Rigamonti1,4, Annarosa Florean2, Angela Variola2, Giovanni Casazza2, Andrew K. Burroughs4, David Patch4; 1First Division of Gastroenterology, IRCCS Fondazione Ospedale Maggiore Policlinico, Mangiagalli e Regina Elena, Milan, Italy; 2Department of Surgical and Gastroenterological Sciences, University of Padua, Padua, Italy; 3Department of Statistic and Biometry, University of Milan, Milan, Italy; 4Liver Transplantation and Hepatobiliary Medicine, Royal Free Hospital, London, United Kingdom

Background and aims: Early PBC is considered the subgroup which can benefit from long-term UDCA therapy. We evaluated a cohort of early PBC patients with prolonged follow-up, treated or untreated with UDCA in order to confirm this assumption. Methods: 204 PBC patients with ≤17 µmol/L serum bilirubin concentration at referral (149 patients referred to Royal Free Hospital, London and 55 referred to University of Padua). 88 (84 females, median age 58 yrs) were treated with UDCA and 116 (110 females, 57 yrs) remained untreated. All but 2 patients continued UDCA treatment for the entire follow-up time. Survival free of death and liver transplantation (LT) and time to onset of complications were evaluated with Kaplan-Meier plots and log rank test. Results: At referral untreated group and UDCA group were not different for symptoms (48% vs 39% asymptomatic, respectively), albumin (median 43 vs 42 g/L), alkaline phosphatase (median 232 vs 251 IU/L), Mayo risk score (median 3.9 vs 4.0). Median bilirubin was 8 µmol/L (range 3-16) in non-UDCA group and 9 µmol/L (range 2-17) in UDCA group (p=0.04). Follow-up ranged from 1 to 22 yrs in both groups (median 6 yrs in untreated and 8 in treated). Median rate of bilirubin increase from referral was significantly higher in untreated (median 0.3 µmol/L/year, range 10.0–70.0) than in UDCA group (median 0.0 µmol/L/year, range 2.6–40.0). LT occurred in 4 (3%) vs 2 (2%) and death in 24 (21%); 16 non liver-related: 9 for cardio-respiratory disease, 2 for cerebrovascular accident and 5 for extrahepatic malignancy) vs 2 (2%, all liver-related) in non-UDCA and UDCA groups respectively. Kaplan-Meier analysis showed significant better survival (p=0.002) in UDCA group, but after censoring non liver-related deaths the difference disappeared (p=0.11). By dividing all patients according to low (≤3.6), intermediate (3.7-4.1) and high (≥4.2) Mayo risk score, overall survival was significantly better in UDCA group with respect to untreated, but only in those with high Mayo risk (p=0.008), and again this difference disappeared after censoring non liver-related deaths (p=0.06). There was no difference in the first onset of any liver
COMBINATION ANTIRETROVIRAL THERAPY WITH COMBIVIR ATTENUATES AUTOIMMUNE BILIARY DISEASE IN THE NOD.c3c4 MOUSE MODEL OF PRIMARY BILIARY CIRRHOSIS

Min Chen1, Don Graham1, Safwat Girgis2, Guangzhi Zhang1, Shawn Wasilenko1, Mark Kneteman1, Chelsea McDougall1, Yun-yuan Li3, Michael Sakalian4, Andrew L. Mason1; 1Division of Gastroenterology, University of Alberta, Edmonton, AB, Canada; 2Pathology, University of Alberta, Edmonton, AB, Canada; 3Department of Microbiology and Immunology, University of Oklahoma Health Sciences Center, Oklahoma, OK

A human betaretrovirus resembling the mouse mammary tumor virus (MMTV) has been characterized in patients with primary biliary cirrhosis (Xu et al., PNAS, 2003). The NOD.c3c4 mouse develops AMA, autoimmune biliary disease and liver failure. We have shown that NOD.c3c4 mice have a significantly higher burden of MMTV infection in the liver compared to control mice without innate immune deficiency and that the virus is predominantly localized to bile ducts. Aim: Clinical trials suggest that PBC patients treated with combination antiviral therapy demonstrate significant histological and biochemical benefit (Mason et al., 2004, American Journal of Gastroenterology). The goal of this study was to investigate whether antiviral therapy can impact on the development of autoimmune biliary disease in the NOD.c3c4 mouse. Methods: Twenty 5 to 8 week old NOD.c3c4 (Taconic) were randomized to either placebo (n=10) or Combivir (n=10), dosed at Zidovudine 3mg and Lamivudine 1.5mg per day. Serial blood samples were taken for hepatic biochemistry studies and mice were sacrificed at 20 weeks of age. A liver pathologist ranked coded liver samples using the Ishak score and the percentage of liver demonstrating biliary cyst formation was measured in 5 magnification sections using MetaVue software analysis. Hepatic RNA was assessed for viral burden using real-time RT-PCR with MMTV gag and pol primers normalized to beta-actin. Results: Serial hepatic biochemistry studies showed diminished alkaline phosphatase in the Combivir treated mice within the first 10 weeks of therapy but this was not sustained. At sacrifice, there was no difference in hepatic weight for Combivir vs. placebo treated animals. Histological evaluation showed a significant decrease in the necro-inflammatory score (0.8 Combivir vs. 1.5 placebo, p=0.015) as well as the bile duct injury [0.3 Combivir vs. 1.0 placebo, p=0.015]. Therapy had little impact on bile duct cyst formation (8% Combivir vs. 10% placebo). When compared to mice receiving placebo, Combivir therapy reduced viral burden by 26% to 47% as measured by the pol and gag gene RT-PCR, respectively. Conclusions: Combivir treatment positively impacted on inflammation and bile duct damage in the NOD.c3c4 mouse, as previously reported for patients with PBC. Even though Combivir therapy lacked potency in inhibiting MMTV, the bile duct damage and inflammation was attenuated suggesting a central role for MMTV in the autoimmune biliary disease. As Combivir treatment is insufficient to halting disease in mice and in humans with PBC, the NOD.c3c4 mouse will provide a good model for testing highly active anti-retroviral therapy.

HLA DRB1 ALLELES IN FRENCH PATIENTS ACCORDING TO THE CLINICAL PRIMARY BILIARY CIRRHOSIS PHENOTYPE

Catherine Johanel1, Pierre Assuied1, Cristophe Corpechot2, Jean-Charles Duclos-Vallee3, Olivier Chazouilleres3, Eric Ballot4, Raoul Poupon2; 1service d’Immunologie, Hopital Saint-Antoine, 75012 Paris, France; 2Service d’Hépatologie, Hopital Saint-Antoine, 75012 Paris, France; 3centre hépato-biliaire, Hopital Paul Brousse, 94807 Villejuif, France

Background: Elucidating predisposing genetic associations is a crucial step in understanding the pathophysiology of complex disease such as primary biliary cirrhosis (PBC). Polymorphic variants of HLA are thought to be determinant not only of susceptibility but also of the clinical phenotype of several autoimmune disorders. This could be one of reasons for the apparent complex relationship between HLA polymorphisms and PBC. The only consistent reported association in PBC is the DRB1*08 allele. However at least, in Europeans, this association accounts for a minority of patients. A strong protective association with DRB1*11 and DRB1*13 has also been reported. Objective: Our study was aimed to investigate the contribution of HLA DRB1 alleles to susceptibility to PBC and to variants of the disease according to mode of presentation and severity. Methods: HLA DRB1 alleles of 146 well-characterized PBC patients (64 with liver transplantation) and 16 PBC-Auto-Immune Hepatitis (AIH) overlap syndrome were typed by reverse line blot assay of PCR-amplified DNA. We used as controls a study of 356 families residing in Paris (1). Results: The allele frequency of HLA DRB1*07 was higher in patients with pure PBC than in controls (19.9% vs 13.5%, p=0.009, odds ratio (OR)=1.6). There were also significant protective associations with DRB1*11 (6.2% vs 13.2%, p=0.001, OR=0.43) and DRB1*15 (5.5% vs 13%, p=0.0004, OR=0.39). Several relevant pronostic parameters and their relationship to HLA DRB1 alleles were analysed. Higher frequencies of HLA DRB1*07 and DRB1*03 were associated to age at diagnosis <45 yrs or positive antinuclear dots and anti-gp210 antibodies status. HLA DRB1*08 and DRB1*15 were less frequent in patients with an age at diagnosis <45yrs, in patients who had liver transplantation or with positive antibodies status. In patients with PBC-AIH overlap syndrome there was a significant association with HLA DRB1*03 compared to healthy controls (25% vs 10.1%, p=0.016, OR=2.97). Conclusions: Our data show that in France: (a) The common form of PBC is associated with HLA DRB1*07; (b) absence of association with DRB1*08, a finding as previously reported in Italy, suggests that PBC in France has a different genetic background than that reported in Northern Europe and United States; (c) HLA DRB1*03 is specifically associated with PBC-AIH overlap syndrome; (d) Taken together these results show that HLA polymorphisms contribute not only susceptibility but also to clinical expression and severity of PBC. CD8 T CELLS PLAY A CRITICAL ROLE IN PRIMARY BILIARY CIRRHOSIS OF DN TGF-βRII MICE

Zhe-Xiong A. Lian1, Guo-Xiang Yang1, Ya-Hui Chuang1, Yuki Moritoki1, Aftab A. Ansari2, Richard A. Flavell3, William M. Ridgway4, M. Eric Gershwin1
1Internal Medicine, University of California, Davis, Davis, CA; 2Department of Pathology, Emory University School of Medicine, Atlanta, GA; 3Section of Immunobiology and Howard Hughes Medical Institute, Yale University School of Medicine, New Haven, CT; 4Division of Rheumatology and Immunology, University of Pittsburgh School of Medicine, Pittsburgh, PA

Human primary biliary cirrhosis (PBC) is characterized serologically by antimitochondrial antibodies (AMA) and histologically by an intense T cell portal infiltrate that destroys bile ducts. The infiltrating T cells have been identified as both CD4 and CD8 cells with a dominance of CD8+ cells with disease progression. Furthermore, using tetramer technology, we have previously demonstrated the presence of a significantly higher autoreactive CD8 T cell precursor frequency in the liver compared to blood of patients with PBC and noted that such cells are higher in early disease. These data suggest that the biliary damage is mediated by CD8 cells. To address this issue, we have taken advantage of the PBC-like disease exhibited by dnTGF-βRII mice and focused our attention on the liver T cell infiltrate. Importantly, these mice have a directed expression of a dominant-negative form of TGF-βRII, under the direction of the CD4 promoter and exhibit nearly identical disease as humans with PBC. One major advantage to this animal model is the ability to perform cell transfer. Therefore to address the issue of T cell effector mechanisms, we isolated dnTGF-βRII splenic CD4+ or CD8+ T cells and transferred these populations into Rag1-/- mice. Importantly, these mice have a direct expression of a dominant-negative form of TGF-β receptor type II (dnTGF-βRII), under the direction of the CD4 promoter and exhibit nearly identical disease as humans with PBC. One major advantage to this animal model is the ability to perform cell transfer. Therefore to address the issue of T cell effector mechanisms, we isolated dnTGF-βRII splenic CD4+ or CD8+ T cells and transferred these populations into Rag1-/- mice. Importantly, the CD8+ T cells transfer group demonstrated a significant expansion of T cells and the presence of portal tract infiltrates in recipient mice. In contrast, although CD4+ T cells did expand in the recipient group, they did not home or focus within the portal tracts. Our results demonstrate that the impaired TGFβ signaling pathway in these mice leads to a CD8 cytotoxic T cell population that plays a critical role in biliary cell damage. These data have implications not only for understanding TGFβ signaling and autoimmunity in these mice, but also in developing appropriate focused immunotherapy to prevent biliary damage.

ANTIBODIES TO SS-A/RO-52KD AND CENTROMERE IN PRIMARY BILIARY CIRRHOSIS

Alessandro Granito1, Georgios Pappas1, Paolo Muratori1, Luigi Muratori1, Fabio Cassani1, Silvia Ferri1, Joy Worthington2, Marco Lenzi3, Roger W. Chapman4, Francesco B. Bianchi1
1Internal Medicine, Cardioangiology, Hepatology, University of Bologna, S. Orsola Malpighi Hospital, Bologna, Italy; 2Department of Gastroenterology, John Radcliffe Hospital, Oxford, United Kingdom

Background: Recent data indicate that antinuclear reactivities are associated with an unfavourable clinical course in primary biliary cirrhosis (PBC). Aim: We investigated frequency and clinical significance of a wide spectrum of “rheumatological” antinuclear antibodies in the field of autoimmune chronic liver disease, with special regard to PBC. Methods: The study population included: 105 patients with PBC [89 anti-mitochondrial antibody (AMA) positive, 16 AMA negative], 80 with type 1 autoimmune hepatitis (AIH), 30 with type 2 AIH, 52 with primary sclerosing cholangitis (PSC), 30 with systemic lupus erythematosus (SLE) and 50 blood donors. Patients and controls were tested by immunoblot assay (IB) (RecomLine-Mikrogen, Germany) for the presence of antibodies to the following extractable nuclear antigens (ENA): RNP-68kD, RNP-A, RNP-C, Sm-B, Sm-D, SS-A/RO-52kD, SS-A/RO-60kD, SS-B/La, P0 (ribosomal phosphoproteins), PCNA, Scl-70 and Jo-1. Anti-centromere antibodies (ACA) were also searched by IB (RecomLine-Mikrogen, Germany) and indirect immunofluorescence on HEp-2 cells. Results: The overall prevalence of IB-detected anti-ENA in PBC (30%) was higher than in AIH-1 (2.5%, p<0.0001), AIH-2 (0%, p<0.0001) and PSC (11.5%, p=0.006) and lower than in SLE (53%, p=0.03). The most frequent anti-ENA reactivity in PBC was anti-SSA/RO-52kD (28%, 29/105), ACA were detected by IB in 21% PBC patients and never in the other subjects (p<0.0001). Anti-SSA/RO-52k and ACA occurred with similar prevalences in PBC cases with and without AMA. However, half of AMA negative PBC cases presented at least one of these antibodies. Anti-SSA/RO-52KD positive PBC patients had a more advanced histological stage (p=0.01), higher serum levels of bilirubin (p=0.01) and IgM (p=0.03) compared with negative ones at the time of diagnosis. Moreover, they were more frequently suffering from Sicca Syndrome, occurring in 27.5% (8/29) anti-SSA/RO-52KD positive, but only in 6.5% (5/76) anti-SSA/RO-52kD negative PBC cases (p=0.006). Conversely, the positivity for anti-CENP-B was not associated with distinct features. Positive cases, however, were more frequently affected by the CREST syndrome, occurring in 32% (7/22) of them, but only in 1% (1/83) of negative patients (p=0.0001). Conclusions: In the autoimmune liver disease setting, anti-SSA/RO-52KD and ACA behave as AMA-independent markers of PBC and can thus be of diagnostic relevance especially in AMA negative PBC. Anti-SSA/RO-52KD antibodies identify PBC patients with a more advanced and active disease.

INTERCELLULAR TRANSPORT AND TRANSLOCATION OF IGA AMA IN PRIMARY BILIARY CIRRHOSIS

Ana Uelo1,2, Phornnop Naiyanet1, Thomas P. Kenny1, Carlo Selmi1,2, Judy Van de Water1, Pietro Invernizzi1,2, Massimo Zuin2, Thomas Huser4, Mauro Podda2, M. Eric Gershwin1, Internal Medicine, University of California, Davis, Davis, CA; 2San Paolo Hospital School of Medicine, University of Milan, Milan, Italy; 3Clinical Sciences ‘Luigi Sacco’, University of Milan, Milan, Italy; 4NSF Center for Biophotonics, University of California, Davis, Davis, CA

Several laboratories, particularly at UC Davis, have attempted to define a role of mucosal anti-mitochondrial antibodies (AMA) of the IgA class in the pathogenesis of primary biliary cirrhosis (PBC) through a combination of cytology assays and/or immunofluorescence microscopy. Indeed, it has been suggested that the presence of the poly immunoglobulin receptor (pIgR) on biliary epithelial cells allows the basolateral transcytosis of IgA. Such studies have been helpful but also limited by availability of monoclonal dimeric IgA and have generally used canine MDCK cells as a surrogate for human biliary cells. We have now taken advantage of a unique patient with PBC who has a monoclonal gammopathy with extraordinary titers of dimeric IgA AMA. We purified such autoantibodies and labeled them with Alexa 488. The ability of these monoclonal antibodies to be...
transported and to co-localize was studied by confocal dual staining microscopy using a well characterized line of human biliary epithelial cells (BECs). The cells were grown on 0.4 μm transwell support membranes, IgA AMA- Alexa 647 was added to the basal compartment of the transwell and the cells were incubated for 15 min at 37 °C. In parallel, control antibodies were used throughout. Importantly, the monoclonal IgA AMA from our patient with PBC, but not control IgA, was transported and translocated to the mitochondria and co-localizes with PDC-E2. We now postulate herein that there is a direct effect of mucosal IgA on mitochondrial function and that a necessary component of this process is the unique pIgR. This extraordinary observation allows us to further postulate that the abnormal kinetics of BEC proliferation is due to the inability of apoptotic BECs to be cleared because of the binding of mucosal IgA.

704 PROGRESSION IN PBC: NEW INSIGHTS FROM FOLLOW-UP LIVER BIOPSIES 10 YEARS AFTER DIAGNOSIS

Teru Kumagi1, Rupert Abdalian1, Maha Guindi2, E. Jenny Heathcote1, 1Gastroenterology, Toronto Western Hospital / University of Toronto, Toronto, ON, Canada; 2Pathology, Toronto General Hospital / University of Toronto, Toronto, ON, Canada

BACKGROUND: Primary Biliary Cirrhosis (PBC) runs a variable course. Biomarkers that predict likely disease progression are needed. AIM: To identify early characteristics that may serve as markers of disease progression in PBC. METHODS: A chart review of PBC patients with a repeat liver biopsy after initial histological diagnosis. Retrievable dual biopsies were reevaluated blinded to date for degree of fibrosis (Ludwig classification), portal inflammation, eosinophilic infiltration, interface hepatitis, lobular hepatitis, lobular necrosis, granulomas, feathery degeneration, ductopenia, duct injury by lymphocytes, florid duct lesions and ductular reaction. Definition of response to ursodeoxycholic acid (UDCA) was: complete responder (CR) normalization of alkaline phosphatase (ALP) within 2 years of initiating therapy, non-responder (NR) less than 50% decline of ALP, partial responder (PR) between CR and NR. Statistical analyses used either paired t tests, Mann-Whitney U test, χ² test, Fisher’s exact test, Kruskal Wallis test or ANOVAs with Bonferroni-adjusted pair wise comparisons. RESULTS: Mean age (56 patients) at baseline was 46 ± 9 (range 30-61), 52 (92.9%) female and 45 (80.4%) AMA positive. All but one received UDCA (13-15mg/kg/d) with CR or PR response in 38 (69.1%), and 17 (30.9%) were NR. On the initial liver biopsy report, 6 (10.7%), 26 (46.4%), 13 (23.2%), 9 (16.1%) and 2 (3.6%) patients had stage 0, 1, 2, 3 and 4 of fibrosis, respectively. Repeat biopsies performed 9.2 ± 2.5 years after their initial biopsy showed NRs to UDCA therapy had more fibrosis progression (14 out of 17, p=0.006). Baseline ALT values in those with fibrosis progression were higher than in those without (114 ± 91 IU/L vs. 73 ± 52 IU/L, p=0.045). Baseline serum gp210 titers were higher with fibrosis progression than without (21.3 ± 35.1 U vs. 8.3 ± 13.9 U, p=0.046) and correlated with response to UDCA (CR: 3.9 ± 0.3 U, PR: 8.6 ± 14.2 U, NR: 36.1 ± 43.8 U, p=0.004). Re-review of 22 retrievable dual biopsies indicated that both interface hepatitis (p=0.037) and ductopenia (p=0.003) on initial biopsy correlated with NR to UDCA but not with fibrosis progression. SUMMARY: Higher ALT and gp210 titer at baseline and failure to achieve a biochemical response with UDCA are associated with fibrosis progression in PBC. Both interface hepatitis and ductopenia may predict responsiveness to UDCA but not fibrosis progression, this latter finding may due to the small sample size.

705 RITUXIMAB FOR PRIMARY BILIARY CIRRHOSIS (PBC) REFRACTORY TO URSEDIOXYCHOLIC ACID (UDCA)

Robert P. Myers, Abdel Aziz Shaheen, Mark Gordon Swain, Samuel S. Lee, Shirley Cole, Shauna Coffey-Williamson, Kelly W. Burak; Liver Unit, Department of Medicine, University of Calgary, Calgary, AB, Canada

Background: Rituximab, an anti-CD20 monoclonal antibody that selectively depletes B-cells, has shown promise in autoimmune-body-associated, immune-mediated disorders including rheumatoid arthritis. Since UDCA leads to biochemical normalization in only a minority of PBC patients, additional treatment options are necessary. The objective of this study was to assess the safety and efficacy of rituximab in patients with PBC refractory to UDCA. METHODS: 14 PBC patients refractory to UDCA (≥13 mg/kg/day for ≥6 months) received two rituximab infusions (1 g) at days 1 and 15 and were followed for up to 12 months. The primary outcome was the proportion of patients with normalization and/or ≥25% improvement in alkaline phosphatase (ALP) at 6 months. Quality of life was assessed by the Fatigue Severity Scale (FSS) and pruritus by an ordinal scale (0=none; 1=mild; 2=severe; 3=excruciating; and substantial sleep disturbance). All data are medians (ranges). Comparisons were made using the signed-ranks test for matched pairs. Results: The median age was 53 years (range 35-71); 92% were female and AMA+. The median PBC duration and UDCA dosage were 3.6 years (0.9-10.8) and 15.3 mg/kg/d (13.6-27.5), respectively. Twelve and 8 patients have completed 6 and 12 months of follow-up, respectively. Although rituximab was well-tolerated, one patient withdrew due to an asthma exacerbation during the first infusion and is excluded from analyses. Effective B-cell depletion was observed in all patients (baseline vs. 6 mo. CD19+ cells: 239 vs. 1/L; P=0.003). ALP normalization and/or ≥25% improvement was observed in 25% of patients at 6 (n=3/12) and 12 months (n=2/8) of follow-up. Significant reductions in median ALP, serum IgM levels, and AMA titers were observed at 6 months. The AMA titer fell by at least one dilution in 75% (9/12); 2 patients became AMA-negative. Pruritus and fatigue also improved (Table). Three patients developed human anti-chimeric antibodies (HACA); all had effective B-cell depletion. Conclusions: Selective B-cell depletion with rituximab shows promise as a therapy for PBC. This phase I study demonstrated no safety concerns with rituximab, but larger controlled studies are necessary to confirm its efficacy.

BILIARY INFECTION WITH MOUSE MAMMARY TUMOR VIRUS IN THE NOD.C3C4 MOUSE AND OTHER MOUSE MODELS OF PRIMARY BILIARY CIRRHOSIS

Min Chen1, Don Graham1, Guangzh Zhang1, Shawn Wasilenko1, Chelsea McDougall1, Mark Kneteman1, Michael Sakalian2, William M. Ridgway2, Richard A. Flavell2, Andrew L. Mason1; 1Division of Gastroenterology, University of Alberta, Edmonton, AB, Canada; 2Microbiology and Immunology, University of Oklahoma Health Sciences Center, Oklahoma, OK; 2Division of Rheumatology and Immunology, University of Pittsburgh School of Medicine, Pittsburg, PA; 4Howard Hughes Medical Institute, Yale University School of Medicine, New Haven, CT

Three mouse models with innate immune defects have recently been reported that develop spontaneous AMA and biliary lesions. Endogenous mouse mammary tumor virus (MMTV) is found in the genome of most mouse strains that can be expressed to form infectious viral particles in mice. A human betaretrovirus resembling MMTV has been linked with PBC (Xu et al. PNAS, 2003). Aim: To assess whether endogenous MMTV is associated with autoimmune biliary disease in the PBC mouse models. Methods: Livers were isolated from female 12 week-old mice. The innate immune deficient models, NOD.c3c4, CD4 directed dominant negative TGF-β receptor II (dnTGF-βRII) and IL-2 receptor α knockout (IL-2Rα/-) were compared with control mice, BALB/c, C57/bl, NOD.1tj, SJL and the Pera/Eij mouse lacking endogenous MMTV. Anti-gp52Su and anti-p27Ca were used to localize MMTV by confocal microscopy and anti-CK7 to identify biliary epithelium. Hepatic RNA was assessed by real-time RT-PCR to quantify MMTV using gag and pol primers normalized to beta-actin. Proviral MMTV was assessed by PCR of hepatic DNA. Results: MMTV gag and pol gene expression was detected in all mice except for the Pera/Eij that lacks endogenous MMTV; this was especially marked in the NOD.c3c4 mice with biliary cyst formations. Conclusions: In mouse liver, MMTV predominantly replicates in the biliary epithelium. The viral burden of MMTV was much higher in mice with innate immune deficiency and autoimmune biliary disease, providing a model to investigate the viral and autoimmune pathogenesis of cholangitis and AMA production. These findings also provide additional support for the association of a human betaretrovirus with PBC.

INCIDENCE AND MORTALITY OF PRIMARY SCLEROSING CHOLANGITIS IN THE UK: A POPULATION-BASED COHORT STUDY

Timothy R. Card, Masoud Solaymani-Dodaran, Joe West; Department of Epidemiology ans Public Health, University of Nottingham, Nottingham, United Kingdom

INTRODUCTION: There is little information about the occurrence in the general population of Primary Sclerosing Cholangitis (PSC) in the UK and the risk of associated mortality and malignancy compared with the general population. The few population based studies available from the world literature give incidence figures ranging from 0.07 to 1.3 per 105 per year [1]. Results of the risk of cholangiocarcinoma have been as high as 1.5% per annum [1]. AIM & METHODS: We identified 223 people with PSC and 2,217 control subjects from the General Practice Research Database in the UK. We calculated incidence rates (1991-2001) and mortality rates and used Poisson and Cox regression to make comparisons between populations. RESULTS: Overall there were 149 incident cases corresponding to an incidence rate per 100,000 person years of 0.41 (95% CI 0.34-0.48) and a prevalence in 2001 of 3.85 per 100,000 (95% CI 3.04 to 4.80). PSC was almost twice as common in men as in women, and was associated with inflammatory bowel disease in almost half of cases. There was a 3-fold mortality rate increase (Hazard ratio 2.92 (95% CI 2.16-3.94)) in people with PSC compared to the general population, a 2-fold increase in risk of any malignancy, a similar increase in GI malignancy and a 40-fold increase in the risk of primary liver cancer (HR 2.23 and 37.44 respectively) Conclusions: This study provides we believe the most reliable estimates of the occurrence of PSC in the UK and of its risk in terms of death and malignancy yet available.

708 STIMULATION OF THE INNATE IMMUNE SYSTEM IS NECESSARY FOR LIVER-SPECIFIC CD8+ T LYMPHOCYTES TO INDUCE AN AUTOIMMUNE HEPATITIS

Kathie Bélard1, Pascal Lapiere1,2, Fernando Alvarez1,2, 1Gastroenterology, hepatology and nutrition, CHU Sainte-Justine, Montréal, QC, Canada; 2Pediatric Department, CHU Sainte-Justine, Montreal, QC, Canada

INTRODUCTION. Autoimmune hepatitis (AIH) is a chronic disease characterized by a progressive destruction of the hepatic parenchyma. It is currently hypothesised that a viral infection could trigger an AIH in a genetically predisposed individual. The aim of this study is to determine, using a murine model of AIH, if an activation of the innate immune system by pathogen-like specific ligands for toll-like receptors (TLR) in presence of autoreactive T-cells could induce a break of immunological liver tolerance. METHODOLOGY. NP-specific T-cell clones directed against the main epitope of the LCMV nucleoprotein (NP), were adoptively transferred to TLR-NP transgenic mice expressing NP specifically in the liver. CpG (20ug) and Poly(I:C) (500ug) were injected intraperitoneally to stimulate the TLR-9 and TLR-3 receptors. ALT levels were monitored throughout the experiment. Mice were sacrificed 8 days following cell transfer and liver were excised for histology and immunohistochemistry. The expression level of adhesion molecules, chemokine and chemokine receptors were quantified. Hepatocyte apoptosis was evaluated by TUNEL assay. RESULTS. Mice co-injected with CpG and Poly(I:C) following IV transfer of NP-specific T cells showed elevated serum levels of ALT and liver inflammation. In absence of Toll-like receptor ligands (CpG and Poly(I:C)), mice transferred with liver-specific T cells maintained normal levels of ALT and liver histology (p<0.05). Liver ICAM-1 expression levels increased in response to co-injection of CpG, Poly(I:C) and liver-specific T-cells, while CpG and Poly(I:C) alone were sufficient to induce upregulation of VCAM-1 expression levels (p<0.05). CpG and Poly(I:C) coinjection with or without IV transfer of liver specific T cells did not modify liver Vap-1 expression levels. In mice who received CpG/Poly(I:C) and liver-specific T-cells, CXC3 liver expression was down-regulated. CONCLUSIONS. CD8+ liver antigen-specific cells need the activation of the innate immune system through Toll-like receptors (TLR-9 and TLR-3) by pathogen mimics (CpG and Poly(I:C)) to cause liver inflammation and hepatocyte apoptosis. Stimulation of the innate immune system induces an up-regulation of ICAM-1 and VCAM-1, thus, increasing T cell homing to the liver. Therefore, in genetically predisposed individuals, a viral infection could induce an up-regulation of specific adhesion molecules in the liver resulting in autoreactive T-cell recruitment and development of an autoimmune hepatitis.

709 CLINICAL RELEVANCE OF GENETIC AND SEROLOGIC MARKERS IN AUTOIMMUNE HEPATITIS: A SINGLE CENTER EXPERIENCE WITH 296 PATIENTS

Frauke Metzler, Eyk Heinrich, Christian P. Strassburg, Michael P. Manns, Arndt Vogel; Gastroenterology and Hepatology, Medical School Hannover, Hannover, Germany

Autoimmune hepatitis (AIH) is a chronic necroinflammatory liver disease associated with hypergammaglobulinemia, serum autoantibodies and hepatitis with lymphoplasmacytic infiltration, which is responsive to immunosuppressive therapy. The aim of our study was to determine genetic and serologic factors in a cohort of patients with AIH and to correlate them with clinical features. 296 patients diagnosed as having AIH were enrolled. Clinical data were retrospectively reviewed. Genomic DNA was available from 210 patients and the frequency of HLA alleles A1, B8, DRB1*03, DRB3*01, DQA1*05, DQA1*03 and DQB1*02 were analysed and compared with 100 healthy controls. 170 patients were diagnosed as type 1, 44 as type 2 and 82 as type 3. 73% of the patients were female and 27% male. 88% of the patients were younger and 12% older than 65 years. Median duration of follow-up was 11.3 years. Based on the serologic profile, there were no significant differences between the different groups with respect to extrahepatic manifestations, response to therapy, progression to cirrhosis, liver transplantation and liver-related deaths. However, patients with type 2 were significantly younger at diagnosis than patients with type 1 or 3. Similar to previous studies, the above mentioned HLA alleles were more frequently detected in patients with AIH in comparison to controls. Regarding the AIH subgroups, there were no significant differences in the distribution of alleles between type 1 and 2 patients. Patients with AIH type 3 displayed more often the haplotype A1-B8-DRB1*03-DRB3*01 than type 2 patients, and DRB1*03 when compared to AIH type 1 and type 2. Patients with DR3, DR52 and DR3-DR52 were more often male, showed an advanced fibrosis, a worse clinical outcome and a higher frequency of SLA/LP, but less immune mediated syndromes than subjects with other HLA antigens. Overall, there were no significant differences in the clinical course of male and female patients, but DRB1*04 and DRB1*04-DRB4*01 were more often detected in women; in contrast, men had a higher frequency of B8, DRB1*03, DRB3*01 and A1-B8-DRB1*03-DRB3*01. Patients older than 65 years had a more moderate clinical course than younger patients. Frequency of DRB4*01 and DRB1*04-DRB4*01 was increased in patients over 65 and the frequency of DRB1*03 and DRB1*03-DRB3*01 in patients under 65 years. Taken together, our data suggest that clinical features of adult AIH patients are not influenced by the antibody status. In contrast, HLA alleles appear to not only determine susceptibility to AIH, but also the clinical expression of the disease.

710 PERIPHERAL, BUT NOT CENTRAL, TOLERANCE NOR LEVEL OF AUTOANTIGENIC EXPRESSION IS RESPONSIBLE FOR THE GENDER BIAS IN SUSCEPTIBILITY TO EXPERIMENTAL TYPE 2 AUTOIMMUNE HEPATITIS

Pascal Lapiere1,2, Kathie Bélard1, Fernando Alvarez1,2, 1Gastroenterology, hepatology and nutrition division, CHU Sainte-Justine, Montreal, QC, Canada; 2Department of Biomedical Sciences, University of Montreal, Montreal, QC, Canada

INTRODUCTION. Autoimmune hepatitis (AIH) is a disease of unknown etiology characterized by a progressive destruction of the hepatic parenchyma. In type 2 AIH, 90% of cases are 80% diagnosed before the age of 18. Recently, we have developed an experimental model of type 2 AIH based on DNA vaccination with human autoantigens (CYP2D6 and FTCD) in C57BL/6 mice. Through molecular mimicry, this xenoinmunisation breaks the immune tolerance to murine hepatic autoantigens and induces an AIH. This model shows clinical, laboratory and histological characteristics of
711 PREDICTIVE FACTORS FOR HEPATOCELLULAR CARCINOMA IN TYPE 1 AUTOIMMUNE HEPATITIS: IMPACT OF GENDER, STAGE, HLA PHENOTYPE AND TREATMENT

Aldo J. Montano-Loza, Herschel A. Carpenter, Albert J. Czaja

Background/Aim: Hepatocellular carcinoma (HCC) is an uncommon but serious occurrence in autoimmune hepatitis, and factors predictive of this risk are needed to optimize early detection. Our aim was to determine the predictors of HCC in autoimmune hepatitis that could focus and improve screening strategies. Methods: 227 patients with definite type 1 autoimmune hepatitis underwent ultrasonography and serum alpha fetoprotein determinations at 6-12 month intervals during 114±6 months (range, 6-409 months; median, 93 months). All patients were negative for viral infection, and they had been screened at least once for HCC (screening episodes, 1212; range, 1-30). Results: Nine patients developed HCC (4%), and each had cirrhosis for at least 73 months prior to the neoplasm (mean duration of cirrhosis, 132±14 months; range, 73-200 months; median, 132 months). Patients developing HCC were more commonly male (56% vs 17%, P=0.01) than patients without HCC, and they had cirrhosis at accession or during follow-up (100% vs 40%, P=0.0003) and features of portal hypertension (esophageal varices, ascites, or edema) more frequently (67% vs 12%, P=0.0004). Patients with HCC also had worsening laboratory tests during corticosteroid therapy (treatment failure) [33% vs 16%, P=0.03] and progression to cirrhosis (56% vs 18%, P=0.002) more often than patients without HCC as well as longer periods of immunosuppressive treatment (57±27 months vs 29±3 months, P=0.04). Male gender (OR, 6.8; 95% CI, 1.6-23.9, P=0.009), cirrhosis for ≥10 years (OR, 14.7; 95% CI, 2.9-73.2, P=0.001), features of portal hypertension (OR, 14.1; 95% CI, 3.3-59.9, P=0.0003), immunosuppressive treatment for ≥3 years (OR, 4.4; 95% CI, 1.2-17.1, P=0.03), and treatment failure (OR, 6.3; 95% CI, 1.4-27.6, P=0.01) were associated with increased risk of HCC by logistic regression analysis. The incidence of HCC in men with cirrhosis was 4-fold greater than in women with cirrhosis (13 vs 3 cases per 1000 patient-years), and the men were distinguished from the women by younger age (42±3 years vs 47±1 years, P=0.03) and lower frequency of HLA DRB1*04 (28% vs 48%, P=0.03). Women with cirrhosis and HLA DRB1*04 had a lower frequency of HCC than men with cirrhosis (0% vs. 21%, P=0.01), especially men without HLA DRB1*04 (0% vs 19%, P=0.04). Conclusions: Male gender, cirrhosis of ≥10 years duration, features of portal hypertension, immunosuppressive treatment for ≥3 years, and worsening laboratory tests during corticosteroid therapy identify patients at risk for HCC, and these risk factors should focus the screening strategy. Women with cirrhosis and HLA DRB1*04 have a low risk of HCC. Disclosures: The following people have nothing to disclose: Aldo J. Montano-Loza, Herschel A. Carpenter, Albert J. Czaja

712 GLUCOCORTICOID RESISTANCE IN AUTOIMMUNE HEPATITIS ASSOCIATES TO INCREASED EXPRESSION AND ACTIVITY OF P-GLYCOPEPTIDE IN T CELL

Hiroki Takahashi, Masanori Nakano, Shigeo Tamaki, Yushi Kuniyasu, Mikio Zeniya; Gastroenterology and Hepatology, Department of Internal Medicine, JIKEI University School of Medicine, Tokyo, Japan

Background and Aim: Though autoimmune hepatitis (AIH) patients respond to glucocorticoid (GC) therapy comparatively well, resistant to GC and relapse are often observed clinically. Recently, it has been reported that ABC transporter such as MRPl and P-glycoprotein (Pgp), which excrete intracellular GC, were expressed on T cell and Pgp relates to GC resistance in autoimmune diseases. We studied how these molecules relate to GC resistance in AIH by analyzing the expression and activity of Pgp and MRPl in T cell of AIH patients. Patients and Methods: Clinically and pathologically diagnosed 43 AIH patients and 36 healthy volunteers were enrolled. CD4 and CD8 cells were separated from peripheral blood. Surface expression of Pgp and MRPl were analyzed by FACS using Pgp specific MRK-1.6 antibody and MRPl specific MRPm5 antibody. Pgp activity was evaluated by measuring intracellular rhodamine123, which was added cell culture in advance, in the presence of Pgp blocker PSC833. AIH patients were divided to GC therapy resistant group (n=17: daily maintenance dosage of GU was more than 10mg) and responded group (n=26: less than 10mg). They were also divided into relapsed group (n=27: patient who had relapse during maintenance therapy) and non-relapsed group (n=16). Results: Pgp expression of AIH were significantly higher than control
GCD: 16.4 vs 3.7, CD8: 16.5 vs 3.1, p < 0.001. Pgp expression in resistant group or relapsed group were significantly higher than responded group (CD4: 20.1 vs 10.5, p < 0.01, CD8: 17.6 vs 12.7, p < 0.05) or non-relapsed group (CD4: 20.6 vs 12.6, p < 0.01, CD8: 19.5 vs 13.2, p < 0.05). Pgp activity of AIH was higher than control, however no significant difference was observed. Pgp activity of resistant group was significantly higher than responded group (CD4: 35.4 vs 28.2, p < 0.05, CD8: 34.5 vs 22.9, p < 0.05). Though Pgp activities of relapsed group were not significantly higher compared with non-relapsed group, they were significantly higher compared with control (CD4: 35.5 vs 25.9, p < 0.05, CD8: 33.1 vs 23.8, p < 0.05). There was no significant correlation between the level of Pgp activity and serum levels of ALT, IgG. MRP1 expression was not different between AIH and control. MRP1 expression was different between resistant group and responded group, relapsed group and non-relapsed group; either. The expression of Pgp and MRP1 were not correlated. Conclusion: Our analysis revealed that increased expression and activity of Pgp in T cell participate in the mechanisms of GC resistance in AIH. These results indicated that the expression and activity of Pgp in T cell could be used as the marker to predict GC resistance in AIH therapy.

713 POTENTIATION OF THE INHIBITORY EFFECT OF INTRAHEPATIC NKT LYMPHOCYTES BY A NOVEL NON-DEGRADABLE Beta-Glucosylceramide ANALOG IS ASSOCIATED WITH DECREASED STAT 1 PHOSPHORYLATION

Gadi Lalazar1, Ami Ben Ya'acov1, Madi El-Haj1, Dan M. Livovsky1, Orit Pappo2, Gunter Schwartzman1, Yaron Ilan1, 1Liver Unit, Hadassah Hebrew University Medical Center, Jerusalem, Israel; 2Pathology, Hadassah Hebrew University Medical Center, Jerusalem, Israel; 3Institut für Organische Chemie und Biochemie, University of Bonn, Bonn, Germany

Glycolipid presentation by the CD1 receptor to NKT regulatory lymphocytes is important for antigen recognition. The therapeutically potential for harnessing NKT cell responses has been demonstrated in several immune-mediated disorders. Betaglycolipids were recently suggested to exert an immune-modulatory effect on NKT lymphocytes, alleviating immune-mediated disorders. The addition of a thio-group has been shown to turn beta-glycolipids, into a non-degradable molecule. Purpose: To determine the effect of the ligand structure on intrahepatic NKT lymphocyte function in NKT-mediated immune hepatitis. Methods: ConA hepatitis, an NKT-mediated disorder, was induced in C57BL/6 mice (n=8). Mice were injected with non-degradable beta-glucosylceramide containing the thio-group (GCT), beta-glycolipid (GC), or PBS. FACS analysis of intrahepatic NKT lymphocytes and measurement of the serum IFN-g levels by ELISA were performed. Phosphorylation of STAT1 and 6 were determined by western blot. Liver damage was assessed by determination of serum transaminases and degree of apoptosis, using TUNEL assay. Results: Administration of GCT led to a more pronounced inhibitory effect on intrahepatic NKT lymphocytes than GC (a decrease of 84% versus 53%, compared with PBS, respectively, p < 0.05). This effect was associated with a significant increase in STAT 1 expression observed in GCT versus GC-treated mice (130% versus 68%, respectively, compared with PBS). Both GCT and GC led to a decrease of STAT1 phosphorylation (43% and 29%, respectively) along with a decrease in IFN-g serum levels (16% and 26%, for GCT and GC, p < 0.05). Serum IL-4 levels did not change significantly. These effects were associated with alleviation of ConA immune-mediated hepatitis, as determined by a similar substantial decrease in serum transaminases (AST: 58.1% and 55.3%; and ALT: 70.4% and 63.4% for GCT and GC, respectively, p < 0.05), and a profound decrease in apoptosis found in TUNEL assay (66% and 55% for GCT and GC, respectively). Conclusion: Alteration of the chemical structure of the beta-glucosylceramide by replacing the O-glycosidic bond with a S-glycosidic bond resulting in a non-degradable molecule, significantly suppresses intrahepatic NKT lymphocytes. These results suggest that cellular events that alter the enzymatic pathways of glycosylceramidases, serve as an initial stimulus for NKT-cell activation in vivo. This novel ligand may serve as an immune-modulatory therapy in patients with immune-mediated liver injury.

714 ASSOCIATION OF CYTOTOXIC T-LYMPHOCYTE ANTIGEN 4 GENE POLYMORPHISMS WITH TYPE 1 AUTOIMMUNE HEPATITIS IN JAPANESE

Takeji Umemura1, Masao Ota2, Kaname Yoshizawa1, Yoshiko Katsuyama3, Sataru Joshi4, Tetsuya Ichijo5, Eiji Tanaka6, Shigeyuki Kawa2, Kendo Kiyosawa1, 1Internal Medicine, Shinshu University School of Medicine, Matsumoto, Japan; 2Legal Medicine, Shinshu University School of Medicine, Matsumoto, Japan; 3Pharmacy, Shinshu University School of Medicine, Matsumoto, Japan; 4Center for Health, Safety and Environmental Management, Shinshu University, Matsumoto, Japan

Background & Aims: Autoimmune hepatitis (AIH) is an organ-specific autoimmune disease characterized by chronic inflammation of the liver, elevated transaminase levels, hypergammaglobulinemia, serum autoantibodies, histologic evidence of interface hepatitis, and a favorable response to immunosuppressive treatment. Although the HLA DRB1*0405 allele in Japanese has been identified as independent determinants of susceptibility to AIH, the role of other genetic factors is largely unknown. The cytotoxic T lymphocyte antigen 4 (CTLA4; CD152) is an inhibitory receptor expressed on the cell surface of activated memory T cells and on CD4+CD25+ regulatory T cells, and acts largely as a negative regulator of T cell responses. As CTLA4 polymorphisms have recently been linked with several autoimmune diseases including AIH in Caucasians, we sought to clarify if CTLA4 polymorphisms are associated with disease susceptibility in Japanese patients with type 1 AIH. Methods: We genotyped 76 patients with AIH (median 56 years: female 82%) and 100 ethically matched controls for allelic determinants using TaqMan genotyping assays at four polymorphism sites: -1722 and -318 in the promoter, +49 in exon 1, and +6230 in the 3' untranslated region. Results: Positivity for the SNP -1722C was significantly increased in patients with AIH (OR = 2.13, 95% CI, 1.14–3.98; P = 0.026) than in healthy subjects, indicating a significant association of the -1722T/T genotype with AIH, which was significantly decreased (OR = 0.47, 95% CI, 0.25–0.88; P = 0.026) in comparison with healthy controls. Compared with -1722 C/C patients, these patients were younger (56 vs. 63 yrs; P = 0.01) and had significantly lower serum levels of aspartate aminotransferase (313 vs. 765 IU/L; P = 0.031) and bilirubin (1.1 vs. 8.6 mg/dL; P = 0.027). Analysis of allelic frequencies revealed no significant difference between patients with and without the
715
OUTCOME AND SURVIVAL IN CHILDHOOD ONSET AUTOIMMUNE SCLerosing CHOLANGITIS AND AUTOIMMUNE HEPATITIS: A 13 YEARS FOLLOW-UP STUDY

Astrid Scalori, Michael A. Heneghan, Nedim D. Hadzic, Diego Vergani, Giorgina Mieli-Vergani; King’s college hospital, London, United Kingdom

Background: As part of a long-term prospective study (Hepatology 2001;33:544-553), we have previously reported that autoimmune hepatitis (AIH) and autoimmune sclerosing cholangitis (ASC) in childhood are distinct entities, with similar modes of presentation, histological features and response to treatment. The prevalence of ASC is similar to AIH but ASC affects boys and girls equally. Diagnosis of ASC relies on the demonstration of cholangiopathy on radiological imaging at presentation. Aim: To assess long-term outcome of patients with AIH and ASC recruited in our original study. Patients and Methods: 55 consecutive paediatric patients with clinical and/or biochemical evidence of liver disease and a serological profile compatible with AIH were recruited from 1984 to 1997 and prospectively followed-up, to date. At the time of diagnosis, all underwent liver biopsy and direct cholangiography. Twenty-eight patients were diagnosed with AIH (F:M ratio 22:6) and 27 with ASC (F:M ratio 15:13) based on the absence or presence of radiological features of cholangiopathy. Most patients were treated with prednisolone and azathioprine (Az). Ursodeoxycholic acid (UDCA) was added in those with ASC. Results: At last follow-up (median 13 yrs, range 8-29 yrs), 53/54 patients are alive, one patient with ASC having been lost to follow-up. Of the 28 patients with AIH, 5 (18%) have successfully stopped all immunosuppression, 3 are on Az alone, 1 on prednisolone alone, 13 on prednisolone and Az, 2 on prednisolone, Az and UDCA, 1 on prednisolone, MMF and UDCA, one on CyA and prednisolone. Two patients (7%) underwent liver transplantation for end-stage liver disease. Of the 26 patients with ASC, 1 (4%) are off medication, 5 are on UDCA alone, 3 on UDCA and Az, 3 on prednisolone and UDCA, 1 on Az alone and 2 on prednisolone and Az, no treatment information being available for 3. Six patients with ASC (22%) have required liver transplantation, 3 of whom (50%) had recurrence of ASC 1, 3, 4 years after surgery, and requiring re-transplantation in two. One of these two patients had further ASC recurrence in the graft requiring re-transplantation 12 year later. One cirrhotic girl with ASC died of intra-abdominal haemorrhage after delivering a healthy infant. Conclusion: Although AIH and ASC have similar features at presentation, and initial response to immunosuppressive treatment is satisfactory, long-term follow-up shows that patients with ASC are significantly more likely to die or need transplantation than those with AIH (p < 0.009, Log Rank), and have a high rate of disease recurrence after liver transplantation.

716
GENETICALLY DETERMINED ABNORMALITY OF THE PD-1/PD-LS PATHWAY MAY PREDISPOSE TO AUTOIMMUNE LIVER DISEASE

Pengyun Wang, Maria Serena Longhi, Giorgina Mieli-Vergani, Diego Vergani, Yun Ma; Institute of Liver Studies, King’s College London School of Medicine at King’s College Hospital, London, United Kingdom

Background: Programmed death-1 (PD-1) and its ligands - members of the CD28/B7 super-family - are central to the maintenance of peripheral tolerance, their experimental impairment resulting in autoimmune disease. Aims: To evaluate the expression of PD-1 on peripheral blood mononuclear cells (PBMCs) and T cells, and its ligand PD-L1 (B7-H1) on PBMCs and dendritic cells (DCs) in autoimmune liver disease (AILD). Methods: PD-1 and PD-L1 expression on PBMCs and DCs was evaluated by FACS using anti-Cd4, -CD8, -blood DC antigen-1 (BDCA-1), -PD-1 and -PD-L1 monoclonal antibodies in 32 AILD patients (PtS, 22 autoimmune hepatitis, 10 autoimmune sclerosing cholangitis, median age 10 years, range 3-19; 18 females). Fourteen patients’ first-degree relatives (FDR, median age 45, range 5 to 49; 7 females) and 9 healthy subjects (HS, median age 31 years, range 21-48; all females) were also studied. Up-regulation of PD-1 and PD-L1 was induced by 500 ng/ml lipopolysaccharide (LPS) 4-hour stimulation. Results: At baseline the frequencies of PD-1 expressing PBMCs (Pts 3.71 ±0.37, FDR 3.68±0.5 vs HS 6.31±0.78, P<0.01) and CD4 T cells (Pts 1.45±0.17, FDR 2.06±0.77 vs HS 2.67±0.28, P=0.001 and P=0.23) were lower in patients and relatives than in controls. PD-L1 expressing PBMCs (Pts 1.31±0.26, FDR 0.58±0.13 vs HS 1.35±0.43) and DCs (Pts 0.35±0.07, FDR 0.19±0.05 vs HS 0.48±0.09) were similar in Pts and HS but lower in FDR than in HS (P<0.05 for both). After LPS stimulation, PD-1 expressing PBMCs (Pts 4.39±0.63, FDR 5.23±0.93 vs HS 7.37±1.32, P=0.017 and P=0.14) and CD4 T cells (Pts 1.95±0.26, FDR 2.61±0.71 vs HS 2.27±0.23, P=0.05 and P=NS) increased marginally in all groups but remained lower in Pts and FDR than HS, while PD-L1 expressing PBMCs increased marginally in Pts (from 1.31±0.26 to 1.48±0.21) and HS (from 1.35±0.43 to 1.89±0.43) but significantly in FDR (from 0.58±0.13 to 1.38±0.41, P=0.05). PD-L1 expressing DCs increased significantly in Pts (from 0.35±0.07 to 0.88±0.15, P=0.002), FDR (from 0.19±0.05 to 0.49±0.06, P=0.003) and HS (from 0.48±0.09 to 1.17±0.22, P=0.07), remaining lower in FDR than HS (P<0.02). Summary and conclusion: Our data show that PD-1 expressing PBMCs and CD4 T cells are numerically impaired in AILD patients and their first degree relatives, and that AILD patients have an imbalance between PD-1 and PD-L1 expression. The abnormality of the PD-1/PD-L1 pathway appears to be genetically determined and may predispose to the development of AILD.

717
THE USE OF MYCOPHENOLATE MOFETIL IN THE TREATMENT OF AUTOIMMUNE HEPATITIS IN PATIENTS REFRACTORY TO OR INTOLERANT OF CONVENTIONAL TREATMENT

Kaveh Sharzehi, Kimberly Brown, Mary Ann H. Sherbondy; Henry Ford Hospital, Detroit, MI

Background: Autoimmune hepatitis (AIH) is characterized by progressive hepatocellular inflammation often progressing to
cirdrosis. Standard treatment consists of corticosteroids alone or in combination with azathioprine (AZA). Remission will be achieved in over 80% of cases and long-term treatment with azathioprine with or without steroids has been shown to be effective at preventing relapse and maintaining remission. Alternative therapies are warranted for individuals who are refractory to or intolerant to standard therapy. There is no standard treatment for steroid refractory AIH or for those intolerant to azathioprine. Mycophenolate mofetil (MMF), a potent inhibitor of guanosine nucleotide synthesis, is a promising alternative treatment of autoimmune hepatitis. Aim: To assess the outcome of therapy with MMF in patients with refractory AIH or intolerance to azathioprine. Methods: Patients diagnosed and treated for AIH from 1994 to 2007 at our center were identified. Response to medication was recorded. Patients converted to MMF were evaluated for tolerance and response. Results: 90 patients were included in the study. 48% had complete clinical and laboratory resolution of their disease, 30% had relapsing disease and 22% had partial or no response on prednisone and AZA. MMF was initiated in 21 patients (24%) after an average of 42 months of treatment with conventional therapy. The reason for MMF conversion was failure of conventional treatment (group 1) in 57% and intolerance to steroids or azathioprine (group 2) in 43%. 17/21 patients had a follow up greater than 6 months. 8/17 patients were converted to MMF for refractory disease. 0/8 patients had biochemical resolution of disease following conversion. 9/17 patients were converted to MMF for intolerance to conventional treatment. 8/9 patients (88%) maintained complete remission following conversion (p=0.002). In patients converted to MMF, a mean decrease in steroids from 17.5 mg to 6.5 mg was seen (p<0.001). Conclusion: In patients with AIH who are intolerant to conventional therapy, mycophenolate mofetil is well tolerated. The majority of patients switched to MMF secondary to azathioprine intolerance remain in clinical and laboratory remission. Mycophenolate mofetil did not induce remission in those refractory to conventional therapy, but use of mycophenolate mofetil did allow a significant mean decrease in steroid use in those patients. Larger, prospective studies are needed to better assess the role of MMF as a frontline and second line agent in the treatment of AIH.

LYMPHOTOXIN ALPHA GENE POLYMORPHISMS IN PEDIATRIC AUTOIMMUNE HEPATITIS TYPE 1
Gilda Porta1, L. C. Oliveira2, R. Ramasawmy3, P. L. Bittencourt4, I. K. Miura5, R. S. Pugliese1, V. B. Danesi1, J. Kalil4, A. C. Gold-
of serum transaminases compared with a decrease in GC and combined treatment groups (an increase of 231% and 136%, vs. a decrease of 72%, 66% and 81%, 76%, for ALT and AST, respectively, p< 0.05). aGalCer led to a 10% decrease in TUNEL-positive hepatocytes, while treatment with GC or the combination led to a significant decrease of 82% and 61%, respectively (p< 0.05). Conclusion: GC, a natural betaglycolipid, decreases the immune-mediated liver damage of aGalCer, associated with a decrease in intrahepatic NKT cells and a Th2 shift. These data suggest that optimization of the NKT ligand structure can determine its immune modulatory effect, with a role for CD1d, and that different ligands may ameliorate immune mediated damage.

ANTIBODIES TO DOUBLE-STRANDED DNA (ANTI-DSDNA) IN LIVER DISEASE: HIGH SPECIFICITY FOR TYPE 1 AUTOIMMUNE HEPATITIS (AIH-1) AND USEFUL MARKER FOR THE DIAGNOSIS OF PRIMARY BILARY CIRRHOSIS (PBC) - AIH OVERLAP SYNDROME  
Georgios Pappas, Alessandro Granito, Paolo Moraturi, Silvana Maccariello, Luigi Muratori, Rodolfo Ferrari, Fabio Cassani, Silvia Ferri, Valentina Cipriani, Chiara Quarneti, Francesco B. Bianchi; Department of Internal Medicine, Hepatology, Cardioangiology, University of Bologna S.Orsola-Malpighi Hospital, Bologna, Italy  
BACKGROUND AND AIMS Antibodies to ds-DNA play a well established role in the diagnosis, pathogenesis and prognosis of systemic lupus erythematosus. Anti-dsDNA have been detected also in AIH-1 and sporadically in other chronic liver diseases. Conclusive data are still lacking about their prevalence in other autoimmune liver disorders and their specificity for AIH-1, especially in European patients. To determine the prevalence of anti ds-DNA in the whole spectrum of autoimmune liver disease: type I and type II AIH, PBC and PSC. To evaluate whether anti-dsDNA are specific for type I AIH and whether in this setting they are of clinical and prognostic relevance.  
PATIENTS AND METHODS: 310 consecutive patients with autoimmune liver diseases and 114 matched controls with other chronic liver diseases were studied (table 1). Anti-dsDNA were searched for by IIF on Crithidia luciliae a test considered to be high specific. RESULTS: The frequency of anti-dsDNA in the studied population is reported on table 1. Their overall specificity for type-1 AIH was 96%. Anti-dsDNA seropositivity in AIH-1 was associated with older age (p = 0.006), higher γ-globulin, IgG (p = 0.01) and bilirubine serum levels (p = 0.01) and lower albumine (p = 0.03). Seropositive patients tend to have a higher prevalence of severe fibrosis and cirrhosis (p = 0.07) and had more frequently the allele DR4 (p = 0.06). Six out of the 10 anti ds-DNA positive PBC patients had an IAIHG score corresponding to “probable” AIH. In these patients an overlap PBC-AIH syndrome could thus be suspected. These overlap cases had a higher titer of anti-dsDNA. None of the seronegative PBC patients reached a score sufficient for “probable” AIH. CONCLUSIONS: In the spectrum of liver disease anti-dsDNA represent a diagnostic marker of AIH-1. Their occurrence at a high titer in PBC should suggest the diagnosis of overlap PBC-AIH syndrome. In AIH-1 anti-dsDNA correlate with older age, DR4, higher bilirubin and lower albumin serum levels and histological evidence of severe fibrosis and cirrhosis. Their presence thus suggests a more advanced stage of liver disease.

721  
THE IMPACT OF ETHNICITY ON THE NATURAL HISTORY OF AUTOIMMUNE HEPATITIS  
Sumita Verma2,1, Michael Torbenson2, Paul J. Thuluvath2; 1Brighton and Sussex Medical School, Brighton, United Kingdom; 2Johns Hopkins University Hospitals, Baltimore, MD  
Background and aims: The impact of ethnicity on the natural history of autoimmune hepatitis [AIH] has not been well characterized. The aim of this study was to assess the natural history of AIH in Blacks compared to others (non-Blacks). Patients and methods: This was a 10-year (June 1996 to June 2006) retrospective analysis of patients with AIH from a single tertiary care center. The diagnosis of AIH was defined by the criteria established by the International AIH Club. Poor outcome was defined as liver failure at presentation, failure to achieve remission, need for liver transplantation and or death. Results: 101 patients with AIH were found eligible for the study. Black patients were more likely to have cirrhosis (56.7% vs. 37.5%, p=0.061), have liver failure at initial presentation (37.8% vs. 9.3%, p=0.001) and be referred for liver transplantation (51.3% vs. 23.4%, p=0.004). The overall mortality was also significantly higher in Black patients (24.3% vs. 6.2%, p=0.009). Compared to non-Blacks, Blacks had more advanced hepatic fibrosis (3.6 ± 2.7 vs. 2.1 ± 2.4, p=0.013). Kaplan Meier analysis showed that probability of developing a poor outcome was significantly higher in Blacks (p=0.003). Independent predictors of poor outcome were Black ethnicity, presence of cirrhosis, and fibrosis stage at presentation. Black males were the group most likely to have a poor outcome (85.7%). Conclusions: Blacks, especially Black men with AIH, have more aggressive disease at initial presentation, are less likely to respond to conventional immunosuppression and have a worse outcome compared to non-Blacks.

POPULATION-BASED STUDY OF ALASKA NATIVE PERSONS WITH AUTOIMMUNE HEPATITIS: CLINICAL PRESENTATION, RESPONSE TO TREATMENT AND RELAPSES

Kathy J. Hurlbut, Brian J. McMahon, Stephen Livingston, James Gove, Henry Cagle; Liver Disease and Hepatitis Program, Alaska Native Tribal Health Consortium, Anchorage, AK

Background: Studies have demonstrated a high prevalence of autoimmune hepatitis (AIH) in Alaska Native persons (AN). Clinicians have felt these patients showed a dramatic response to treatment with rapid drops in transaminase levels after initiating therapy. The conventional wisdom is that achievement of remission in adults averages 6 months or more. We conducted a review of AN diagnosed with AIH to determine clinical presentation, how rapidly patients responded to treatment and the frequency of relapse after treatment was initiated. Methods: A review of patient records was performed from a statewide (Alaska) registry of AN diagnosed with AIH since 1981. All persons included met the International Autoimmune Hepatitis Group criteria for definite or probable AIH and excluded those with overlap syndrome. Unlike the AASLD guidelines, which define remission as ALT and AST less than twice the upper limit of normal, we defined remission as ALT and AST less than 40. Standard treatment was initiated with methylprednisolone 32 mg/day or prednisone 40 mg/day and azathioprine 50-150 mg/day, with a slow tapering of the corticosteroid based on

200 patients with autoimmune hepatitis between 1999 and 2004. 84 of 200 patients met the diagnosis of AIH according to revised scoring system of the International Autoimmune Hepatitis Group. 29 patients were excluded secondary to insufficient clinical information or absence of liver biopsy specimens. The charts of the remaining 55 patients were analyzed for age, gender, serum aminotransferase levels, serum autoantibody levels and treatment regimens. Seropositivity was defined as ANA >1:40 and ASMA >1:40. Liver biopsy specimens were reviewed by two pathologists who were blinded to clinical and serological data. Degree of liver injury on histology was defined by four individual categories including portal inflammation, lobular inflammatory activity, piecemeal necrosis and cirrhotic nodules. Each category was graded on a scale of 0 to 4. Mann-Whitney test was used to evaluate the difference between means. Results: The 55 patients with AIH had a mean age of 52 years ± 15 years, with 41 (75%) being female. Positive ANA titers were found in 36 patients (66%), 36 patients (66%) were ASMA positive, 27 (49%) were both ANA/ASMA positive and 10 (18%) were both ANA/ASMA negative. The patients with autoantibodies were similar to the patients without autoantibodies with respect to age, gender and treatment regimen. There was no statistically significant difference in the ALT and/or AST at diagnosis and at 1, 6 and 12 months post treatment between the seropositive and the seronegative patients. Degree of lobular inflammatory activity was slightly higher in the seropositive group vs. the seronegative group (mean score, 1.4 vs. 1) but results were not statistically significant (p=0.25). Both groups had similar degree of portal inflammation (1.4 vs. 1.6, p=0.71) and piecemeal necrosis (0.93 vs. 1, p=0.69). Centrilobular necrosis was found in liver biopsy specimens of 2 (4%) seropositive patients and 0 seronegative patients. Conclusions: The presence or absence of autoantibodies does not appear to correlate with histological severity of disease and does not predict response to immunosuppressive therapy in these patients. Based on our study, autoantibodies should not be used to predict AIH activity or outcome and patients with clinical features consistent with AIH should be treated regardless of serologic status.

SEROLOGICAL MARKERS DO NOT PREDICT LIVER HISTOLOGY IN AUTOIMMUNE HEPATITIS

Vaibhav Mehendiratta, Pradnya Mitroo, Alessandro Bombonati, Raphael Rubin, Victor J. Navarro, Simona Rossi, Steven K. Herrine; 1Division of Gastroenterology & Hepatology, Thomas Jefferson University, Philadelphia, PA; 2Department of Medicine, Thomas Jefferson University, Philadelphia, PA; 3Pathology, Anatomy and Cell Biology, Thomas Jefferson University, Philadelphia, PA

Objective: The present study is to determine if the presence of serum autoantibodies in patients diagnosed with autoimmune hepatitis (AIH) correlates with histological and biochemical severity of disease and response to treatment. Methods: Electronic billing records at our university hepatology practice revealed 200 patients with autoimmune hepatitis between 1999 and 2004. 84 of 200 patients met the diagnosis of AIH according to revised scoring system of the International Autoimmune Hepatitis group. 29 patients were excluded secondary to insufficient clinical information or absence of liver

after stimulation by their natural ligand lypopolysaccharide (LPS) through Toll-like-receptor-4 (TLR4), trigger adaptive immune responses. Monocytes abound in the portal/pericellular infiltrate in autoimmune hepatitis (AIH). Aim: To investigate the effect of T-regs on monocyte TLR4 expression in the presence or absence of LPS in AIH. Patients and methods: 16 patients with ANA/ASMA-ve AIH (median age: 14.7 years; 7 females) and 7 normal controls (median age 28 years; 7 females) were studied. Monocytes, T-cells and CD4+CD25- T-cells were isolated from peripheral-blood-mononuclear-cells using immunomagnetic beads. Monocyte TLR4 expression (assessed as mean fluorescence intensity) was evaluated by flow cytometry before and after 24-hour co-culture with T-regs (or with CD4+CD25- T-cells as control) in the absence or presence of LPS. To assess whether T-reg effect on monocytes is due to cell-to-cell contact and whether is mediated by IL-10, transwell experiments and neutralization assays using anti-IL-10 antibodies were performed. Results: Before LPS stimulation and in the absence of T-regs the expression of TLR4 on monocytes was similar in controls and patients. Following T-reg addition it increased by 29% (from 34.6±4.9 to 44.5±5.8; P=0.03) in controls and by 39.8% (from 41.9±3.4 to 58.7±6.7; P=0.025) in AIH. Following LPS stimulation in the absence of T-regs, monocyte TLR4 expression increased by 21% (P=0.1) in normal and by 15.9% (P=0.1) in AIH. After T-reg addition in the presence of LPS, TLR4 increased by 23% (from 42.5±4.2 to 52.3±7.7; P=0.046) in controls and by 33% (from 48.7±3.5 to 64.6±5.1; P=0.016) in AIH. Following T-reg addition, the expression of TLR4 on monocytes was higher in patients than in controls both in the absence (P=0.12) and presence (P=0.059) of LPS. No effect on monocyte TLR4 expression was observed when CD4+CD25- T-cells were added instead of T-regs. T-reg effect on monocyte was mainly mediated by a cell-to-cell mechanism, the increased TLR4 expression being lower (17% in normal and 16% in AIH) when monocytes were kept separated from T-regs than when they were in direct contact (29% and 39.8% respectively). Increased TLR4 expression was inhibited by addition of anti-IL-10 by 86% in controls and 91% in patients. Conclusions: Unexpectedly, T-regs increase TLR4 on monocytes through cell-to-cell contact in the presence or absence of IL-10, the effect on monocyte was mainly mediated by a cell-to-cell mechanism. treatment response. Results: Eighty patients (76 women, 4 men) met the criteria for definite (68) or probable (12) AIH. The average age at diagnosis was 51.2 years (range 15-78). Twenty-one (26%) presented with symptoms of acute hepatitis; 4 were diagnosed incidentally with normal liver function tests; 4 had mild symptoms (fatigue) with transaminase elevation, and 35 had no reported symptoms but elevated transaminases. Ten patients were not treated and 7 treated had inadequate follow-up. Of the remaining 63, one (1.5%) has not achieved remission; time to achieve normal transaminase levels was 3-6 months in 7 (11%), 1-2 months in 8 (13%), and less than one month in 47 (76%). In 70 treated patients, relapses were documented in 20 (29%): 4 were noncompliant in taking their medications, 7 had bone marrow suppression and had to stop azathioprine, and 9 were unable to tolerate azathioprine or the dose could not be raised above 50 mg/day due to neutropenia. Conclusions: Alaska Native persons with AIH appeared to respond more rapidly to treatment than other reported populations, as the majority normalized their liver enzymes within one month or less of starting therapy. The majority of those who relapsed received inadequate dosing of azathioprine due to intolerance, noncompliance or bone marrow suppression.

BROAD CLINICAL VARIABILITY OF A CHOLESTATIC LIVER DISEASE IN ELEVEN SIBLINGS WITH ONE SINGLE MUTATION IN THE ABCB4 GENE

Daniel Gotthardt1, Heiko Runz2, Verena Keitel2, Christa Flechtenmacher2, Sandra Imparato1, Christine Fischer4, Wirtzberger Michael5, Karl Heinz Weiss1, Wolfgang Stremmel1, Barbara Burwinkel3, Adolf Steihl1, Peter Schirmacher2, Johannes Zschocke3, Peter Sauer1,1 Internal Medicine IV, University Hospital Heidelberg, Heidelberg, Germany; 2Dept. of Pathology, University Hospital Heidelberg, Heidelberg, Germany; 3Dept. of Human Genetics, University Hospital Heidelberg, Heidelberg, Germany; 4Dept. of Gastroenterology, University Hospital Dusseldorf, Dusseldorf, Germany; 5Molecular Genetic Epidemiology, German Cancer Research Center, Heidelberg, Germany

Background: Cholestatic liver disease is one of the major reasons for progressive liver damage and liver failure. A family of eleven siblings from a small village in Transylvania allowed us to study the broad clinical variability of cholestatic liver diseases with one single gene defect. Methods: Clinical and histopathological features of the family members were analysed to assign them to the different groups of: affected with elevated liver parameters and/or definite histological changes, mildly affected with intrahepatic cholestasis of pregnancy or subtle histological changes and healthy. Assuming a monogenetic inheritance linkage analysis was performed using Affymetrix 50K Gene Chips. Genes that cause cholestatic disease and candidates from the linkage analysis were analyzed by immunofluorescence, expression level and sequencing. Results: Three patients died at the age of 5, 7 and 43 due to biliary cirrhosis. Three patients developed elevated liver parameters and histologic fibrosis/cirrhosis during adulthood. These six were considered strongly affected. Five others had normal liver values but pruritus during pregnancy or very subtle histological changes. These were considered mildly affected. None of the above were considered healthy. Extensive pedigree studies revealed distant consanguinity. Under the autosomal-recessive model taking into account the relationship, a maximal LOD-score of 3.88 could be obtained on chromosome 7q21.1-7q22. Detailed characterization of the 149 genes at the locus revealed that homozygosity for the single variant Arg788Trp (c.2364c>t) in the ABCB4 gene co-segregated with severity of liver disease, whereas heterozygosity was found in all mildly affected patients. The variant is located in a transmembrane domain of the ABCB4 protein which is involved in phospholipid-export into the bile. Expression level and localization were normal compared to controls. The overall histological changes were unspecific showing ductopenia and subtle periductal fibrosis in some samples. Conclusion: Both, linkage analysis and sequencing led to the recognition of one single genetic defect of the ABCB4 gene as the cause for the variety of cholestatic liver disease from intrahepatic cholestasis of pregnancy to fibrosis, and cirrhosis and death in childhood and adulthood.

IDENTIFYING LEARNING NEEDS OF ADULT LIVER TRANSPLANT RECIPIENTS

Jaime Myers1,3, Teresa A. Pellino2, Michael Armbrust1; 1Transplant, UW Hospital & Clinics, Madison, WI; 2Nursing, University of Wisconsin Hospital & Clinics, Madison, WI; 3University of Wisconsin School of Nursing, Madison, WI

Purpose: The purpose of this study was to determine how informed patients felt after liver transplant in terms of various aspects of follow-up care and to identify factors that influence knowledge deficits. Methods: A survey was sent to 129 patients who received a liver transplant in 2005 and 2006. It consisted of 102 questions and included a modified version of the Patient Learning Needs Scale (PLNS), which was used to measure patients' perceptions of how informed they felt about managing their health care after transplant. This scale consisted of multiple items divided into four categories: (1) Medications; (2) Health Problems; (3) Follow Up; and (4) Quality of Life / Psychosocial Issues. Patients rated how informed they felt about items in each category. Other survey questions addressed factors likely to impact perceptions of learning. Results: Sixty-eight (53%) surveys were returned. The majority of respondents indicated not having an accurate idea about life after transplant. PLNS items relating to quality of life and psychosocial issues scored significantly lower (indicating patients felt less informed) when compared to the three other categories (p < .001). Also, items relating to health problems, particularly those that dealt with symptom management, scored lower when compared to medications (p = .008) and follow-up categories (p = .048). Factors that may have influenced PLNS scores were analyzed by t-test or one-way ANOVA. Seven patients had a previous transplant, but showed no difference in learning outcomes. Time on the waiting list and length of stay did not have a significant impact. Scores did show a trend towards greater levels of knowledge reported in patients who waited 13 to 24 months and toward more informational needs in patients who were hospitalized for longer periods of time. Factors having the greatest impact on information deficits included pain, fatigue, feeling overwhelmed, and side effects of medications while hospitalized. Time away from the transplant unit, inability to attend inpatient classes, and absence of a support person were identified as additional obstacles in patients with longer lengths of stay. Conclusions: Patients felt inadequately informed about psychosocial and quality of life issues after liver transplant. Overall, patients felt informed about medications and follow-up cares required
after liver transplant, but felt less informed in terms of management of the symptoms and health problems they may have. We are currently developing innovative patient education methods, including a DVD and online tutorial, to address these concerns.

727
RESULTS OF A UNIQUE HEPATITIS C OUTREACH PROGRAM IN PROVIDING SCREENING, EDUCATION, AND REFERRAL IN A MIDWEST STATE

Suzanne Opperman1, Bruce Burkett1; 1Sc/GI, Veterans Administration, Columbia, MO; 2Missouri Hepatitis C Alliance, RAIN of Mid Missouri, Columbia, MO

Introduction: Hepatitis C virus (HCV) has been found to be an unrecognized viral infection in many individuals who may be at risk. However, education and screening of the general public by federal or state health agencies is not mandated or funded. The Missouri Hepatitis C Alliance (MOHCA) is a non-profit, primarily volunteer organization. MOHCA was started in 1998 to provide support for those diagnosed and undergoing treatment for HCV. MOHCA provided public educational presentations, local awareness advertising, newspaper articles, support/education group announcements, fund raising events, radio interviews, television talk shows. MOHCA also worked with 44 different County Health Departments and Clinics. MOHCA provided public educational presentations, local awareness advertising, newspaper articles, support/education group announcements, fund raising events, radio interviews, television talk shows. MOHCA also worked with 44 different County Health Departments and Clinics. Aim: The purpose of this retrospective study was to evaluate and report the number of individuals who have received education and screening by MOHCA through various efforts. It was presumed by bringing this service to the public higher rate of HCV virus exposure would be found than has been previously reported by health agencies. Methods: The MOHCA database was searched from January 2005 through May 2007 to identify HCV positive individuals. HCV antibody screenings were done using the IgM Elisa-3 and 2005 individuals were tested in Mid-Missouri. Results: During the period from Jan 2005 through May 2007 MOHCA provided education to 1846 individuals, businesses, and various settings. The eight various monthly support/education groups had a total of 704 in attendance. Of those tested, 593 (29.6%) were found to be HCV antibody positive. When Positive amplification was done by PCR, 84 (4.2%) were found not to be viremic (PCR < 5 IU/ml). Of those tested 1062 (53%) were male and 942 (47%) were female. However, HCV antibody positivity was found to be lower in both males 261 (13%) than females 332 (21.8%) of those tested. Conclusion: In rural Mid-Missouri when education and screening are offered to those at risk, screening finds more individuals who are HCV antibody positive. The time and effort of this organization is an example of how those who are potentially at risk can be sought out through educational and support efforts, resulting in higher rates of previously reported infection rates through general screening methods used.

HEALTH-RELATED QUALITY OF LIFE IN PATIENTS WITH CHRONIC LIVER DISEASE WITH OR WITHOUT HEPATOCELLULAR CARCINOMA (HCC) AWAITING ORTHOPHIC LIVER TRANSPLANTATION (OLT)

Teresa Casanovas1, Laia Jane1, Michael Herdman2, Alfonso Casado3, Joan Fabregat1; 1Unit of Liver Transplantation, Hospital Universitari Bellvitge, L'Hospitalet de Llobregat, Spain; 23D-HealthResearch, Barcelona, Spain; 3Dynamicsolutions, Madrid, Spain

Background: There have been relatively few studies of health-related quality of life (HRQOL) in patients with HCC (hepato-cellular carcinoma) awaiting an OLT. These patients are usually asymptomatic and the tumours have been found in routine follow-up. Objective: To compare the HRQOL of patients with HCC who are candidates for OLT with that of patients with other indications for OLT and without HCC. Methods: Observational study performed in the Liver Transplant Unit of the University Hospital of Bellvitge, Spain (May 2002- June 2006). Patients included were candidates for OLT with or without HCC. HRQOL was measured using the disease-specific Liver Disease Quality of Life (LDQOL) questionnaire. Three groups were compared: patients with HCC, patients with cirrhosis (CH) and VHC but no HCC, and patients with CH due to alcohol (CH ENOL), but no HCC. Sex, age, HCV, HBV, Child A, B, C, and MELD scores were also recorded. Results: A total of 157 patients were included for analysis (68 patients with HCC, 46 patients with CH ENOL, and 43 patients with CH VHC). Mean age (SD) of the overall sample was 52.6 (9.8) years and 73% were male. Distribution by age and sex was similar in the three groups studied. Patients with HCC had statistically significant higher scores (better HRQOL) on eight of the twelve disease-specific scales of the LDQOL than the group with CH and VHC, including symptoms of liver disease (p=0.000), effects of liver disease (p=0.000), concentration (p=0.002), memory (p=0.015), quality of social interaction (p=0.030), sleep (p=0.000), loneliness (p=0.043) and stigma (p=0.028). Statistically significant differences were found between HCC patients and patients with alcoholic cirrhosis on only two dimensions, symptoms of liver disease (p=0.014) and effects of liver disease (p=0.035). Conclusions: Patients with HCC who are candidates for OLT had better scores on several of the disease-specific scales of the LDQOL compared with candidates without tumours. This may have important consequences for measuring change over time and for between group comparisons where case mix varies between groups.

POST TRANSPLANT TREATMENT OF HEPATITIS C: IS THERE AN IDEAL MONITORING PARAMETER?

Victoria Zacharias, Nyingi Kemmer, Kamran Safdar, Ryan Neff, Grace Bell, Nicole Majoras, Tiffany E. Kaiser, Guy W. Neff, University of Cincinnati, Cincinnati, OH

Background: The treatment of recurrent Hepatitis C (HCV) in the post transplant population has advanced with the use of pegylated interferons and ribavirin. The successes have been fraught with viral recurrence following the cessation of therapy. In the past, presence of HCV by liver tissue polymerase chain reaction (PCR) has been evaluated as a predictor of virologic relapse post therapy. With the introduction of the super sensitive transcription-mediated amplification (TMA) testing, results to <5 IU/ml, into clinical practice, the utility of tissue PCR in our treat-
ment algorithm is unknown. The aim of this study was to evaluate the need for tissue PCR in the present setting of super sensitive serum PCR testing. Methods: This retrospective study was conducted for patients transplanted and subsequently treated for HCV. Data collected included demographics, time from transplant, viral load at start of treatment, genotype, tissue PCR analysis by the National Genetics Institute, Los Angeles, CA, length of treatment, and 6 month post treatment viral load. Results: Fourteen patients met inclusion criteria. They were all male, with a mean age of 51.8 (range 43-60 years) and ethnicity including Caucasian (n=12), African American (n=1), and Asian (n=1). Average time from liver transplant to treatment was 30 months (range 3-92 months). Viral load average at start of treatment was 3,920,000IU/ml (range 400,000 - 11,600,000IU/ml) and there was a predominance of Genotype 1 (86%). The end of treatment serum PCR and liver tissue quantitative assay were negative (<1 copy/μl) in all patients and six month post treatment for serum PCR using TMA was negative in 13(93%). Conclusion: The above results indicate that successful termination in the treatment of recurrent HCV can be monitored using only serum TMA. In comparison to previous work using PCR values with higher limit of detection numbers, these results suggest that TMA serum PCR sensitivity is currently high enough to obviate the need for tissue PCR testing. These findings will impact the treatment algorithm for the post transplant recurrent HCV patient by allowing for the development of standard of care treatment timeline and testing parameters.

TITLE: MULTIDISCIPLINARY COLLABORATION IMPROVES HEPATITIS C MANAGEMENT AND CARE FOR HIGH-RISK PATIENTS IN A METHADONE MAINTENANCE CLINIC

Marian Kerbleski, Alexander Monto, Sue Currie, Patricia Lane, David Kan; GI, Department of Veterans Affairs Medical Center, San Francisco, San Francisco, CA

Background: Patients accessing care through the ORT (Opiate Replacement Therapy) are at high risk for chronic blood borne illnesses. Frequently veterans in the ORT clinic and other substance abuse programs have missed appointments to assess their hepatitis and other liver-related risks, obtain education/counseling, vaccinations, and follow-up care. In order to improve access to care, and improve compliance; formal communication was initiated between the liver and substance abuse/mental health teams. Aim: To describe the interdisciplinary collaborations and outcomes of a liver well-being initiative in a methadone clinic. Results: Over 105 patients accessed the ORT clinic at the San Francisco Veterans Administration for methadone in 2006. Prior to program implementation in 2006, 60% are HCV antibody positive and 75% of these patients did not return for follow-up care (including labs, vaccinations for hepatitis A and B, and appointments with a provider for ‘liver’ evaluation). However, 10 months after the program was initiated the following was completed: a formal joint team meeting and protocol established between clinic chiefs/nurses, a protocol was established for HAV and HBV vaccinations, staff (100%) within the ORT clinic have become familiar with HAV/HBV/HCV screening, a survey to all patients to assess their needs (90% participation), and space was dedicated to liver and non-ORT care. To date, all patients have received HCV education and counseling, 80% have received the flu vaccine, and all (100%) ORT patients now have a primary medical provider. As well, two patients have agreed to and successfully initiated HCV treatment through weekly on-site injections at the ORT clinic site. Conclusion: Collaboration between the ORT and liver nurses is critical in providing optimal care to veterans infected or at risk for hepatitis C. Interdisciplinary collaboration can result in improved liver health and treatment opportunities for methadone patients. Program participant feedback, including responses from a HCV Awareness Day, patient surveys and other providers suggest that this may be a model for other liver and other health services to improve HCV management and care in high risk patients.

IMPROVEMENT OF QUALITY AND EFFICIENCY IN HEPATOLOGY CLINIC AT A VA MEDICAL CENTER

Christine Pocha; Stratton VAMC, Albany, NY

1. Background: The high prevalence of chronic hepatitis C (HCV) among veterans has a significant impact on current and future health care resources. Unpredicted shortage of providers led to a mismatch between available clinic slots and number of requested consultation. 2. Method: Retrospective data abstraction from work load reports between 2004 and 2006 was performed. Several interventions were initiated in 2004 and 2005. a) Establishing of a dedicated HCV care team (physician, nurse practitioner, nurse, pharmacist) b) Optimizing the scheduling process to reduce no-show rates and clinic down time c) Streamline the visit with delegating non-physician work d) Implementation of pre-set order menus for blood work and medication e) Introduction of a HCV group class for new patients 3. Result: MD and NP provided Hepatology service for 44 weeks each in 2004, and for 44 and 20 weeks in 2006, respectively. In 2004 and 2006, the number of available appointment slots were 880 and 735 with 677 and 700 slots used, respectively leading to an increase in used clinic capacity from 77% to 95%. The total number of visits increased by 121. On average, 7.7 patients per week were seen in clinic in 2004 and 17.4 patients in 2006 demonstrating an increase in efficiency by a factor of 2.25. Forty-four more patients can be seen in clinic in 2005. a) Establishing of a dedicated HCV care team (physician, nurse practitioner, nurse, pharmacist) b) Optimizing the scheduling process to reduce no-show rates and clinic down time c) Streamline the visit with delegating non-physician work d) Implementation of pre-set order menus for blood work and medication e) Introduction of a HCV group class for new patients 4. Conclusion: Clinic management and patient care in Hepatology clinic at our VA medical center could be improved with simple but effective measures, considerably leading to an increase of scheduled appointments, patient visits, and reduction of no-show rate. A dedicated team combined with a trusting patient/provider-relationship is the keystone for continuity of care in patients with chronic diseases. The HCV group class ensured a standardized education for new patients. This project may be applied to other specialty clinics to improve clinic management and patient care.

732 SURVIVAL OUTCOMES IN LIVER TRANSPLANT RECIPIENTS SUFFERING FROM NON-ALCOHOLIC STEATOHEPATITIS

Grace Bell, George Tannous, Victoria Zacharias, Nyenig Kemmer, Muslim Atiq, Kamran Safdar, Nadia Malik, Beverley Borjas, Tiffany E. Kaiser, Guy W. Neff; University of Cincinnati, Cincinnati, OH

Background: Recent reports from the Center for Disease Control suggest that the obesity trends in the United States will continue to worsen in the coming decades. As a result, liver transplant centers can expect a higher number of non-alcoholic steatohepatitis (NASH) patients to present for liver transplantation (LTx). Information pertaining to NASH recidivism is available but long-term survival and lifestyle change data is limited. The aim of this study is to explore long-term outcomes and recidivism in LTx recipients suffering from NASH. Methods: A retrospective review of LTx patients with NASH from the pre-transplant evaluation up to five years posttransplant was completed. All patients underwent transplantation between 1997 and 2006, inclusive. Data collected included demographics, morbidity issues, presence of coronary artery disease (CAD), presence of diabetes mellitus, serum hemoglobin A1C values, body mass index (BMI), lifestyle changes, and survival information. Nutritional consultation by a registered dietitian was available to all pre and post liver transplant patients. Kaplan Meier survival analysis was employed. Results: Twenty-eight patients with NASH received LTx during the study period. There were 15 female (54%) and 13 male (46%) with 27 Caucasians and 1 African American. Mean age was 57.6 (range 44 to 76 years of age). All patients had diabetes mellitus. The mean BMI was 32.3 (range 25.8 to 43.9). Post-LTx, there was no significant change in BMI (32.3 vs 32.8) or mean Hgb A1C (7.1% vs 5.7%) (p>0.5). The one year survival was 77% and the three year survival was also 77%. There were no predictors for graft or patient survival. Conclusion: This cohort of NASH related patient demonstrates a poor short- and long-term survival, hampered ability to lose BMI points following liver transplantation. In light of the recent CDC data demonstrating a marked increase in obesity for our nation, the above patient cohort reveals a health care concern for liver transplant patients in terms of long-term survival and multiple post-transplant morbidities.

733 OCTREOTIDE BOLUS INJECTION AND AZYGOS BLOOD FLOW (AZBF) IN PATIENTS WITH CIRRHOSIS: SUSTAINED DECLINE AND VISIBLE EFFECT AT READMINISTRATION

Laurent Spahr1, Emiliano Giostra1, Gilles Menthia2, Antoine Hadengue1; 1Transplantation Unit, University Hospital of Geneva, Geneva, Switzerland; 2Gastroenterology, University Hospital of Geneva, Geneva, Switzerland

Octreotide (OCT) improves the initial control of variceal bleeding, but hemodynamic changes are usually transient and attributable to the effect of bolus administration. Whether a repeat bolus infusion may induce hemodynamic changes in the collateral is not fully elucidated. Aim: To study the acute effects of octreotide on AzBF in patients with cirrhosis and portal hypertension, following, 1) a 50 mcg bolus infusion, and 2) a repeat 50 mcg bolus after 60 minutes. Patients and Methods: We performed invasive measurements of AzBF (azygous vein cannulation and continuous thermal dilution technique) in 12 consecutive patients at baseline and at 10 minutes interval following a 50 mcg OCT bolus infusion, for a total of 60 minutes. Then, a 50 mcg OCT bolus was readministered and AzBF measured for another 20 minutes. Patients (mean age 51.4 yrs [30-69]) had biopsy-proven cirrhosis (alcoholic in 9 patients; Pugh’s score 8.8 + 0.3) and clinically significant portal hypertension (HVPG 19 + 1 mmHg). Four patients were on beta-blockers. Cardiac output was 6.7 + 0.4 L/min, and mean arterial pressure (MAP) was 84 + 1.8 mmHg. Results: (expressed as mean + SEM). Protocol 1: Mean AzBF value at baseline was 660 + 138 ml/min. The 50 mcg OCT bolus was followed at 10 minutes by a 34% decrease in AzBF as compared to baseline value. This AzBF decline was maintained over the 60-minute study period (36% + 1.4%). All values were statistically significant from baseline AzBF measurement (p<0.01). MAP values remained stable. Protocol 2: At 60 minutes, the repeat 50 mcg bolus infusion caused a further significant (p<0.01) decline in AzBF, although the response was blunted (-18% + 1.2%). Conclusion: in patients with cirrhosis and portal hypertension, the hemodynamic effect of a 50 mcg OCT bolus on mean AzBF is sustained and amenable to a further (but blunted) response at readministration. These findings suggest the clinical benefit of OCT is mostly related to OCT given as a bolus.

734 SLEEP-WAKE ABNORMALITIES DO NOT CORRELATE WITH NEUROPSYCHIATRIC PERFORMANCE IN PATIENTS WITH CIRRHOSIS

Sara Montagnese1, Benita Middleton2, Debra J. Skene2, Marsha Y. Morgan1; 1Centre for Hepatology, Royal Free and UCL Medical School, London, United Kingdom; 2School of Biomedical and Molecular Sciences, University of Surrey, Guildford, United Kingdom

Sleep-wake inversion is a feature of overt hepatic encephalopathy (HE; Sherlock et al, 1954); while milder sleep disturbances are common in patients with cirrhosis, even in the absence of significant neuropsychiatric impairment (Córdoba et al, 1998). The aim of this study was to determine the relationship between sleep-wake abnormalities and the presence and the degree of HE in patients with cirrhosis. Ninety-three patients with biopsy-proven cirrhosis (56 males, Child A 62, B 20, C 11; mean age 57 yrs, range [34-80]), classified as neuropsychatically unimpaired (n=61) or as having minimal (n=12) or overt HE (n=20) using clinical (Conn et al, 1977), psychometric (Weissenborn et al, 2001) and EEG (Amadio et al, 1999) criteria, underwent evaluation of their sleep-wake patterns. A structured interview (subjective sleep evaluation - SSE) and a set of validated questionnaires were used to assess diurnal preference (Horne & Östberg, 1976), night sleep quality (Pittsburgh Sleep Quality Index - PSQI; Buysse et al, 1989) and day-time sleepiness (Epworth Sleepiness Scale - ESS; Johns et al, 1991). Twenty-six healthy volunteers (16 males, 47 [21-84] yrs) served as controls. Differences in sleep-wake indices between groups were examined by one-way ANOVA/ANCOVA (age adjustment); post-hoc analysis was performed using the Scheffé test; values are expressed as weighted averages. Categorized indices (normal/abnormal) were compared by the Pearson $\chi^2$. Patients
with cirrhosis slept significantly less well than healthy volunteers both subjectively (SSE: 1.87 vs. 1.35, p = 0.004) and objectively (PSQI: 8.39 vs. 4.22, p = 0.0001; PSQI abnormal 66% vs. 24%, χ2 = 13.7, p = 0.0002) and had more pronounced day-time sleepiness (ESS: 7.2 vs. 4.9, p = 0.069; ESS abnormal 32% vs. 0%, χ2 = 6.2, p = 0.012); a significantly higher number of awakenings (2.2 vs. 1.0, p = 0.001) and a longer time-to-fall-asleep (32 vs. 12 min, p = 0.043); there were no differences in diurnal preference, mean bed-time and mean wake-up time. There was no significant relationship between the presence or degree of HE and any of the sleep-wake indices. Similarly there was no relationship between the degree of hepatic dysfunction and sleep-wake variables, apart from the fact that patients with decompensated cirrhosis had more pronounced day-time sleepiness (p = 0.03). These results confirm the high prevalence and the severity of sleep-wake disturbances in patients with cirrhosis, which are independent of the presence and degree of HE. This sheds doubt on the appropriateness of including sleep parameters in scales for the diagnosis and grading of HE (Ferenci et al, 2001; Hourmand-Ollivier, 2006; Spahr et al, 2007).

735 MIDODRINE VERSUS ALBUMIN IN THE PREVENTION OF PARACENTESIS – INDUCED CIRCULATORY DYSFUNCTION IN CIRRHOTICS: A RANDOMIZED PILOT STUDY

Virendra Singh1, Prashant C. Dheerendra2, Baljinder Singh3, Chander K. Nain4, Divya Chawla5, Navneet Sharma6, Ashish Bhalla7, Sushil K. Mahi8, 1Hepatology, Postgraduate Institute of Medical Education and Research, Chandigarh, India; 2Internal Medicine, Postgraduate Institute of Medical Education and Research, Chandigarh, India; 3Hepatology, Postgraduate Institute of Medical Education and Research, Chandigarh, India; 4Nuclear Medicine, Postgraduate Institute of Medical Education and Research, Chandigarh, India; 5Gastroenterology, Postgraduate Institute of Medical Education and Research, Chandigarh, India; 6Radiology, Hôpital Beaujon, Clichy, France; 7Hematology and Hemostasis, Université Libre de Bruxelles, Brussels, Belgium; 8Endocrinology, Hôpital Beaujon, Clichy, France.

Intraavenous albumin has been used to combat paracentesis – induced circulatory dysfunction (PICD) in patients with cirrhosis with tense ascites. However, the use of albumin is costly and controversial. Splanchnic arterial vasodilatation is primarily responsible for circulatory dysfunction in these patients. Vasodilator therapy has been used to prevent PICD in cirrhotics. However, there are various problems with their use. There are no reports of use of midodrine, an oral α-adrenergic agonist, on the prevention of PICD in cirrhotics. In this randomized pilot study, we evaluated the effects of midodrine and albumin in the prevention of PICD in cirrhotics with tense ascites. Forty patients with cirrhosis and tense ascites underwent therapeutic paracentesis with midodrine or albumin in a randomized controlled trial at a tertiary centre. Effective arterial blood volume was assessed by measuring plasma renin activity at baseline and 6 days after paracentesis. Effective arterial blood volume as assessed by plasma renin activity before and 6 days after paracentesis did not differ in two groups (43.18 ± 10.73 to 45.90 ± 8.59 ng/ml/hr; p = 0.273 in the albumin group and 44.44 ± 8.44 to 41.39 ± 10.21 ng/ml/hr; p = 0.115 in the midodrine group). A significant increase in 24 hours urine volume and urine sodium excretion was also noted in midodrine group (p < 0.01 and p < 0.001, respectively). The cost of midodrine therapy was significantly lower when compared with that of albumin (p < 0.001). Conclusion: Midodrine is as effective as albumin in preventing PICD in cirrhotics, but at a fraction of the cost. Midodrine also resulted in increase in 24 hours urine volume and sodium excretion.

736 MATERNAL AND FETAL OUTCOME IN 27 WOMEN WITH BUDD-CHIARI SYNDROME (BCS) AND 41 PREGNANCIES

Pierre-Emmanuel Rautou1, Bernhard Angermayr2, Sebastian Raffa3, Markus Peck-Radosavljevic2, Juan Carlos Garcia-Pagan2, Ramzi Moucan1, Audrey Imbert1, Violaine Ozenne1, Jacques Bernau1, Annie Sibert1, Bertrand Condat1, Dominique Cazals-Hatem2, Michel Levardon6, Karine Yvert1, Marie-Hélène Denninger2, Dominique Valla1, Aurelie Plassier1, 1Hepatology, Hôpital Beaujon, Clichy, France; 2Gastroenterology and Hepatology, Medizinische Universität & AKH Wien, Vienna, Austria; 3Hepatic Hemodynamic Laboratory, Liver Unit, Hospital Clinic, University of Barcelona, Barcelona, Spain; 4Radiology, Hôpital Beaujon, Clichy, France; 5Pathology, Hôpital Beaujon, Clichy, France; 6Gynecology, Hôpital Beaujon, Clichy, France; 7Hematology and Hemostasis, Hôpital Beaujon, Clichy, France.

Although BCS mainly affects young women, data on BCS and pregnancy are sparse. Prognosis, when revealed by pregnancy, seems poor (1-year survival <50%). Pregnancy is often contraindicated in women with BCS. AIMS: (1) to assess characteristics and outcome of BCS revealed by pregnancy; (2) to determine if pregnancy should be contraindicated in women with known BCS. PATIENTS AND METHODS: Maternal and fetal features were assessed in 2 groups: Group 1, 7 patients who had BCS revealed by pregnancy; Group 2, a multicenter cohort of 20 women with BCS who became pregnant during follow-up; Compared with Group 3: 37 women with BCS without pregnancy at diagnosis or during follow-up. RESULTS: (1) In Group 1 (mean age 31 ± 5 yrs), diagnosis of BCS occurred in 3 patients during pregnancy and in 4 during postpartum. There were 3 miscarriages, 1 early preterm delivery and 3 healthy newborns (2 preeclampsia). Within 2 months of delivery, 2 underwent TIPS and 1 emergency liver transplantation (LT). All patients were alive at 38 ± 6 months. (2) In Group 2, 20 patients (mean age 29 ± 7 yrs), all asymptomatic for at least 1 year, had 34 pregnancies within 73 ± 56 months after BCS diagnosis. Anticoagulation was used in 24 pregnancies, antiplatelet therapy in 4: 14 decompressive therapies were performed in 10 patients (angioplasties in 4, TIPS in 2, surgical shunt in 6, and LT in 2) 59 ± 40 months before pregnancy. Child-Pugh score was lower (6.6 ± 1.7 vs 8 ± 1.9, p = 0.03) in group 2 vs 3. Until 20 weeks’ gestation, 15/34 abortions or miscarriages occurred. The 19 other deliveries occurred before 32 weeks in 2 patients, between 32-36 weeks in 10 and after 37 weeks in 6. There was 1 intrauterine fetal death, but 18 infants had a favorable outcome. Obstetrical complications included intrauterine haematoma (n=3), preeclampsia (n=1) and placententa praevia (n=1). Absence of venous collaterals (7/8 vs 3/9; p = 0.05) and presence of factor II mutation (9/15 vs 3/9; p = 0.05) were significantly associated with poor outcome pregnancies. No patient had died 41 ± 38 months after last delivery. Ascites occurred in 2 patients: 1 had portal vein thrombosis with heparin-induced thrombocytopenia and 1, without anticoagulation, had TIPS obstruction. CONCLUSION: (1) 15% of BCS in women are revealed by pregnancy. Maternal outcome is excellent using current therapies, but infant’s prognosis is severely impaired. (2) When pregnancies occur in women with known BCS, half give birth to healthy infants. In presence of factor II mutation, and when venous collaterals...
are not identified, pregnancies seem particularly at risk. Anticoagulation should be maintained. Liver dysfunction is rare and due to new thrombosis.

737 PROGNOSTIC FACTORS FOR HEPATORENAL SYNDROME (HRS) REVERSAL IN PATIENTS WITH TYPE 1 HRS ENROLLED IN A RANDOMIZED, DOUBLE-BLIND, PLACEBO-CONTROLLED TRIAL

Arun J. Sanyal1, Thomas D. Boyer2, Peter Teuber3; 1Internal Medicine, University of Arizona, Tucson, AZ; 2Orphan Therapeutics LLC, Lebanon, NJ

Background: Type 1 HRS is characterized by rapid onset of functional renal failure (i.e., doubling of serum creatinine (Scr) within 2 weeks in cirrhotic patients, and is associated with a poor prognosis (median survival of 2-4 weeks). Preliminary results from 2 recently reported randomized, placebo controlled clinical trials have demonstrated that terlipressin + albumin has superior HRS reversal rates compared to albumin alone. Objective: To identify factors predictive of outcome in patients with Type 1 HRS. Methods: This analysis investigated the following 8 baseline patient characteristics collected from 112 Type 1 HRS patients enrolled in the randomized, double-blind, placebo-controlled HRS trial known as OT-0412: treatment (terlipressin, placebo), age (>65, ≤65 years), gender (male, female), race (non-White, White), alcoholic hepatitis (absent, present), MELD score (per 1 point increase), Child-Pugh score, and Scr concentration. Wald Chi-Square tests from individual logistic regressions were conducted to determine those baseline patient characteristics that are predictive of HRS Reversal. An individual log-binomial regression model was used to assess probability of HRS Reversal. Results: Baseline Scr concentration (p = 0.010), baseline MELD score (p = 0.024) and treatment with terlipressin (p = 0.009) were found to be significant predictors of HRS Reversal for the ITT population; with lower baseline Scr levels, lower baseline MELD scores and initiation of terlipressin therapy being more predictive of HRS Reversal. The probability for HRS Reversal decreases by 39% and 5.5%, respectively, for each 1 mg/dL increase in Scr or 1 point increase in MELD score; while the probability for HRS Reversal improves by 271% with terlipressin treatment. Finally, further analysis showed that only patients with baseline Scr < 5.6 mg/dL and receiving ≥ 3 days therapy achieved HRS Reversal. Summary: Less severe disease (i.e., lower Scr and MELD scores) in Type 1 HRS patients provides the best chance for HRS reversal. Additionally, treatment with terlipressin + albumin provides significantly improved chance for HRS reversal compared to albumin alone. However, patients appear to need ≥ 3 days therapy in order for HRS therapy to be effective. Conclusion: These data suggest that there may be a benefit in earlier HRS diagnosis and initiation of terlipressin + albumin treatment in order to maximize the chance for HRS Reversal.

738 PAROXYSMAL NOCTURNAL HEMOGLOBINURIA IN BUDD-CHIARI SYNDROME – RESULTS OF THE EN-VIE STUDY

Jildou Hoekstra1, Sarwa Darwish Murad2, Aurelie Plessier2, Manuel Hernandez-Guerra2, Dominique Valla2, Juan Carlos Garcia-Pagan3, Elwyn Elias4, Massimo Primignani5, Frank W. Leebeek6; 1Department of Gastroenterology and Hepatology, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands; 2Department of Hepatology, Hôpital Beaujon, Clichy, France; 3Liver Unit, Hospital Clinic, Barcelona, Spain; 4Liver Unit, Queen Elizabeth University Hospital, Birmingham, United Kingdom; 5Department of Hepatogastroenterology, IRCSS Ospedale Maggiore di Milano, Milan, Italy; 6Department of Hematology, Erasmus Medical Center, Rotterdam, Netherlands

Background and aims. Approximately 5-10% of cases of Budd-Chiari Syndrome (BCS) is caused by paroxysmal nocturnal hemoglobinuria (PNH). PNH is an acquired disorder of hematopoietic stem cells, characterized by intravascular hemolysis and venous thrombosis. We have studied the relationship between BCS and PNH with respect to clinical characteristics, treatment outcome and prognosis. Methods. Data on baseline characteristics, treatment and survival was obtained from the EN-Vie Study, a prospective international multi-center cohort study of 163 patients with BCS. Study guidelines recommended testing for PNH by flow cytometry or Ham’s test and this was done in 77 patients. Results. From the group of 77 patients tested for PNH, 15 tests were positive (19%). These 15 patients with PNH were compared to the group of BCS-patients without PNH (n=62). Median follow-up for the total tested group was 19 months (range 0-31 months). Of the 15 patients with BCS and PNH, 10 had already been diagnosed with PNH at an earlier time but only 2 of these patients were on anticoagulant treatment when the diagnosis of BCS was made, both because of previous thrombosis elsewhere. When comparing the PNH-patients to the group of non-PNH-patients, sex ratio, age at diagnosis of BCS, clinical presentation and liver function tests did not differ significantly between the groups. Comparison of radiological data however, revealed that BCS-patients with underlying PNH presented with a significantly higher percentage of additional splanchnic vein thrombosis (SVT; i.e. portal vein, mesenteric vein or splenic vein thrombosis) (47% vs. 10%, p=0.002) at diagnosis. Despite the higher frequency of SVT in the PNH-group, the number of patients treated with Transjugular Intrahepatic Portosystemic Shunt (TIPS) during follow-up was similar between both groups (6/15 in PNH group vs. 22/62 in non-PNH-group). Of the 15 PNH-patients, 4 successfully underwent bone marrow or stem cell transplantation after the diagnosis of BCS. There was no significant difference in survival between patients with and without PNH. Conclusions. The EN-Vie Study shows that PNH appears to be a more frequent cause of BCS than previously thought. Despite the high risk of (fatal) thrombosis in PNH, none of the patients known to have PNH before diagnosis of BCS had anticoagulant treatment as primary prophylaxis. Our data shows that, despite a higher frequency of additional SVT, short-term prognosis of patients with BCS caused by PNH does not differ from BCS-patients without PNH. Bone marrow/stem cell transplantation and TIPS appear to be safe treatment options for patients with PNH and BCS.

UROTENSIN II INCREASES PORTAL PRESSURE AND INDUCES HEPATIC FIBROSIS

William Kemp,1,2 Henry Krum2, Andrew Kompa2, Jia Zhiyuan3, Peter W. Angus1, Stuart K. Roberts1; 1Gastroenterology, Alfred Hospital, Melbourne, VIC, Australia; 2Epidemiology and Preventive Medicine, Monash university, Melbourne, VIC, Australia; 3Medicine, Melbourne University, Melbourne, VIC, Australia

BACKGROUND: Serum urotensin II (UII), a potent vasoactive mediator, is upregulated in chronic liver disease and correlates with the degree of portal hypertension. However, the relevance of these findings in the pathogenesis of cirrhotic portal hypertension is unknown. AIM: To determine whether UII executes a pathogenetic role in the development of chronic liver disease and portal hypertension. METHODS: UII was administered by continuous infusion over 4 weeks using osmotic mini pumps in 20 Sprague-Dawley rats divided into three treatment groups: Controls (saline, n=7), low dose UII (1 nmol/kg/hr, n=8) and high dose UII (3 nmol/kg/hr, n=5). Systemic and portal haemodynamics were assessed and tissues harvested for RT-PCR analysis of transcripts of profibrotic markers, and morphometric quantification of fibrosis. RESULTS: Infusion of UII induced a significant dose-dependent increase in portal venous pressure (5.8 ± 0.4, 6.4 ± 0.3 and 7.6 ± 0.7 respectively, p = 0.03) and splenic weights (p < 0.01). Concurrently, high dose UII infusion was associated with an increase in hepatic transcript for TGF-β (p < 0.05) while collagen 1 transcript expression was increased (p < 0.05) following the low dose infusion. Liver tissue hydroxyproline content was elevated in rats receiving high dose UII infusion (p < 0.05). By computer morphometric analysis there was a dose response relationship between UII and portal tract fibrosis (p < 0.05). No systemic haemodynamic alterations were noted. CONCLUSION: Sustained infusion of UII over 4 weeks in rats is associated with an elevation in portal venous pressure and induction of hepatic fibrosis as evidenced by an elevation in hepatic hydroxyproline content and increased portal tract fibrosis. This response may be mediated in part via an induction of TGF-β. These findings have pathophysiological implications in human liver disease where increased UII levels have been observed.

PROTON PUMP INHIBITOR USE IS ASSOCIATED WITH A HIGH RISK OF SPONTANEOUS BACTERIAL PERITONITIS

Jasmohan S. Bajaj, Muhammad Hafeezullah, Yelena Zadvornova, Kia Saedian; Gastroenterology and Hepatology, Medical College of Wisconsin, Milwaukee, WI

Spontaneous bacterial peritonitis (SBP) is associated with a poor prognosis and predicts early mortality. It is hypothesized that bacterial translocation causes SBP. Proton pump inhibitors (PPIs) promote gastric bacterial overgrowth and have been associated with infectious complications. The aim of this study was to determine the association of PPI use with SBP occurrence in a case-control study. Methods: 985 inpatient charts of cirrhotics were reviewed for SBP (ascitic fluid WBC >500 ± bacteriologic confirmation without prior GI bleed). PPI use was defined as outpatient PPI intake before SBP admission. Appropriate PPI use was defined as Gerd, Barrett’s, non-variceal GI bleed & peptic ulcer; rest were inappropriate. Charts without SBP confirmation or clear medication lists and SBP with GI bleed were excluded. Demographic information, Child (CTP) score, outpatient SBP prophylaxis and PPI use were collected. Each SBP patient was matched to 2 cirrhotics without SBP during the same time period per chart review according to age. Each SBP patient was also matched to one age and CTP-score matched non-SBP patient to evaluate the effect of PPI separately. Results: 130 patients had suspected SBP but only 44 had ascitic fluid confirmation. These 44 were matched to 88 inpatient non-SBP cirrhotics by age (Table) and 44 by age and CTP score; all non-SBP patients had been admitted for conditions other than GI bleeding or SBP. Bacteriologic confirmation (n=12) showed 7 gram positive (5 on PPI) & 5 negative (3 on PPI p=NS) bacteria. CTP score and SBP prophylaxis rate was significantly higher in the SBP group (Table). On univariate logistic regression with SBP as the outcome, only CTP score (p=0.0001 OR: 9.9 CI: 3.4-28.8) and PPI use (p=0.0001 OR: 7.8 CI: 3.4-18) were significant. This significant association with SBP continued on multivariate logistic regression; CTP (p=0.0001, OR: 9.3 CI: 4.3-30) and PPI (p=0.0001, OR: 6.4, CI: 2.5-16). When only CTP C SBP and non-SBP cirrhotics were studied, PPI use was still significantly associated with SBP (p=0.0001 OR: 5.7 CI: 2.1-15). Conclusion: PPI therapy and as expected, high CTP scores are independently associated with SBP despite a higher antibiotic prophylaxis rate in SBP patients.

PREDICTORS OF INTERMEDIATE-TERM RISK IN CIRRHOSIS: IMPLICATIONS FOR MINIMAL LISTING CRITERIA IN LIVER TRANSPLANTATION (LT)

Douglas M. Heuman1,2, HoChong Gilles1, Lisa Pinsey1, Edith Gavis1, Adil Habib1,2; 1GI Section (111-N), McGuire VA Medical Center, Richmond, VA; 2Medicine, Virginia Commonwealth University, Richmond, VA

Background: MELD score, jaundice, coagulopathy, renal failure, hyponatremia and uncontrolled ascites identify patients in the terminal stages of cirrhosis whose short term prognosis (< 180 days) is poor, and who therefore merit “sickest first” priority for LT. However the role of these and other indicators for predicting survival or need for LT in the intermediate term (180 days to 2 years) has not been determined. Methods: We prospectively collected clinical data from 774 cirrhotic veterans referred for consideration of LT between 1/1/98 and 4/1/05; of these, 108 patients with hepatocellular carcinoma at time of referral were excluded. Outcomes (death, transplantation) through 4/1/07 were measured from date of referral and were confirmed through patient electronic records, VA central office transplant database and the social security death index. Findings: Of 666 cirrhotic patients, 174 died or were transplanted within 180 days. Of the remaining 492 patients, an additional 117 died and 98 underwent LT within 2 years (intermediate term). Compared to survivors, patients who died or underwent LT in the intermediate term were more likely to have history at referral of ascites, uncontrolled ascites, past SBP or encephalopathy, but did not differ with regard to history of variceal bleeding. Laboratory values that differed significantly
TERULIPRESSIN IMPROVES RENAL FUNCTION AND INDUCES NATRIURESIS IN PATIENTS WITH CIRRHOSIS AND ASCITES WITHOUT HEPATORENAL SYNDROME

Background & Aims: Patients with advanced cirrhosis and ascites are characterised by circulatory dysfunction with splanchnic vasodilatation and renal vasoconstriction. Treatment with the potent vasoconstrictor terlipressin has a positive effect on renal function in patients with hepatorenal syndrome (HRS), which is often the end-stage of patients with decompensated cirrhosis and ascites. In this pathophysiological study we aimed to evaluate, if the acute administration of terlipressin also improves renal function in patients with ascites without HRS. Methods: 23 cirrhotic patients participated; 15 with non-refractory ascites were randomised to either terlipressin (n=11) or placebo (n=4); 8 had refractory ascites and all received terlipressin. Glomerular filtration rate (GFR) and clearances of sodium (CNa), lithium (CLi) and osmoles (Cosm) and urine sodium concentration (UNa) were assessed before and after injection of 2 mg terlipressin/placebo. Results: In the non-refractory ascites group (n=11), terlipressin induced an increase in: GFR (68.8 ± 5.8 vs. 91.6 ± 7.4 mL/min, p<0.005), CNa (0.89 ± 0.06 vs. 1.52 ± 0.44 mM/min, p<0.05), CLi (17.3 ± 2.7 vs. 21.5 ± 3.5 mM/min, p<0.05), Cosm (2.10 ± 0.24 vs. 3.06 ± 0.60 mL/min, p<0.05) and UNa (66 ± 12 vs. 87 ± 11, p=0.005) [Mean ±SEM]. In the refractory ascites group (n=8), terlipressin induced an increase in: GFR (31.3 ± 6.7 vs. 41.1 ± 11.0 mL/min, p<0.05), CNa (0.11 ± 0.06 vs. 0.35 ± 0.14 mM/min, p<0.05), CLi (5.5 ± 1.5 vs. 9.5 ± 3.0 mM/min, p<0.05) and UNa (12 ± 6 vs. 27 ± 8, p<0.005). In both treatment groups plasma norepinephrine (p<0.05) and renin (p=0.05) decreased and proANP increased (p<0.01) after terlipressin. All parameters remained unchanged after placebo.

Conclusion: Terlipressin improves renal function and induces natriuresis in cirrhotic patients with ascites without HRS. Vasoconstrictors may represent a novel future treatment modality in these patients.

THE DEGREE OF DISTURBANCE OF RENAL BLOOD FLOW AUTOREGULATION IN CIRRHOSIS DETERMINES THE SEVERITY OF RENAL DYSFUNCTION

Vanessa Stadlbauer1, Gavin A. Wright1, Murad Banaji2, Ashis Mukhopadhyay1, Kevin P. Moore2, Rajiv Jalan1; 1The Institute of Hepatology, University College London, London, United Kingdom; 2Department of Medical Physics and Bioengineering, University College London, London, United Kingdom; 3Centre for Hepatology, Royal Free & University College Medical School, University College London, London, United Kingdom

Background and Aims: The mechanisms leading to altered renal blood flow (RBF) and renal function in hepatorenal syndrome are unclear. It has been proposed that activation of the sympathetic nervous system causes a rightward shift in the renal autoregulatory curve, such that RBF becomes critically dependent on renal perfusion pressure (RPP), which then contributes to the development of the hepatorenal syndrome. The aims of the study were to determine the relationship of RBF and RPP in patients with decompensated liver disease, and the effect on renal hemodynamics following insertion of a transjugular intrahepatic portosystemic shunt (TIPSS). Methods: Fifty-six patients were recruited into groups with 1) no ascites (n=13), 2) diuretic-responsive ascites (n=13), 3) intractable ascites (n=12), 4) type II hepatorenal syndrome (n=10) and 5) requiring a TIPSS for refractory ascites (n=8). We measured cardiac hemodynamics, RBF, RPP, portal pressure and norepinephrine levels, and mathematically modeled the renal autoregulatory curve using heuristic methods. Results: RBF correlated with RPP (r²=0.78, p<0.001) and inversely with the hepatic venous pressure gradient (r²=0.61, p<0.0001) and plasma norepinephrine levels (r²=0.78, p<0.0001). Norepinephrine increased with increasing disease severity, and this was associated with a rightward and downward shift of the RBF/RPP autoregulatory curve. (Figure 1A) TIPSS insertion reduced the hepatic venous pressure gradient and plasma norepinephrine levels (<0.001), and the RBF/RPP curve was shifted upwards. (Figure 1B) Conclusion: The relationship between RBF and RPP involves interplay between the sympathetic nervous system and the kidney. Disturbance in this relationship determines the severity of renal dysfunction in cirrhosis. An important mechanism through which TIPSS insertion improves renal function is through positive effects on RBF autoregulation.
HYponatremia: A MAJOR DETERMINANT OF IMPAIRED HEALTH-RELATED QUALITY OF LIFE IN CIRRHOSIS WITH ASCITES

Background: Patients with liver cirrhosis and ascites are prone to develop spontaneous bacterial peritonitis (SBP), leading to a substantial increase of morbidity and mortality in cirrhotic patients. SBP is commonly attributed to bacterial translocation from the intestine due to impaired mucosal barrier function (Wiest & Garcia-Tsao, Hepatology 2005;41:422-33). Recently, mutations in the NOD2 (nucleotide-binding oligomerization domain containing 2) gene have been associated with altered permeability of the intestinal wall in Crohn’s disease. Thus, we hypothesized that SBP in patients with liver cirrhosis is also associated with common NOD2 gene variants.

Patients and methods: Overall, we prospectively included 84 patients with histology proven liver cirrhosis or clinical signs of cirrhosis and ascites and monitored these patients for the development of SBP. SBP was defined as presence of PMN count > 250 cells/μL or positive bacterial culture from ascitic fluid. NOD2 gene variants (rs2066844 [R702W], rs2066845 [G908R], rs2066847 [3020insC]) were genotyped in all patients using S' exonuclease Taqman assays with fluorescent dye labeled probes. Power calculations were performed using P&S; the study was designed to detect a significantly increased OR of 5 with a power of >80%, based on risk allele frequency of 0.04. All genotype distributions are consistent with Hardy-Weinberg-equilibrium.

Results: Employing PMN count and bacterial growth in culture as diagnostic criteria, 20 patients (24%) and 12 patients (14%) were diagnosed with SBP during follow-up. Overall, the occurrence of SBP is associated significantly with carriage of the risk allele of the NOD2 G908R variant (PMN count: odds ratio (OR) = 7.63; p < 0.01). In addition, carriers of the minor allele of the NOD2 R702W variant display a higher risk for SBP indicated by bacterial growth only (OR = 7.00; P = 0.04). All NOD2 genotype distributions are consistent with Hardy-Weinberg-equilibrium.

Conclusions: Here we report a significant association of SBP with common coding variants of...
the NOD2 gene. NOD2 variants linked previously to impaired mucosal barrier function confer an increased SBP risk. We speculate that our findings, when validated in independent cohorts, serve to identify patients with cirrhotic ascites eligible for preemptive antibiotic treatment.

746 PLATELET COUNT/SPLEEN DIAMETER RATIO AND AASLD CRITERION FOR SCREENING ESOPHAGEAL VARICES IN PATIENTS WITH HEPATITIS C VIRUS-RELATED COMPENSATED CIRRHOSIS
Eedoardo G. Giannini1, Eram Anwar2, Kaukab Bashir3, Vincenzo Savarino1, Adnan Agha2; 1Department of Internal Medicine, University of Genoa, Gastroenterology Unit, Genova, Italy; 2Department of Internal Medicine, Allama Iqbal Medical College and Jinnah Hospital, Lahore, Pakistan; 3Department of Internal Medicine, Faculty of Medicine, Medical Unit I, Allama Iqbal Medical College and Jinnah Hospital, Lahore, Pakistan

Background: Screening for esophageal varices (EV) is a mandatory yet expensive part of the diagnostic work-up of cirrhotic patients. Recently, attention was put on non-invasive, accurate, and cost-effective assessment of EV with the aim of improving the management of cirrhotic patients from both the medical and the financial point of view. Aims: To evaluate the diagnostic efficiency of the platelet count/spleen diameter in comparison with the criterion suggested by the AASLD (portal vein diameter >13mm and/or platelet count <140,000/mm3) for screening EV in patients with HCV-related compensated cirrhosis. Methods: Among a total of 311 cirrhotic undergoing EV screening, 114 had no hepatic encephalopathy and no ascites detected by abdominal ultrasound. Sensitivity, specificity, positive and negative predictive values, and efficiency for EV diagnosis of the platelet count/spleen diameter ratio (cut-off value=909) and of the AASLD criterion were evaluated in patients with compensated cirrhosis. Results: Prevalence of EV was 26.3% (6% with large EV). According to the AASLD criterion, endoscopy would have been avoided in 75 of these patients (none with EV) with a sensitivity of 100% (88.8-99.9%, 95% confidence interval) and a negative predictive value of 100% (95.3-100%), while 39 patients would have undergone endoscopy (9 without EV) with 89.3% (80.1-94.2%) specificity, 76.9% (61.5-87.3%) positive predictive value, and 92.1% (85.7-95.8%) diagnostic efficiency. Noteworthy, all the "false positive diagnoses" made by using the AASLD criterion were due to thrombocytopenia (i.e., platelet count <140,000). A platelet count/spleen diameter ratio value of 909 showed 100% sensitivity (88.8-99.9%), 97.6% specificity (91.8-99.3%), 100% negative predictive value (97.5-100%), 93.8% positive predictive value (79.8-98.1%), 2 patients without EV undergoing unnecessary endoscopy, and 98.3% efficiency (93.9-99.5%) for the diagnosis of EV. Conclusions: In patients with HCV-related compensated cirrhosis, the platelet count/spleen diameter ratio is a useful non-invasive tool for evaluating which patients should undergo endoscopy for EV screening, and its diagnostic efficiency is even better than the one obtained by applying the AASLD criterion. This study also provides the first practical evidence supporting the utility of the AASLD criterion.

747 INTRANASAL DESMOPRESSIN IS EFFECTIVE IN PREVENTING BLEEDING AFTER DENTAL EXTRACTION IN CIRRHOTIC PATIENTS HAVING MODERATE DEGREES OF COAGULOPATHY
Carmen M. Stanca1, Andre H. Montazem2, Jin X. Zhang1, Adeyemi Lawal1, Thomas D. Schiano1,2; 1Medicine, Mount Sinai School of Medicine, New York, NY; 2Oral and Maxillofacial Surgery, Mount Sinai School of Medicine, New York, NY; 3Reca-nati/Miller Transplantation Institute, New York, NY

BACKGROUND. Many patients with advanced liver disease have extremely poor dentition and require dental extractions. Cirrhotic patients waiting for liver transplantation who need dental extractions are typically given fresh frozen plasma (FFP) and/or platelets to correct coagulopathy. This is costly and may be associated with transfusion reactions and fluid overload. AIM. We evaluated the efficacy of intranasal desmopressin as an alternative to prevent bleeding in cirrhotic patients undergoing dental extraction. PATIENTS AND METHODS. Cirrhotic patients with platelet counts of 30,000-50,000/µL and/or INR 2.0-3.0 were randomized to receive blood transfusion (FFP 10ml/kg and/or 1 unit of single donor platelets, respectively) or intranasal desmopressin (300µg) before dental extraction. Patients with other bleeding disorders, receipt of blood transfusion within 2 weeks prior to study, renal insufficiency, allergy to desmopressin, or treatment with anti-platelet medications were excluded. All patients received prophylactic antibiotics 1 hour prior to procedure. A standard oromaxillofacial surgical treatment protocol was performed by the same surgeon (AM). Patients were followed up for post-extraction bleeding and side-effects over the next 24-48 hours. Study medication was provided by CSL Behring. RESULTS. Forty-one patients (21 in desmopressin group and 20 in blood transfusion group) were enrolled into the study. No significant differences were noted between the two groups in terms of gender (% males 67 vs. 70, respectively), age (median 51 vs. 50), INR (2.0 vs. 2.2), platelet levels (46,000 vs. 45,000/µL), creatinine (0.9 vs. 0.8 mg/dL), total bilirubin (2.8 vs. 2.8 mg/dL), ALT (30 vs. 42 U/L), albumin (2.7 vs. 2.5 g/dL), MELD score (16 vs. 17), or median number of teeth removed (3 vs. 4) (all p values > 0.28). The number of teeth removed ranged between 1-31 in the desmopressin group and 1-22 in the blood transfusion group. No patients in the desmopressin group required rescue blood transfusion after extraction. Four patients reused desmopressin at home. One patient in the transfusion group had bleeding after the procedure and required an additional transfusion. Another patient in the transfusion group experienced an allergic reaction at the end of transfusion, which was effectively treated with diphenhydramine. Treatment associated costs were lower for desmopressin ($700/patient) than for blood transfusion ($1500-3000/patient). CONCLUSION. Intranasal desmopressin is as effective as blood transfusion in achieving hemostasis in coagulopathic cirrhotic patients who undergo dental extractions, is much more convenient, less expensive and well tolerated.

Disclosures:
The following people have nothing to disclose: Carmen M. Stanca, Andre H. Montazem, Jin X. Zhang, Adeyemi Lawal, Thomas D. Schiano
Background and Aims. The study of refill kinetics after microbubbles destruction at contrast-enhanced ultrasound (CEUS) has proven useful to assess myocardial and renal perfusion. Preliminary data in healthy subjects suggested that this method may be used also for hepatic perfusion study. This study was aimed at assessing the use of regional hepatic perfusion (RHP) by CEUS in cirrhosis. Methods. 52 patients with liver cirrhosis undergoing hepatic vein catheterisation were included in the study. During a continuous iv infusion of microbubbles (SonoVue®, bolus of 0.5 mL followed by 3 mL/min), RHP was quantified using CEUS by destroying microbubbles at 95 seconds and measuring their tissue refill with intermittent harmonic imaging. A 25 seconds film of the refill curve, expressed by the exponential function $y = A(1-e^{-t})$ was electronically analysed; $A$ expresses blood volume fraction and $e$ microbubbles velocity. RHP is calculated as $A \times e$. Hepatic blood flow (HBF) was measured during ICG infusion at hepatic vein catheterisation. Hepatic venous pressure gradient (HVPG) was determined in the main hepatic vein (balloon-catheter), and cardiac index by thermal dilution (Swan-Ganz catheter).

Results. 26 patients had compensated cirrhosis, and 26 were decompensated. Overall, microbubble velocity was significantly higher than in a group of 10 healthy subjects ($r = 0.38 \pm 0.20$ vs. $0.22 \pm 0.05, p = 0.015$). RHP correlated with Child-Pugh score ($r = 0.333, p = 0.016$), and its objective components (albumin $r = 0.351, p = 0.011$; bilirubin $r = 0.291, p = 0.037$; prothrombin time $r = 0.341, p = 0.029$). RHP showed a direct correlation with HBF ($r = 0.515, p = 0.003$), and inverse correlations with indices of hepatic functional reserve: ICG extraction $r = 0.543, p = 0.001$; ICG plasma clearance $r = 0.391, p = 0.027$; ICG intrinsic clearance $r = 0.338, p = 0.050$. In addition, RHP correlated with the hyperdynamic state (cardiac index $r = 0.364, p = 0.019$; mean arterial pressure $r = 0.429, p = 0.003$; systemic vascular resistance $r = 0.459, p = 0.003$), and showed a weak direct correlation with HVPG ($r = 0.282, p = 0.050$).

Conclusions. Regional hepatic perfusion is increased in patients with cirrhosis, and correlates with the degree of liver failure and hyperdynamic state. Moreover, RHP correlates directly with HBF and with the reduction of liver functional reserve expressed by ICG clearance and extraction, suggesting that increased liver regional perfusion is mainly through anatomical or functional shunts. The determination of RHP by CEUS is a novel, objective, quantitative, non-invasive tool to assess disease severity in patients with liver cirrhosis.

749 SILDENAFIL HAS NO EFFECT ON PORTAL PRESSURE BUT LOWERS ARTERIAL PRESSURE

Iritza Inayal1,2, Puneeta Tandon1, Michael G. Tai3,4, Marcelo Spector3,4, Khurram Barri1,2, Roberto J. Groszmann1,2, Guadalupe Garcia-Tsao1,2; 1Internal Medicine, Section of Digestive Diseases, Yale University, New Haven, CT; 2Internal Medicine, Section of Digestive Disease, VA CT Healthcare System, West Haven, CT; 3Interventional Radiology, VA CT Healthcare System, West Haven, CT; 4Interventional Radiology, Yale University, New Haven, CT

Background: In cirrhosis, portal hypertension is partially due to intrahepatic vasocstriction attributed to local underproduction of nitric oxide (NO). Phosphodiesterase V (PDE-V) inhibitors increase NO availability and can decrease portal pressure by decreasing intrahepatic resistance, however this vasodilatory effect may also occur in the systemic circulation. Unlike experimental studies, a study in 5 patients with cirrhosis showed that vardenafil, a PDE-V inhibitor, lowers portal pressure (Aliment Pharmacol Ther 2006;23:121). Aim: To re-evaluate the effect of sildenafil, a short-acting PDE-V inhibitor more commonly used for erectile dysfunction (ED) by patients with cirrhosis, on systemic and portal hemodynamics. Methods: Open label study of the effect of single oral doses of sildenafil on mean arterial and portal pressures in patients with compensated cirrhosis and portal hypertension as defined by a hepatic venous pressure gradient (HVPG) > 6 mmHg. HVPG was obtained by subtracting the free hepatic venous pressure (FHVP) from the wedged hepatic venous pressure (WHVP). After obtaining baseline measurements, patients received an oral dose of 25 mg of sildenafil, with repeat measurements at 30 and 60 minutes. In a subset of patients, an additional 25 mg was administered if no significant drop in blood pressure was observed at 60 minutes and measurements repeated 30 minutes later (i.e. 90 minutes from baseline). WHVP and FHVP tracings were read blindly and in random sequence by three independent observers. Results: Twelve patients were enrolled in the study. All were male; 10 had HCV cirrhosis (7 with alcohol) and 1 each had HBV and cryptogenic cirrhosis. Median age was 54 years (range 51-58). All were Child A. As shown in the table there was a significant decrease in systolic, diastolic and mean arterial pressure without any effect on WHVP or HVPG. Conclusion: As previously shown with other vasodilators, sildenafil at therapeutic doses for ED has a potentially deleterious systemic effect without a portal pressure-reducing effect. Therefore, its daily use is not recommendable. The search should continue for vasodilators that are specifically targeted to the intrahepatic circulation and that lack a systemic effect.

750 OXYGEN DESATURATION DURING SLEEP IN HEPATOPULMONARY SYNDROME

David T. Palma1, Miguel R. Arguedas1, Susan M. Harding2, Michael B. Fallon1, 1Medicine, University of Alabama at Birmingham, Birmingham, AL; 2Sleep-Wake Disorders Center, University of Alabama at Birmingham, Birmingham, AL

Background & Aim: Sleep alters respiratory mechanics and gas exchange that can adversely impact arterial oxygenation. Whether sleep affects oxygenation in hepatopulmonary syndrome is unknown. The aim of this study was to evaluate subjects with hepatopulmonary syndrome for the presence of oxygen desaturation during sleep. Methods: Twenty cirrhotic adults including 10 controls and 10 hepatopulmonary syndrome were recruited from the UAB cirrhosis clinic and underwent home pulse oximetry during sleep. Subjects at high risk for obstructive sleep apnea were excluded through the Berlin questionnaire. Subjects who spent > 10% of total sleep time with arterial oxygen saturation < 90% were classified as sleeptime oxygen desaturators. Sleeptime desaturation was correlated with clinical variables. Results: The mean age of the entire cohort was 54 years and 9 participants were males. The most common causes of liver disease were hepatitis C infection (45%) and alcoholic liver disease (15%). There was no statistically significant difference in age, gender, race, cause of cirrhosis, Model for End-Stage Liver Disease score or Body Mass Index between hepatopulmonary syndrome and control subjects. 7 of 10 hepatopulmonary syndrome subjects and none of 10 controls had sleeptime oxygen desaturation. The median percentage of total sleep time with arterial oxygen saturation < 90% was significantly higher in hepatopulmonary syndrome subjects than in controls (medians 25% vs. 0%, p = 0.005). Hepatopulmonary syndrome subjects had significantly lower wake time arterial oxygen saturation (medians 97% vs. 95%, p = 0.003) and mean sleeptime arterial oxygen saturation levels (medians 96% vs. 91%, p = 0.0008) than controls. Sleeptime desaturation directly correlated with alveolar-arterial oxygen gradient (p = 0.0007) and inversely with waketime arterial oxygen tension (p = 0.0007) and oxygen saturation (p < 0.0001). Conclusions: Oxygen desaturation occurred during sleep in 70% of hepatopulmonary syndrome subjects, the degree of which correlated with the severity of hepatopulmonary syndrome. Marked hypoxemia during sleep may occur in hepatopulmonary syndrome patients who by waketime oxygen values have only mild to moderate hypoxemia. We speculate that nocturnal oxygen desaturation could contribute to the observation that increased mortality in patients with hepatopulmonary syndrome is not confined solely to those with severe daytime hypoxemia.

751 A MULTI-CENTER CASE-CONTROL STUDY OF CLINICAL PREDICTORS AND FUNCTIONAL STATUS IN HEPATOPULMONARY SYNDROME (HPS)

Michael B. Fallon1, Michael J. Krowka2, Miguel R. Arguedas3, James F. Trotter2, Lisa Forman2, Vijay Shah3, R. S. Brown4, Steven Zacks5, Steven M. Kawut6, 1Medicine, University of Alabama at Birmingham, Birmingham, AL; 2Medicine, Columbia University, New York, NY; 3Mayo Clinic, Rochester, MN; 4Tufts-NEMC, Boston, MA; 5University of Colorado, Denver, CO; 6University of North Carolina, Chapel Hill, NC

Introduction: The hepatopulmonary syndrome (HPS) occurs in 10-30% of cirrhotic patients and adversely affects survival with or without liver transplantation (OLT). Whether specific clinical features are associated with the presence of HPS and if HPS influences functional status are poorly defined. We evaluated clinical risk factors and functional status in patients undergoing OLT evaluation. Methods: We performed a case-control study at six US academic medical centers between 2004-2006. HPS cases had an abnormal alveolar-arterial oxygen gradient (A-aPaO2) and intrapulmonary vascular shunting on contrast enhanced transthoracic echocardiography (CE) in the absence of significant restrictive or obstructive lung disease. Controls had negative CEs or positive CEs with normal A-aPaO2 in the absence of lung disease. Health related quality of life was assessed using an SF-36 based disease-targeted quality of life instrument (LDQOL 1.0). Results: 71 patients with HPS were compared to 178 controls. The groups were similar in terms of age, gender, and etiology of cirrhosis. Clubbing and cyanosis were uncommon but more frequent in HPS (p<0.05), while spider angiomas and ascites were similar between the groups. HPS patients were less likely to have a smoking history than controls (48% vs 62%, respectively, p <0.05), while the frequency of TIPS, abnormal CXR findings, beta-blocker or antibiotic use were similar between the groups. Mean (±SD) MELD scores were identical between cases and controls (13 ± 4 vs 13 ± 6). HPS patients had significantly higher median [IQR] A-aPaO2 than controls [23 [19-35] vs 9 [3-12], p<0.0001] and lower PaO2 (75±13 mmHg vs 93±13 mmHg, p<0.0001). Patients with HPS reported more dyspnea than controls (46% vs 25%, p< 0.001) and had worse NYHA functional class (p<0.005). Cases also had lower mean (±SD) SF-36 global mental component scores (40±10 vs 45±11, p=0.02) and worse general health perceptions (26±14 vs 37±22, p<0.015), physical (28±24 vs 42±32, p<0.033) and emotional (50±34 vs 66±32, p<0.01) role limitations and emotional well being (56±21 vs 66±22, p<0.01) relative to controls. Symptoms of liver disease were also greater in HPS patients relative to controls (51±19 vs 59±22, p<0.03). Conclusions: Commonly assessed clinical variables do not reliably predict the presence of HPS and therapies targeted towards modulation of portal pressure or bacterial translocation do not appear to affect its presence. HPS is associated with pulmonary symptoms, impaired functional class and reduced quality of life. These findings highlight the importance of developing HPS screening algorithms and developing effective medical therapies.

Background: The gold standard test for the diagnosis of SBP is based on manual count of ascitic fluid polymorphonuclear (PMN) cells. However, the procedure is operator dependent and lysis of PMN cells during transport to the laboratory may lead to false negative results. Furthermore, ascites fluid culture is insensitive and leads to delays in diagnosis. Lactoferrin is a major component of PMN cell granules and has been shown to be a sensitive and specific marker of leukocyte activation. Aims: 1) To assess the sensitivity and specificity of ascitic fluid lactoferrin for the diagnosis of SBP and 2) To identify a clinically useful cutoff level that can be used for future development of a rapid bedside test. Methods: 218 consecutive ascites fluid samples from 148 patients (1-8 samples per patient) with liver cirrhosis at two tertiary care medical centers were examined for PMN counts, bedside culture, Gram stain and lactoferrin concentration. Quantitative measurements of ascitic fluid lactoferrin concentration were determined using a polyclonal antibody-based enzyme-linked immunosorbent assay (ELISA) specific for human lactoferrin by a laboratory blinded to the patients' clinical information and other laboratory results. Ascites fluid PMN cell count > 250/mL and/or a positive gram stain/culture were used for the diagnosis of SBP. Results: 22 (10%) samples fulfilled diagnostic criteria for SBP. Samples from patients with SBP had significantly higher lactoferrin concentration (median 3744 ng/mL, interquartile range (IQR) 788-9617) compared to non-infected samples (median 31 ng/mL, IQR 12-67); P<0.001. Using a cutoff level of 242 ng/mL, the assay had 96% sensitivity and 97% specificity to identify those with SBP.

AQUAPORIN-1 DEMONSTRATES ARTERIAL CAPILLARY PROLIFERATION AND HEPATIC SINUSOIDAL TRANSFORMATION IN HUMAN CIRRHOTIC LIVER-RELEVANCE TO PORTAL HYPERTENSION

Hiroaki Yokomori1, Masaya Oda2, Toshifumi Hibi3; 1Kitasato Institute Medical Center, Saitama, Japan; 2Organized Center of Clinical Medicine, International University of Health and Welfare, Tokyo, Japan; 3Internal Medicine, School of Medicine, Keio University, Tokyo, Japan

Background: Defenestration of hepatic sinusoidal endothelial cells concomitant with collagen deposition in the space of Disse causes an increase in peripheral portal microvascular resistance in liver cirrhosis. Moreover, the development of scars in the cirrhotic liver is invariably accompanied by an intense microvascular proliferation, and is involved in portal hypertension. Aquaporins (AQP)s are key regulators in water channels across the cell cytoplasm. Although AQP's in the normal hepatobiliary system have been studied in mammals, little is known about the AQP localizations and changes in the hepatic microvascular system including sinusoids in cirrhotic liver, which may contribute to portal hypertension. The aim of this study is to clarify the localization of AQP-1 in the microvessels in normal and cirrhotic human liver. Methods: As human control liver samples, wedge biopsy specimens from the non-cirrhotic liver were obtained from patients who underwent surgical resection for metastatic liver carcinoma. Cirrhotic liver specimens were obtained from macroscopically cirrhotic portions surgically resected from patients who had hepatocellular carcinoma combined with hepatitis C-related cirrhosis. Immunostaining was performed on serial sections. Four-micrometer sections were cut from paraffin blocks of formalin-fixed tissue, liver specimens were reacted with anti-AQP-1 polyclonal antibody. Western blotting was conducted using fresh control and cirrhotic liver tissues. For in situ hybridization(ISH), Human AQP-1 peptide nucleic acid probes were used with a catalyzed signal amplification system. Results: In control liver tissue, AQP-1 was mainly localized in the portal venules, hepatic arterioles, and bile ducts in the portal tract, while AQP-1 was hardly detected in the sinusoids. In human cirrhotic liver tissue, AQP-1 expressions were observed mainly on periportal SECs, proliferative arterial capillaries opening into the sinusoid in the generating hepatic nodule, and proliferated bile ductules at the peripheral edge of nodules and fibrotic septa. In cirrhotic liver tissue, overexpressions of AQP-1 at protein and mRNA levels were demonstrated by Western blot and ISH, respectively. Conclusion: AQP-1 immunoreactivities were aberrantly expressed in response to the transformation hepatic sinusoidal endothelial cells as well as the proliferated arterial capillaries in cirrhotic liver, indicating angiogenetic responses induced AQP-1, leading to the pouring of arterial blood into the sinusoids, increasing sinusoidal microvascular resistance, and contributing to exaggerating portal hypertension in liver cirrhosis.

LONG-TERM SURVIVAL IN PATIENTS WITH REGRESSION OF VIRAL-RELATED CIRRHOSIS

Vincent Mallet1, Helene Gilgenkrantz2, Jeanne Serpaggi1, Virginie Verkarre2, Aanis Vallet-Pichard1, Hélène Fontaine1, Stanislas Pol1; 1Université Paris-Descartes, APHP, Hôpital Cohn, Département d’hépatologie, INSERM U. 567, Paris, France; 2APHP, Hôpital Necker, Anatomopathologie, Paris, France; 3INSERM U. 567, équipe 34, Paris, France

BACKGROUND Historically thought as irreversible, there is mounting evidence that cirrhosis can regress, given that the underlying liver disease is controlled. Whether regression of cirrhosis has a beneficial clinical effect is uncertain and highly debated. METHODS We have prospectively followed 10 years (range 3 to 17 years) 100 patients with compensated biopsy-proven cirrhosis related to chronic viral hepatitis B or C. All received specific therapy. Patients were stratified on the basis of the decrease of their histopathological fibrosis score on a post-therapeutic liver biopsy. Regression of cirrhosis was defined as a decrease in the fibrosis score from F4 to less than or equal to F2 from the METAVIR classification. Observed liver-related complications and survival rates were compared between patients with or without regression of cirrhosis. RESULTS Regression of cirrhosis was observed in 24 patients (22 hepatitis C virus-infected patients, 2 hepatitis B virus-infected patients), among which 21 were long-term responders to therapy and 3 biochemical responders. The platelet count, the prothrombin time and the response to therapy were independent predictors of regression of cirrhosis. The incidence of liver-related complications, including hepatocellular carcinoma, ascitis, hepatic encephalopathy, varical bleiding was null in the group with regression of cirrhosis compared to 19 percent without regression (P<0.05 — log-rank test). The incidence of cirrhosis-related complications was also lower in patients with a sustained virological response, although 3 patients with chronic hepatitis C, without regression of cirrhosis, developed hepatocellular carcinoma despite complete response to therapy (P<0.01 — log-rank test). Finally, 15 patients without regression of cirrhosis died or underwent liver transplantation while none of the patients with regression of cirrhosis died or underwent liver transplantation (P<0.05 — log-rank test). CONCLUSION In this prospective follow-up of patients with viral hepatitis-related cirrhosis who received specific therapy, the absence of liver-related morbidity and mortality in patients with histologically-proven regression of cirrhosis establishes that regression of viral cirrhosis has a clear impact on morbidity and mortality. It is therefore important to check the fibrotic status of cirrhotic patients after treatment since both the prognosis and the follow-up can be completely different in case of cirrhosis regression.

PROGNOSTIC VALUE OF LIVER STIFFNESS MEASUREMENT AND HEPATIC VENOUS PRESSURE GRADIENT IN PATIENTS WITH CHRONIC LIVER DISEASE: A PROSPECTIVE STUDY

Christophe Bureau1,2, Marie-Angèle Robic1, Sophie Métivier1, Jean-Marie Pérón1,2, Olivier Rouquet1, Emmanuel Dupuis1, Laurent Alric2, Jean-Pierre Vinel1,2; 1Hepato-Gastro-Enterologie, CHU Toulouse-Purpan, Toulouse, France; 2INSERM U858, Toulouse, France; 3Service de Médecine Interne, CHU Purpan, Toulouse, France

Hepatic venous pressure gradient (HVPG) has been proved to have a prognostic value in patients with chronic liver disease, on the one hand. On the other hand, liver stiffness (LS) as measured by transient elastography has been found to be correlated with the amount of fibrosis within the liver and to HVPG. The present study aimed to assess the prognostic value of LS and to compare it with HVPG performances. METHODS: LS and HVPG were measured on the same day in consecutive patients presenting with chronic liver disease and an indication for a transjugular liver biopsy. 78 of these patients were followed for one year, or until liver transplantation or the occurrence of a complication of their liver disease, namely: variceal bleeding, ascites, sepsis, encephalopathy, hepatocarcinoma or death. RESULTS: 27 (35%) of the 78 patients experienced at least one complication: bleeding in 6, ascites in 4, sepsis in 10, encephalopathy in 2, hepatocarcinoma in 1, or died (16). The performances of LS in predicting the occurrence of a complication were: AUROC = 0.83 [0.74-0.92], with a cut-off of 21.1 kPa, sensitivity was 83%, specificity 64%, PPV 53% and NPV 89%. Using HVPG, AUROC was 0.85 [0.76-0.94], and with a cut-off of 10 mmHg, sensitivity was 85%, specificity 63%, PPV 56% and NPV 89%. According to whether LS was below or above 21.1 kPa, the actuarial rates of the occurrence of a complication at one year were 10% and 50% respectively (p<0.05). These rates were 10% and 53% (p<0.05) in patients with a HVPG below or above 10 mmHg respectively. Results were similar when only patients with cirrhosis were considered. CONCLUSION: LS as assessed by transient elastography and HVPG have similar performances in predicting complications at one year in patients with chronic liver disease. PROGNOSTIC INDICATORS OF REBLEEDING IN POOR HEMODYNAMIC RESPONDERS TO TREATMENT OF PORTAL HYPERTENSION

Alan Colomo, Carles Aracil, Ingrid Ordas, Carlos Guarner, Jordi Gordillo, Cristina Alvarez, Xavier Torras, Candid Villanueva, Joaquim Balanzó, Gastroenterology, Hospital Santa Creu i Sant Pau, Barcelona, Spain

Hemodynamic response to treatment of portal hypertension is considered adequate when the hepatic venous pressure gradient (HVPG) decrease to <12 mmHg or by >20% of baseline. It is strongly established that responders have a lower risk of variceal bleeding and better survival. Non-responders may benefit of a rescue therapy. However, up to 40%-50% of non-responders do not have rebleeding suggesting that further therapy is not required in this subgroup. The aim of this study was to investigate which factors may predict rebleeding among poor hemodynamic responders. METHODS: During a 10-years period 400 patients were included after an acute variceal
bleeding episode and received chronic treatment with drugs (β-blockers ± nitrates) or endoscopic ligation or both, to prevent recurrent bleeding. A baseline hemodynamic study was performed in 344 patients and a second study was performed in 302 patients 1-3 months later to assess response that was defined as a decrease in HVPG to <12 mmHg or >20%.

RESULTS: Mean age of included was 59±12 years, 65% were male, 48% had alcoholic cirrhosis, 81% were Child-Pugh class B/C at baseline and 49% at third month of follow-up. 114 patients (38%) were hemodynamic responders and 188 (62%) were non-responders. During the follow-up of 43±40 months 148 patients (37%) rebleed and 207 (52%) died. Rebleeding occurred in 16% of responders and 48% of non-responders (P<0.001) and death in 32% vs 52% respectively (P=0.001). Among non-responders, those who rebleed had as compared with those without rebleeding, a higher baseline bilirubin (P=0.01) and platelets (P=0.05) at 1-3rd month of follow-up, a greater rate of failure to control the acute bleeding episode (P<0.001) and were older (P=0.01). The multivariate analysis performed including these parameters identified the Child-Pugh score at 3rd month (OR=2.4, 95% Cl=1.5-3.7), failure to control the index bleeding (OR=1.7, 95% Cl=1.1-2.8) and HVPG at 1-3rd month (OR=1.1, 95% Cl=1.01-1.2) as independent predictors of rebleeding in non-responders. Rebleeding occurred in 70% of non-responders with Child-Pugh >7 at 3rd month, failure to control bleeding or HVPG >20 mmHg at 1-3rd month, and in 39% of those without any of these factors (P<0.001). CONCLUSIONS: Child-Pugh score at 3rd month, failure to control the index bleeding and HVPG at 1-3rd month of follow-up are independent prognostic indicators of rebleeding in poor hemodynamic responders to treatment of portal hypertension. These factors may improve the selection of non-responders that may benefit of rescue therapies.

757 ADRENAI IMPAIRMENT IS FREQUENT FINDING IN STABLE CIRRHOSIS AND IS RELATED TO DISEASE SEVERITY

Alexandros Sigalas, Elias Xiouchakis, Pinelopi Manousou, Alice Corbani, Vincenza Calvaruso, David Patch, Andrew K. Burroughs, James O’Beirne; Liver Transplantation and Hepatobiliary Unit, Royal Free Hospital, London, United Kingdom

Introduction Patients with cirrhosis and sepsis have recently been reported to have impaired responses to adrenal stimulation. This adrenal insufficiency has been correlated with liver disease severity and outcome. It is currently unknown whether this adrenal insufficiency is related to the critical illness or is an exacerbation of pre-existing adrenal insufficiency. We hypothesised that adrenal insufficiency may be prevalent in stable patients with cirrhosis. Methods: We evaluated patients with stable cirrhosis admitted to our unit for TIPS or transplant assessment. Cirrhosis was defined histologically or on imaging, clinical or laboratory findings. Adrenal function was tested using the 1µg or 250µg short synacthen tests (SST). Results 47 patients were studied. Median age 53 yrs (IQR 45-60). Disease severity was evaluated using the MELD score (median 17 IQR 13-21), MELD-Na (median 20 IQR 15-26), and Child Pugh score (CPS) (median 10, IQR 8-12). 57% of patients were Child-Pugh grade C, 32% grade B and 10% grade A. Baseline cortisol was <250µmol/L in 62% of patients. 60% showed an increment in cortisol less than 250 µmol/L and in 55% the peak cortisol level was less than 300 µmol/L after adrenal stimulation. Adrenal failure (AF) was defined as baseline cortisol <250µmol/L and increment <250µmol/L. AF was observed in 36 % of patients. There was no difference in the incidence of AF between patients who received the 1µg or 250µg synacthen tests, (p= 0.480) therefore the group was analysed as a whole. AF was observed more frequently in Childs-Pugh C patients versus Childs-Pugh B and A patients (p=0.047). Post stimulation cortisol levels were lower at all time points in Childs C compared to Childs A/B patients (p < 0.03). In univariate analysis albumin, INR and Bilirubin were significantly associated with AF. In multivariate logistic regression only INR was a significant predictor of AF (p=0.005). Conclusion Patients with stable cirrhosis show a high incidence of adrenal insufficiency when tested with SST. Abnormal SST responses are observed more frequently in patients with more severe liver disease. These data suggest that the high prevalence of adrenal insufficiency in septic cirrhotics may be an exacerbation of an underlying condition. Further work is needed to clarify the pathogenetic mechanisms involved and the prognostic significance of this finding.

758 HEPATIC VENOUS PRESSURE GRADIENT PREDICTS THE FIRST CLINICAL DECOMPENSATION IN PATIENTS WITH CHRONIC HEPATITIS C-RELATED CIRRHOSIS

Diego Rincón, Ana Hernando, Oreste Lo Iacono, Alain Huerta, Judith Gómez, Magdalena Salcedo, Maria Vega Catalina, Cristina A. Ripoll, Cecilia Sanz, Oscar Nuñez, Ana Matilla, Gerardo Clemente, Rafael Banares; Liver and Transplant Unit, Hospital General Universitario Gregorio Marañón, Madrid, Spain

BACKGROUND: Hepatic venous pressure gradient (HVPG) has a marked prognostic value in compensated patients with chronic hepatitis C (HCV)-related cirrhosis. However, it has not been tested in the compensated setting. AIM: To study the capacity of HVPG to predict the first clinical decompensation (CD) in patients with compensated HCV-related cirrhosis.

METHODS: All patients with compensated HCV-related cirrhosis who underwent a hepatic hemodynamic study (HHS) between 1/1997-12/2005 in our center were included. Clinical decompensation was defined as the appearance of ascites, variceal bleeding or encephalopathy. ROC curves were performed to select the best predictive value for CD of several predictors. Then, a multivariate Cox regression analysis was used to identify independent predictors of decompensation.

RESULTS: In the study period, 798 patients with HCV underwent HHS. Six hundred-twenty five patients were excluded due to: decompensated disease (259), previous liver transplantation (200), inadequate follow-up (59), chronic hepatitis without cirrhosis (55), previous TIPS (28) and other reasons (24). The remaining 173 patients with compensated disease (76% male; median age 55 [29-78] years; 74% genotype 1) were included in the study. They received HHS because of: transjugular liver biopsy (54), hepatocellular carcinoma (HCC, 50), evaluation for liver transplantation (23), before antiviral (20) or propranolol (15) therapy, and other reasons (11). Median follow-up was 25 [1-123] months. Fifty-seven (33%) patients developed CD during follow-up: 43 (75.5%) ascites, 10 (17.5%) variceal bleeding, and 4 (7%) hepatic encephalopathy. The probability of CD was 13%, 30% and 52% at 1, 3 and 5 years respectively. In univariate analysis age> 60 years, HVPG> 13 mmHg, MELD score> 9, albumin< 3.8 g/dL, previous antiviral therapy and existence of varices or HCC were significantly related to
CD. In multivariate analysis only age > 60 [HR 4.09 [2.29-7.32]; p=0.0001] and HVPG > 13 [HR 2.76 [1.50-5.12]; p=0.001] were independently associated to CD. HVPG value > 13 discriminated two populations with a different risk of CD: 19%, 31% and 65% Vs. 6%, 20% and 25% at 1, 3 and 5 years [HR 2.96 [1.65-5.31] p=0.0001]. A sensitivity analysis excluding those patients with HCC was performed. HVPG > 13 [HR 2.41 [1.02-5.67]; p=0.045], besides MELD score > 9 [HR 3.28 [1.35-8.01]; p=0.009] and previous antiviral therapy [HR 0.47 [0.24-0.93]; p=0.03], was retained in the model. CONCLUSION: HVPG independently predicts CD in patients with compensated HCV-related cirrhosis. Patients with a HVPG > 13 mmHg have a significantly higher risk of developing CD.

759 COMPARISON BETWEEN ENDOGENOUS THROMBIN POTENTIAL (ETP) AND INR TO ASSESS LIVER FUNCTION DECREASE IN PATIENTS WITH LIVER CIRRHOSIS

Jeoffrey Schouten1, Sven M. Francque1, Peter P. Michielsen1, Alain Gadisseur2; 1Hematology, UZA, Antwerp, Belgium

Introduction: Advanced liver cirrhosis is characterized by a reduced synthesis of coagulation factors. Conventional coagulation tests (PT/INR and aPTT) poorly correlate with bleeding problems in patients with cirrhosis possibly because they do not adequately reflect the balance between procoagulant and anticoagulant factors. The INR was originally developed for use in patients under oral anticoagulation and may not adequately reflect the changes in the coagulation system in patients with cirrhosis of the liver, since it reflects only changes in Factor VII, X and II. Recently a test has become available which will make it possible to routinely measure the endogenous thrombin generation potential (ETP). Aims: To compare INR and ETP as predictors of synthetic and metabolic liver function (according to Child classification, serum-cholinesterase and 13C-aminopyrine breath test [ABT]). Patients: Patients with biopsy proven liver cirrhosis (n=112: 73 Child A, 21 Child B, 18 Child C) without known pre-existing coagulation abnormalities except liver disease, outside the setting of acute infections and without coagulation correction were prospectively included after informed consent. In these patients ETP, PT/INR and S-cholinesterase were measured. 13C Aminopyrine was performed in each patient. We used a fully automated assay for the determination of the endogenous thrombin potential (ETP) on the BCS® System (both Dade Behring, Marburg, Germany). Results: INR and ETP show good correlation with the Child score (P<0.05). There is no better correlation for ETP (R2:0.28) with S-cholinesterase than there is for INR (R2:0.10). ETP is a significant better predicting factor (P<0.05) for low S-cholinesterase in linear regression analyses than INR (p=0.53). ETP and INR show a good correlation with 13C-Aminopyrine breath test. A linear regression model ETP (β= 0.27, p<0.05) is the main predictive factor for decreasing thrombin generation. No such relationship can be identified for the INR (β= -0.16, p=0.083). Conclusion: Our results indicate that the integrity of the coagulation as measured through the thrombin generation decreases in line with deterioration of other liver functions in patients with liver cirrhosis. The ETP correlates significantly better with parameters of synthetic liver function compared to INR, currently being part of the MELD. ETP measurement is therefore a promising tool for assessing liver function impairment.

760 EARLY PRIMARY PROPHYLAXIS WITH BETA-BLOCKERS AND ROLE OF HEPATIC VENOUS PRESSURE GRADIENT ASSESSMENT IN PREVENTION OF GROWTH OF SMALL ESOPHAGEAL VARICES IN CIRRHOSIS

Smruti R. Mishra, Ashish Kumar, Lal B. Gupta, Rahul Kishore, Barjesh C. Sharma, Shiv Kumar Sarin; Gastroenterology, G B Pant Hospital, New Delhi, India

Background: Efficacy of Beta-blockers (BB) and Efficacy of HVPG in early primary prophylaxis of variceal bleed in small varices is not clear. Methods: 85 cirrhotics with small varices (gr I or II) without previous bleeding were enrolled. Baseline HVPG was done. 43 randomized to receive propranolol [Gp A] (dose titrated to decrease resting HR to 55; median dose 120 mg/day, range 20-240) and 42 to placebo [Gp B]. Patients further randomized to either repeat HVPG after 1 yr or no repeat HVPG in both groups. Primary endpoints were progression of esophageal varices by 1 grade or hemodynamic response (≥20% reduction in HVPG) and secondary endpoints were bleeding and death. Endoscopy was done every 3 mo. Results: Both groups were comparable for baseline characteristics (table). Baseline Child score [Gp B=7.9, Gp A=7.6; p=0.45] and follow up score [Gp B=8.0, Gp A=7.6; p=0.40] were comparable. Baseline HVPG values were similar [Gp B=14.8, Gp A=15.1; p=0.77]. During a median follow up of 18 (range 3-60) mo, the rate of growth of varices did not differ between groups A & B (n=8 [19%] and n=9 [21%], P=0.9). Categorizing these patients on baseline HVPG value ≤10 and >10 mmHg, there were no differences in variceal progression (p=0.32), bleed (p=1.0) or mortality (p=1.0) in Gp B. Similarly in BB group variceal progression (p=0.32), bleed (p=0.40) or mortality (p=0.39) did not reach significance. In the placebo group, median HVPG change is 0 [range -1.4 to +1.1] and those in BB group median HVPG decreased by 3 mmHg [range -11 to +3] (p=0.07). Hemodynamic response achieved in 11/22 (50%) in Gp A and 5/17 (29%) in Gp B (p=0.32). Variceal progression in responders was similar to non responders (p=0.47). Outcome response by endoscopic method or by serial HVPG correlated closely and did not vary (p=ns) between groups A1 vs. A2 and B1 vs B2. Conclusions: Nonselective BB prophylaxis is ineffective in preventing growth of small esophageal varices, variceal bleeding, and mortality. While baseline HVPG helps in assessing the severity of portal hypertension, it did not reliably predict the growth or bleeding rate of small varices. Close endoscopic monitoring could reliably be used instead of serial HVPG measurements in these patients.

SPLINE STIFFNESS MEASUREMENT BY MAGNETIC RESONANCE ELASTOGRAPHY IS AN INDEPENDENT PREDICTOR OF ESOPHAGEAL VARICES IN PATIENTS WITH COMPENSATED CIRRHOSIS

Jayant A. Talwalkar, Meng Yin, Sudhakar Venkatesh, Phillip Rossman, Patrick S. Kamath, Richard Ehman

Background: A strong relationship between spleen stiffness and portal pressure has recently been described. However, the relationship between spleen stiffness, liver stiffness, and esophageal varices remains unknown. Aim: 1) To identify the clinical factors associated with spleen stiffness in patients with chronic liver disease. 2) To determine the relationship between spleen and liver stiffness with esophageal varices. Methods: Individuals with chronic liver disease (n=38) and healthy volunteers (n=12) were studied. All MR elastography examinations used a 1.5 T whole-body imager. In the supine position, a 19 cm cylindrical passive pneumatic driver was placed against the anterior abdominal wall. Shear waves at 60 Hz were generated by the driver from an active speaker. Axial wave images of liver and spleen were obtained by GRE-based sequences. Quantitative shear stiffness images were obtained by LFE inversion algorithms. Results: Mean age was 56 yrs with 50 % women for liver disease patients. Average BMI was 29.7 kg/m2 (range, 18-42). Major diseases were hepatitis C (20%), NASH (20%), alcohol (11%), AIH (11%), and PBC (11%). Fibrosis stage was 0I in 36%, I-II in 18%, and IV in 45% of cases. Average MELD score was 6 (range, 6-8). Mean serum platelet count was 193,000/mm3 (range, 36,000-358,000). Prevalence of splenomegaly was 34%. Esophageal varices were identified in 9 of 38 (24%) patients (grade 1, 56%; grade 2, 22%; grade 3, 22%). Spleen elastograms were obtained in all subjects. Mean spleen stiffness was higher in patients compared to healthy volunteers (8.0 kPa vs 2.2 kPa, p<0.0001). Univariate analysis identified splenomegaly, liver stiffness, and platelet count as significant factors (p<0.01 for all) associated with spleen stiffness. Age, sex, BMI, and disease etiology did not influence spleen stiffness. Patients with esophageal varices had significantly higher median liver stiffness (7.5 kPa vs 4.1 kPa, p=0.009) and median spleen stiffness (11.7 kPa vs. 6.25 kPa, p=0.001) values compared to unaffected patients. Both spleen stiffness (p=0.005) and splenomegaly (p=0.001) were independent predictors of esophageal varices adjusted for platelet count and liver stiffness value. Conclusions: 1) Spleen stiffness, platelet count and liver stiffness value were associated with spleen stiffness. 2) Patients with esophageal varices had significantly higher median liver and spleen stiffness values compared to unaffected patients. 3) From this preliminary study, the spleen stiffness value and presence of splenomegaly were independent predictors of esophageal varices regardless of platelet count and liver stiffness value.

LEUKOPENIA AND THROMBOCYTOPENIA PREDICT A POOR PROGNOSIS IN COMPENSATED CIRRHOSIS

Amir A. Qamar, Norman D. Grace, Roberto J. Groszmann, Guadalupe Garcia-Tsao, Jaime Bosch, Andrew K. Burroughs, Cristina A. Ripol, Rie Maurer, Ramon Planas, Angeles Escorsell, Juan Carlos Garcia-Pagan, David Patch, Daniel S. Matloff, Robert Makuch, Gabriel Rendon, Badalona, Spain

Background: Abnormal hematological indices (HI) occur in cirrhosis due to multiple factors including hypersplenism. A correlation between serum platelet count (PLT) and hepatic venous pressure gradient (HVPG) has been shown [Hepatology 2006; 44: A721]. The aim of this study was to determine if hemoglobin (Hgb) and white blood cell count (WBC) correlate with HVPG and whether abnormal HI have prognostic significance. Methods: Secondary analysis was conducted of a database of subjects with compensated cirrhosis without esophageal varices enrolled in a randomized, placebo controlled trial of beta-blockers in the prevention of varices. (NEJM 2005; 353:2254). Subjects were followed until the development of varices or variceal bleeding or completion of the study. 84 subjects developed varices. Patients were followed until 9/02. Baseline HVPG measurements, PLT, WBC and Hgb were analyzed. Abnormal HI was defined as the baseline occurrence of anemia (Hgb < 13.5 g/dl for men and 11.5 g/dl for women), leukopenia (WBC ≤ 4,000/ mm3) or thrombocytopenia (PLT ≤ 150,000/ mm3). HI were categorized into 4 groups (Table). The main event was death or transplant. Statistical analysis: ANOVA, Spearman correlation, Kaplan-Meier with log rank test and Cox proportional regression. Results: There was significant correlation of HVPG with both Hgb and WBC (Hgb: r = 0.35, p<0.0001, WBC: r = -0.31, p<0.0001). The Table shows median baseline HVPG (mm Hg) among different HI groups. A significant difference (p<0.0001) in death or transplant between patients who had thrombocytopenia and leukopenia compared to patients with normal HI was observed over a median follow-up of 4.2 years. Similarly, death only was more frequent in subjects with thrombocytopenia and leukopenia compared to normal HI group (p = 0.0128). The differences in death or transplant among the HI groups remained significant when adjusted for HVPG and Child-Pugh score (p=0.0048). Summary: There is a significant correlation between HVPG and WBC or Hgb. Occurrence of abnormal HI at baseline is associated with a markedly elevated HVPG and poor prognosis. Conclusion: Portal hypertension contributes to HI abnormalities in cirrhosis. The occurrence of leukopenia and thrombocytopenia in patients with compensated cirrhosis is a poor prognostic indicator.
Liver failure represents a major cause of death in alcoholic steatohepatitis (ASH). The extent to which the liver can regenerate is a key point in the outcome of liver diseases. Aim: To study the short-term effects of GCSF on mobilization of CD34+ hematopoietic stem cells, hepatocyte lineage proliferation, and biological parameters in patients with ASH and variable degree of liver failure. Patients and Methods: 24 consecutive patients with biopsy-proven ASH (age 54 yrs [34-69]; Maddrey’s score 36 [21-60]; Pugh’s score 10 [7-12]) were randomized to standard care alone (Group A: n=11; 7 received steroids) or associated to a 5-day mobilization course with GCSF 10 mcg/kg sc (Group B: n=13; 5 received steroids). The number of hematopoietic progenitor cells (HPC) and mature hepatocytes which entered into a proliferative phase were identified and manually counted on the entire biopsy specimen at baseline and repeat liver biopsy at day 7, using a double immunostaining method MIB1/CK7 and MIB1/CK18, respectively. Circulating CD34+ cells (flow cytometry) and cytokines involved in regeneration (HGF) and inflammation (IL-6), and liver function tests were also measured. Results: Groups were similar at baseline. Tolerance to GCSF was excellent. Table presented for comparison. Percent Death or Transplant (n=) 6 (2) 8 (1) 24 (28) 49 (23) Percent Death (n=) 6 (2) 8 (1) 18 (21) 28 (13)

an alterations of the self-reactive antibody repertoire. CON-CLUSION: Acquired auto-immune PS-deficiency is probably central to the cause of NRH in HIV-infected patients, resulting in thrombotic venopathy, NRH, portal hypertension and sometimes to liver failure.

SURVIVAL BENEFIT IN PATIENTS WITH ACUTE VARICEAL BLEEDING AND HEMODYNAMIC REPERCUSSIONS FOLLOWING EARLY ADMINISTRATION OF VAPRETIDE
Paul Cales1, Robert Platt2,3, 1Service d’Hepato-Gastroenterologie, Centre Hospitalier Universitaire (CHU), Angers, France, 2The Montreal Children’s Hospital, Montreal, QC, Canada; 3Pediatrics and Epidemiology/Biostatistics, McGill University, Montreal, QC, Canada

Purpose: Bleeding from esophageal varices is a life-threatening complication of portal hypertension in patients with cirrhosis. A subset of these patients experience hemodynamic repercussions, which increase the risk of organ failure and mortality. In the first major clinical trial conducted to evaluate the effectiveness of the somatostatin analog vapreotide administered early in combination with endoscopy in patients with cirrhosis and acute esophageal bleeding, treatment with vapreotide and endoscopic therapy improved bleeding control and 15-day mortality versus endoscopic therapy alone, but did not significantly affect 42-day mortality. The objective of this post hoc analysis was to determine if vapreotide treatment prior to endoscopy increased survival in a subset of patients with active variceal bleeding accompanied by hemodynamic repercussions. Methods: Consecutive patients aged 18 to 75 years diagnosed with cirrhosis, acute variceal bleeding, and hemodynamic repercussions between July 1997 and December 1998 were identified. Hemodynamic repercussions were defined according to the protocol-specified criteria for uncontrolled bleeding derived from the Baveno II criteria (ie, heart rate >100 beats per minute or systolic blood pressure <80 mmHg). Patients were administered an intravenous bolus of 50 µg followed by a continuous infusion of vapreotide 50 µg per hour, or placebo, for 5 days. Therapeutic endoscopy was conducted within 12 hours of initiation of infusion, and patients were followed for 42 days. Results: In the intent-to-treat population (N=196), 103 patients had hemodynamic repercussions upon hospitalization. Baseline demographic characteristics were similar among the vapreotide (n=45) and placebo (n=58) treatment groups. Vapreotide significantly reduced the number of patient deaths versus placebo at days 15 (7% vs 24%, respectively; P=0.02) and 42 (7% vs 31%, respectively; P=0.002). Vapreotide treatment also significantly decreased active bleeding at time of endoscopy (29%) versus placebo (50%; P=0.03). Vapreotide-treated patients required significantly fewer alternative interventions at day 42 (16%) versus patients receiving placebo (41%; P=0.005). Conclusions: Early administration of vapreotide significantly reduced active bleeding and mortality in patients experiencing acute variceal bleeding accompanied by hemodynamic repercussions. These findings identify a subgroup of cirrhosis patients with an increased risk of mortality that may benefit substantially from early vapreotide treatment combined with endoscopic therapy.

NODULAR REGENERATIVE HYPERPLASIA: A CLINICO-PATHOLOGICAL EVALUATION

Background: Noncirrhotic portal hypertension may be secondary to several under-recognized disorders of the liver, with
potentially fatal complications. Nodular regenerative hyperplasia (NRH) is one such disorder that can result in noncirrhotic portal hypertension. Portal and hepatic vascular abnormalities have been postulated as a potential underlying etiology of NRH. Aim: To describe the histological characteristics and evaluate for the presence of nodular regenerative hyperplasia liver biopsies of patients with chronic granulomatous disease, sickle cell disease, systemic mastocytosis, and common variable immunodeficiency; all systemic diseases that have been reported to occur in conjunction with NRH. Methods: The liver biopsies of 180 patients enrolled in natural history protocols including chronic granulomatous disease, sickle cell disease, systemic mastocytosis, and common variable immunodeficiency at the National Institutes of Health were reviewed and evaluated for adequacy of tissue. H&E, Masson, Reticulin and anti-cytokeratin 7 (CK7) stains were evaluated. Biopsies were scored for the presence of fibrosis, regeneration, portal venopathy, hemorrhage, pigmented macrophages, sinusoidal dilatation, sinusoidal fibrosis, veno-occlusive changes, ductular proliferation, and CK7 expression in zone 3 hepatocytes. Associations between these scores were performed by disease and by histological findings using the chi squared test and Fisher’s test. Results: 129 biopsies were evaluated. Nodular regenerative hyperplasia was present in 13.6%, 16.7%, and 16.7% of cases of chronic granulomatous disease, sickle cell disease, and systemic mastocytosis, respectively. There was a statistically significant association between the presence of NRH and sinusoidal fibrosis (p<0.0001), NRH and CK7 ductular proliferation (p=0.05), and NRH and CK7 zone 3 hepatocyte expression (p<0.0001), but not with hemorrhage (p=0.172). There was also a significant association between NRH and portal venopathy (p=0.018) consistent with a currently accepted theory of obliterative portal venopathy as a potential underlying mechanism in the pathogenesis of NRH. Veno-occlusive changes were correlated with hemorrhage (p=0.002) and central CK7 expression (p<0.034), but not NRH (p=0.167). Conclusion: NRH appears to be prevalent in patients with systemic disorders which might affect the hepatic microcirculation. Significant histologic associations are apparent on systematic evaluation of liver biopsy specimens. In particular, NRH is correlated with vascular damage and evidence of regeneration. Current evaluation will correlate laboratory values, imaging characteristics, and histology.

THE NEAR-INFRARED SPECTROSCOPY (NIRS) IS USEFUL IN THE DIAGNOSIS OF MINIMAL AND OVERT HEPATIC ENCEPHALOPATHY

Hiroyuki Nakanishi1, Masayuki Kurosaki2, Kaoru Nakanishi2, Takamasa Noda2, Takashi Kitamura3, Itoko Hirayama4, Mitsuaki Satou1, Tomohiro Tanaka1, Nobutoshi Komatsu1, Ken Ueda1, Sayaka Satou3, Takanori Hosokawa1, Naoki Umeda1, Kaoru Tsuchiya, Jun Itakura, Kimitaka Anami, Osamu Saitou, Yasutaka Asahina, Masatoshi Uchihara, Teruhiko Higuchi, Nobuyuki Enomoto, Namiki Izumi

Background: Although some patients with chronic liver disease exert subclinical level of hepatic encephalopathy (HE), there is no established diagnostic tool for this minimal HE. Recently in psychiatric disease, near-infrared spectroscopy (NIRS) has been utilized for the evaluation of the brain functions. NIRS has advantage of noninvasive and bed side measurements of regional cerebral blood volume in terms of the relative concentrations of oxyhemoglobin (oxy Hb) and deoxyhemoglobin (deoxy Hb), with a high time resolution. The aim of the present study was to evaluate the usefulness of NIRS in the diagnosis of minimal hepatic encephalopathy in patients with liver cirrhosis. Methods: Fortyfive patients with chronic liver disease and 12 healthy control subjects were enrolled in the study after giving written consent. Sixteen patients had overt HE. Seven patients who had chronic liver disease and abnormality in electric encephalography (EEG) and did not have overt HE were defined as minimal HE. The relative concentrations of oxy Hb were measured every 0.1 sec during word fluency task, with 52 channel NIRS machine. We analyzed the channels 36-38 and 46-49 that were located in forehead which has been shown to be specific for mental disorder. Results: The overt HE patients were characterized by a smaller and slower oxy Hb increase during the task as compared to that of healthy control subjects. The average peak value of oxy Hb was 0.24±0.14 in overt HE patients compared to 0.68±0.41 in subjects without HE (P<0.001). The average peak value was significantly small in minimal or overt HE. The increase of oxy Hb concentration were also smaller and slower during word fluency task in 18 patients with abnormal EEG were smaller than that of 31 subjects with normal EEG (P=0.02). The patients with minimal or overt HE showed smaller increasing of oxyhemoglobin concentration than that of subjects without HE. The average of respective peak values of channel 36-38 and 46-49 were 0.45±0.35 in minimal or overt HE patients and 0.24±0.13 in subjects without HE (P=0.01). These results indicate that NIRS showed small increase in cerebral blood flow in response to a stimulation imposed in patients with minimal HE, as well as in overt HE. Conclusions: The patients of minimal HE has the characteristic time course of cerebral blood flow in the frontal lobe during the task as measured by NIRS. Simple and noninvasive measurement of cerebral blood flow by NIRS could be a new diagnostic modality for HE.

GROWTH HORMONE-STIMULATED IGF-1 GENERATION IN CIRRHOSIS REFLECTS HEPATOCELLULAR DYSFUNCTION

Nimer Assy1, Yaacov Baruch1,2, Yosef Pruzansky2, Zeev Hochberg3,4, Diana Gaitini1,2, Zila Shen Orr5; 1Liver Unit, Sief Hospital, Safed, Israel; 2Liver Unit, Rambam Hospital, Haifa, Israel; 3Pediatrics, Rambam Hospital, Haifa, Israel; 4Endocrinology, Rambam Hospital, Haifa, Israel; 5Ultrasound Unit, Rambam Hospital, Haifa, Israel; 6Faculty of medicine, Technion institute, Haifa, Israel

Background: Previous studies have demonstrated that serum IGF-1 generation correlate with the extent of hepatic dysfunction. Serum IGF-1 generation correlate may be an influential factor in determine whether basal and/or growth hormone (GH) stimulated IGF-1 levels are decreased in patients with cirrhosis. Aim: To determine whether basal and/or growth hormone (GH) stimulated IGF-1 generation correlate with the extent of hepatic dysfunction. Methods: 53 patients (56±2 yrs) with post viral and cryptogenic cirrhosis and normal renal function were enrolled in the study. Serum IGF-1 levels were measured byRIA before and 24 hours after a single sc injection of GH (0.06 mg/kg/body
SECONDARY PARENCHYMAL DAMAGES IN CIRRHOTIC LIVERS

Cirrhosis is associated with low serum IGF-1 levels and an attenuated response to exogenous GH. These findings correlate with the extent of hepatic dysfunction rather than the presence of portal hypertension or malnutrition.

SECONDARY PARENCHYMAL DAMAGES IN CIRRHOTIC LIVERS ASSOCIATED WITH ACTIVATED PLATELET AGGREGATION IN SINUSOIDS

Yoshihiro Ikura1, Chizuko Kitabayashi2, Masashi Nakagawa1, Hideyuki Ishimoto1, Keita Kinoshita1, Stephen H. Caldwell2, Makiko Ueda3; 1Pathology, Osaka City University Graduate School of Medicine, Osaka, Japan; 2Pathology, Yale University, New Haven, CT; 3Pathology, Yale University, New Haven, CT

Background and Aims: Circulatory disturbances occurring in cirrhotic livers have been believed to cause further hepatic damage. Previous histological studies have shown morphological evidence of parenchymal extinction associated with hepatic thrombosis. However, no study has shown potential contribution of thrombus formation/activated platelet aggregation to parenchymal extinction in cirrhotic livers. On the other hand, thrombocytopenia is one of the common systemic complications of liver cirrhosis. It has been explained by increased platelet destruction due to hypersplenism and by reduced thrombopoietin production in diseased livers. We have hypothesized that consumption of platelets related to parenchymal extinction may also contribute to thrombocytopenia in cirrhotics. To test this hypothesis, we performed the following immunohistochemical investigation.

Methods: Frozen liver samples of chronic hepatitis (n=4), cirrhosis (n=7) and normal livers (n=5) obtained at autopsy were thin-sliced and stained with immunoperoxidase using specific antibodies against platelet glycoprotein IIb/IIIa (GP IIb/IIIa) and P-selectin (both from Dako Corp., Carpinteria, CA) and examined under standard microscopy. The sections were then subjected to immunofluorescent staining with anti-GP IIb/IIIa and anti-P-selectin. Double positive areas, indicating the aggregation of activated platelets, were measured by computer-aided morphometry (NIH image, Bethesda, MD). The data were expressed as % tissue area and analyzed by non-parametric tests [Mann-Whitney U-test and Spearman rank correlation (Rs)].

Results: In normal livers, activated platelet aggregation, namely platelet thrombus, in sinusoids was rarely seen, and there was no parenchymal damage associated with sinusoidal thrombosis. In contrast, cirrhotic livers had many foci of activated platelet aggregation, which was frequently accompanied by patchy liver cell necrosis/degeneration. Areas of activated platelet aggregation were significantly (p<0.028) greater in cirrhotic livers (0.36±0.13%) than in normal livers (0.21±0.06%). Furthermore, the areas of activated platelet aggregation were correlated to peripheral platelet counts (R=0.54, p<0.037).

Conclusion: These findings suggest that secondary parenchymal damage in cirrhotic livers is closely associated with sinusoidal thrombosis characterized by activated platelet aggregation in sinusoids, and that increased platelet consumption in diseased livers is associated with thrombocytopenia in patients with cirrhosis. The results also indicate that cautious consideration be given to the possible role of platelet inhibition in early cirrhosis.

CLOSTRIDIUM DIFFICILE INFECTION IS ASSOCIATED WITH PROTON PUMP INHIBITORS IN PATIENTS WITH CIRRHOSIS

Jasmohan S. Bajaj, Yelena Zadvornova, Muhammad Hafeezullah, Kia Saedian; Gastroenterology and Hepatology, Medical College of Wisconsin, Milwaukee, WI

Clostridium difficile-associated disease (CDAD) is a significant burden on the healthcare system. Proton pump inhibitor therapy (PPI) is associated with increased CDAD rates. Cirrhotic patients have a compromised immune status and are often prescribed PPI due to their propensity to develop upper GI symptoms and bleeding. The aim of this study was to describe whether PPI therapy increases the rate of CDAD in cirrhotics using a case-control method. Method: 985 cirrhotic inpatient charts were evaluated. PPI therapy was defined as PPI use as an outpatient prior to the admission. Antibiotic use was defined as clear evidence of antibiotic use before CDAD diagnosis either during or 7 days prior to admission. Charts without clear medication lists and suspected but not confirmed CDAD were excluded. 250 patients had suspected but only 54 had confirmed CDAD by toxin assay. These 54 were matched to 108 cirrhotics without CDAD admitted during the same time period by age. Demographics, antibiotic use, Child (CTP score) and PPI use were compared between groups and logistic regression with CDAD as the outcome was performed. Results: Both groups were similar with respect to demographic factors and reasons for admission. Antibiotic and PPI use were significantly higher in the CDAD group (Table). 85% of CDAD patients developed diarrhea during admission; the remaining had diarrhea on admission. The reasons for admission were mostly liver-related, but only <20% of admissions in both groups were because of spontaneous bacterial peritonitis. Pneumonia and suspected sepsis were the leading reasons (42% CDAD/36% other group) followed by variceal bleeding prophylaxis for antibiotic use. On univariate logistic regression with CDAD as the outcome, only antibiotic use (p<0.0001 OR: 6.7 CI: 3.2-14) and PPI use (p<0.0001 OR: 8; CI: 3.4-19) were significant predictors. On multivariate logistic regression PPI use (p<0.0001 OR: 6.1 CI: 3-14) and antibiotic use (p<0.0001, OR 7.8, CI: 3.2-19) were again significantly associated with CDAD. Conclusions: PPI use and, as would be expected, antibiotic use are independently associated with a higher risk of CDAD in cirrhotic patients. Trials to prospectively study this issue are warranted in the light of increasing rate of PPI therapy and CDAD.

WHAT IS THE BEST NON INVASIVE METHOD FOR EARLY PREDICTION OF CIRRHOSIS IN CHRONIC HEPATITIS C? PROSPECTIVE COMPARISON BETWEEN FIBROSCAN AND SERUM MARKERS (LOK INDEX, APRI, AST/ALT RATIO, PLATELET COUNT AND FIBROTEST)

Laurent Castera1,2, Pierre-Henri Bernard2, Brigitte Le Bail3, Juliette Foucher1,2, Wassil Merrouche1, Patrice Couzigou1, Victor de Ledinghen1, 1Hepatology, Hospital Haut Leveque, CHU Bordeaux, Pessac, France; 2Hepatology, Hospital St Andre, CHU Bordeaux, Bordeaux, France; 3Pathology, Hospital Pellegrin, CHU Bordeaux, Bordeaux, France

Background: Several non invasive methods have been proposed for the diagnosis of cirrhosis in patient with hepatitis C. They include routinely available markers (platelet count, AST/ALT ratio (AAR), AST to Platelet ratio (APRI), scores (Fibrotest (FT), LOK index (platelet count, AST/ALT ratio, and INR), and lately transient elastography (Fibroscan (FS)). Aim: to prospectively compare the performance of these different methods for the early prediction of cirrhosis in the same population of patients with chronic hepatitis C. Methods: 305 consecutive HCV patients (males 57%, mean age: 52±12) who undergone a liver biopsy (>10 mm) were studied. All patients had FS, FT, APRI, LOK index, AAR and platelet count in the same lab the day of liver biopsy, taken as reference. Cut-offs used for each test were those defined in the original studies. Performances were compared in intention to treat analysis (FS failure was considered as need for liver biopsy). Results: Significant fibrosis (Metavir F2-F3-F4) was present in 228 (75%) and cirrhosis (F4) in 77 (25%) (Child-Pugh A 90%; B 10%, oesophageal varices 39%). The mean liver biopsy length was: 19±8 mm. FS failure was observed in 10 patients (3%). Performances of the different methods are shown in the table. 32 out of 77 (42%) cirrhotic patients had no clinical or biochemical or US signs suggestive of cirrhosis. Among these 32 patients, cirrhosis could have been detected in 5 (16%) using the LOK index, in 5 (16%) using the AAR, in 8 (25%) using the APRI, in 14 (44%) using FT, and in 22 (70%) using FS, respectively. In addition, at a cut-off of 21 kPa, the performance of FS for detecting oesophageal varices was: Se 79%; Sp 72%, PPV 65%, and NPV 84%. Conclusions: Fibroscan is the best non invasive method for prediction of cirrhosis in chronic hepatitis C, as compared with other available methods, saving the need for liver biopsy in 90% of cases. In patients without any signs of cirrhosis, early diagnosis can be made in 70% of cases.

LIMITED EFFICACY OF PROPRANOLOL ALONE OR IN COMBINATION WITH ISOSORBIDE-5-MONONITRATE FOR PRIMARY PROPHYLAXIS OF VARICEAL BLEEDING: A STEP-WISE HEMODYNAMIC EVALUATION

Praveen Sharma, Ashish Kumar, Smruti R. Mishra, Sanjeev K. Jha, Barjesh C. Sharma, Shiv Kumar Sarin; Gastroenterology, G B Pant Hospital, New Delhi, India

Introduction: Response to propranolol is seen only in a proportion of patients receiving beta-blockers (BB) for primary prophylaxis of variceal bleeding. Addition of isosorbide-5-mononitrate (ISMN) enhances the portal pressure reducing effects of propranolol. The percentage efficacy of BB alone or the combination has not been well studied in large clinical studies. Aims: To evaluate (i) the efficacy of propranolol alone in reduction of hepatic venous pressure gradient (HVPG) and prevention of first bleed, and (ii) whether addition of ISMN reduces the non-response to BB. Patients and Methods: Consecutive cirrhotic patients with large (>5 mm) varices, who had not bled in the past, were enrolled. HVPG was measured at baseline and 4 wk after BB administration when target heart rate of 55/min was achieved. Response was defined if HVPG decreased to <12 mm Hg or ≤20% compared with basal value. ISMN was added to a maximum of 40mg/d in non-responders and HVPG measurement was repeated after 4 weeks. Side-effects were recorded and patients followed for a mean of 24 mo. Results: Fifty one cirrhotics (age 47.5±13.7 yr, M:F 41:10, Child-Pugh A:B:C 14:27:10, etiology: hepatitis B [19], hepatitis C [13], alcohol [11], cryptogenic [7] and autoimmune [1]) were enrolled. Baseline HVPG was 18.1±5mmHg. The mean BB dose was 124±49 mg/d. On intention to treat analysis, seventeen (33%) patients responded with mean reduction in HVPG of 30±8%. With ISMN in a mean dose of 32±8mg, six (12%) additional patients responded, with HVPG reduction of 35±14% from baseline. One (4%) of 23 responders and 4 (14%) of 28 non-responders bled during follow up of 12 mo. (p<0.05). Ten (20%) patients developed severe side-effects to BB requiring dose reduction (7 [21%] non responders and 3 [18%] responders [p=ns]). Six patients (18%) developed side-effects to nitrates. We did not find any correlation of response to etiology (p=0.08) or Child’s status (p=0.46). Conclusions: Propranolol alone achieves hemodynamic response in 33% and in combination with nitrates in additional 12% of patients. 55% patients remain non-responsive to current pharmacotherapy and such patients bleed significantly more than responders. A step-wise approach involving serial HVPG measurements is necessary to identify this subset of patients by 8 weeks as alternative treatments need to be administered in them.

CIRRHOTICS ADMITTED TO INTENSIVE CARE UNIT: THE IMPACT OF ACUTE RENAL FAILURE ON MORTALITY

Evangelos Cholongitas1, Marco Senzolo1, David Patch1, Steve Shaw1, James O’Beirne1, Andrew K. Burroughs1

Background: Although renal dysfunction is a well known risk factor of mortality in patients with cirrhosis, its exact role in critically ill cirrhotics admitted to an Intensive Care Unit (ICU), has not been assessed extensively. Aim: To evaluate the impact of acute renal failure (ARF) on 6 weeks mortality in cirrhotics admitted to ICU. Patients/methods: 312 cirrhotics (182 M, mean age 49.6±11.5yrs) were consecutively admitted during the study period. The patients (n=128, 40%) (group 1) with ARF on admission and/or during ICU were compared with the patients whose ICU-stay was not complicated with ARF (n=184, 60%) (group 2). At admission, 40 variables, including demographic, clinical and laboratory data, were available. Child-Pugh (CP), MELD, Apache II, SOFA and OSF scores on admission, were evaluated and compared by ROC curves. Results: Group 1, compared to group 2 patients, had longer period of stay in ICU (5 vs 4 days, p=0.04), were admitted less frequently for upper gastrointestinal bleeding (44% vs 73%) and required cardiovascular support more frequently with inotropes (90% vs 75%), (p<0.001). Mortality was significantly higher in group 1, compared to group 2 (91% vs 47%, p<0.001). At admission, group 1, compared to group 2, had significantly higher CP (12 vs 11), MELD (31 vs 21), SOFA (13 vs 9) and OSF (2 vs 1.5) scores (p<0.001). In the total cohort of patients (n=312), ARF was an independent factor of mortality (OR=5.4, 95 CI:2.4-12.5). In group 1, factors independently associated with mortality were: higher FiO2 (p=0.044), bilirubin (p=0.021) and creatinine (p=0.002) on admission. Predictive value of outcome in terms of ROC was best for SOFA score (AUC>0.75). Amongst group 1 patients, those with ARF on admission, compared to those who developed ARF during ICU stay, needed ventilatory (p=0.04) and haemofiltration (p=0.02) support more frequently and they had higher bilirubin (p=0.002) and prognostic scores (p<0.001) on admission. Conclusions: ARF at admission or during ICU stay is strongly predictive of mortality, which is high, despite supportive therapeutic interventions. Preventive measures are needed to prevent ARF, to improve prognosis.

EVALUATION OF HEPATIC BLOOD FLOW BEFORE AND AFTER TREATMENT FOR ESOPHAGOGASTRIC VARICES BY XENON COMPUTED TOMOGRAPHY - MEASUREMENT OF QUANTITATIVE PORTAL VENOUS AND HEPATIC ARTERIAL TISSUE BLOOD FLOW

Hideaki Takahashi1, Michihiko Suzuki1, Hiroki Ikeda1,Minoru Kobayashi1, Noriaki Okuse1, Nobuyuki Matsumoto1, Chiaki Okuse1, Norie Yamada1,2, Hiroshi Yotsuyanagi2,3, Shiro Maeyama1,3, Shiro Inoue1, Shigeru Sase1, Fumio Itoh1; 1Department of Internal Medicine, Division of Gastroenterology and Hepatology, St.Marianna University, School of Medicine, Kawasaki, Japan; 2Department of Internal Medicine, Division of Infectious Disease, University of Tokyo, Tokyo, Japan; 3Kitakashiwa Rehabilitation General Hospital, Kashiwa, Japan; 4Center for Liver Disease, Kiyokawa Hospital, Tokyo, Japan; 5Anzai Medical Co.Ltd, Tokyo, Japan

Background: Xenon computed tomography (Xe-CT) provides substantial quantitave and visual information on hepatic blood flow (HBF), allowing separate evaluation of hepatic arterial and portal blood flow. We have previously reported that it was useful to measure HBF by Xe-CT in patients with chronic hepatitis C and nonalcoholic steatohepatitis, and noted significant decreases in portal blood flow with increasing hepatic fibrosis (Suzuki et al, 2003AASLD #545, Kobayashi et al, 2006AASLD #1064). Arterial blood flow increases in order to compensate for decreased portal blood flow in patients with liver cirrhosis. In the present study, we thus performed Xe-CT in patients with
esophagogastric varices before and after treatment, and evaluated HBF. Patients: Subjects comprised 36 patients with esophagogastric varices (26 men, 10 women, median patient age was 61 ± 11 years, range 37-77). Etiology was as follows: hepatitis B virus (B), n=1; hepatitis C virus (C), n=13; alcohol (Al), n=12, C+Al, n=5; B+C+Al, n=1; unknown, n=4. All patients received treatment with endoscopic injection sclerotherapy (n=32) or balloon-occluded retrograde transvenous obliteration (n=4). Method: The imaging devices, protocol and processing were the same as reported previously. Using the CT images obtained, portal venous tissue blood flow (PVTBF) and hepatic arterial tissue blood flow (HATBF) were separately calculated (ml/100ml/min) pixel by pixel. Total hepatic tissue blood flow (THBF) was obtained by adding PVTBF to HATBF. Xe-CT was performed before and after treatment. In addition, we measured indocyanine green retention rate after 15 minutes (ICG15) (%), total bile acids (nmol/ml) (TBA), ammonia (µg/dl) (NH3), prothrombin time (%)(PT), albumin (g/dl) (Alb) and total cholesterol (mg/dl) (TC) before and after treatment. Results: PVTBF, HATBF and THBF before treatment were 32.3 ± 14.0, 23.4 ± 13.4 and 55.7 ± 20.7, respectively. Those after treatment were 39.5 ± 13.7, 17.4 ± 7.1, and 56.9 ± 17.0, respectively. PVTBF after treatment was significantly higher than before treatment (p<0.001), and HATBF after treatment were significantly lower than those before treatment (p=0.037). ICG15R, TBA and NH3 after treatment were significantly lower than those before treatment (p=0.026, p=0.010, p=0.014, respectively). Although TC, Alb and PT after treatment was significantly lower than those before treatment, they immediately recovered similar values as before treatment. Conclusion: In evaluation of HBF using Xe-CT, we confirmed that HATBF decreased in response to increase of PVTBF after treatment for esophagogastric varices. Increase of PVTBF might lead ICG15R, TBA and NH3 to the improvement.

781 PROSPECTIVE ASSESSMENT OF RENAL HISTOPATHOLOGICAL LESIONS PRIOR TO LIVER TRANSPLANTATION

Yvon Calmus1, Dominique Nochy2, Philippe Cluzel3, Corinne Antoine4, Olivier Scatton5, Olivier Saoubrane6, Filomena Conti7, Denis Glotz8; 1Hôpital Cochin, Paris, France; 2Hôpital Européen Georges Pompidou, Paris, France; 3Hôpital Pitié-Salpêtrière, Paris, France; 4Hôpital Saint-Louis, Paris, France

Terminal renal failure occurs in more than 10 % of liver transplant recipients after 10 years. We have previously shown that, beside calcineurin inhibitor nephrotoxicity, substantial renal lesions may be related to diabetes, arterial hypertension, accumulation of hydroxysterolstarch (HES), and the etiology of the liver disease. We made the hypothesis that these lesions may be already present at the time of liver transplantation (LT), a finding that could lead to adapt the perioperative management. This work investigated prospectively whether renal histopathological lesions were present before LT by performing a renal biopsy by endovenous route in 60 candidates to LT with end-stage liver disease. These patients were 58 ± 10 years old; 10 had a diabetes, and 21 an arterial hypertension; the liver disease was related to alcohol in 32 cases, HCV and HBV in 12 and 5 cases, and to a cholestatic disease in 7 cases. The biochemical parameters were : Child score 10 ± 2; MELD score 18 ± 4; prothrombin rate 60 ± 10 %; creatinin serum level 90 ± 6 umol/L; proteinuria 0.12 ± 0.04 g/24h. Severe side effects related to the procedure were limited to 2 cases of macroscopic hematuria, lasting less than 24 hours. In 10 cases, the material obtained during the procedure did not allow histological analysis. Among the 50 samples available, 21 were considered as normal or without significant lesions; in 29 cases, substantial lesions, mainly related to IgA glomerulonephritis (11 cases), glomerulosclerosis (12 cases), and HES accumulation (4 cases), were often combined; in 5 cases, the lesions were severe, leading to combined kidney/liver transplantation in 2 cases. The presence of histological lesions was associated with worse renal function, proteinuria, and more severe liver condition (Table). However, no clear threshold could be found between patients with and without significant lesions. In conclusion, significant renal lesions are detectable in more than 50 % of the candidates to LT. Histological findings often combined lesions related to the liver disease and to an associated cause (diabetes, previous treatment by HES). Significant proteinuria or renal failure should indicate a renal biopsy. Results of histological analysis could help to decide either to perform a combined renal/liver transplantation or to adapt the immunosuppressive regimen.

782 THE USEFULNESS OF MEASURING LIVER STIFFNESS IN PREDICTING THE DEVELOPMENT HEPATOCELLULAR CARCINOMA

Sang Hoon Ahn1,2, Seung Up Kim1, Do Young Kim1,2, Ja Kyung Kim1,2, Hyo Jin Yang1, Yong Han Paik1,2, Kwan Sik Lee1,2, Byung Soo Kim1, Chae Yoon Chan1,2, Young Myoung Moon4, Kwang Hyub Han1,2, 1Department of Internal Medicine, Yonsei University College of Medicine, Seoul, South Korea; 2Liver Cirrhosis Clinical Research Center, Yonsei University College of Medicine, Seoul, South Korea; 3Brain Korea 21 Project for Medical Science, Yonsei University College of Medicine, Seoul, South Korea; 4Department of Internal Medicine, Kwandong University College of Medicine, Seoul, South Korea

Background/Aims: The degree of liver fibrosis is closely correlated with the development of hepatocellular carcinoma (HCC). A new noninvasive method—transient elastography (FibroScan®)—can assess liver fibrosis by measuring liver stiffness and fibrosis. We investigated the effectiveness of FibroScan® in predicting HCC development. Subjects & Methods: Between July 2005 and June 2006, liver stiffness was measured in 273 patients with chronic hepatitis B (n=232), chronic hepatitis C (n=41), alcoholic liver disease (n=11), or other liver disease (n=22). This cohort was followed for the occurrence of HCC. Results: The median follow-up duration was 13.6 months (8.1–21.9) and the median interval from the day of FibroScan® assessment to HCC occurrence was 13.0 months (10.8–20.0). The mean age of the patients without and
with HCC development was 52.6 and 58.4 years, respectively (P=0.296). Male gender predominated (male:female, 211:102). In comparing the two groups, biochemical tests, AFP, HBV DNA levels, and clinical diagnosis (chronic hepatitis/cirrhosis) did not differ significantly, while liver stiffness (16.0 kPa for no HCC occurrence, 26.2 kPa for HCC occurrence, P=0.040) and Child–Pugh class A/B (301/5 for no HCC occurrence, 6/1 for HCC occurrence, P=0.016) differed significantly. The area under the receiver operating curve (AUROC) for stiffness was 0.793. Considering the optimal sensitivity and specificity, the cutoff value for predicting the development of HCC from our data was 16.0 kPa. Using a cutoff of 16.0 kPa, the sensitivity and specificity were 0.86 and 0.65, respectively. Conclusions: Our data suggest that transient elastography is effective in predicting the development of HCC and that patients with an initial liver stiffness score >16.0 kPa have a greater chance of developing HCC than those with a score <16.0 kPa. Keywords: Hepatocellular carcinoma, Prediction, Liver stiffness measurement

783 USEFULNESS OF LIVER STIFFNESS MEASUREMENT IN DISCRIMINATING BETWEEN CHRONIC HEPATITIS B AND COMPENSATED CIRRHOSIS

Do Young Kim1,2, Seung Up Kim1,2, Young Joon Yoon1,2, Sang Hoan Ahn1,3, Yang Han Paik1,2, Kwan Sik Lee1,2, Kwang Hyub Han1,3, Chae Yoon Chan1,2, Young Myoung Moon1,2, Department of Internal Medicine, Yonsei University College of Medicine, Seoul, South Korea; 1Institute of Gastroenterology, Seoul, South Korea; 2Liver Cirrhosis Clinical Research Center, Seoul, South Korea; 3Department of Internal Medicine, Kwandong University College of Medicine, Goyang, South Korea

Background/Aim: It is difficult to differentiate between chronic hepatitis and early compensated cirrhosis solely by laboratory and ultrasonographic features. The aim of this study was to assess the usefulness of liver stiffness measurement (LSM) in discriminating between chronic hepatitis B and compensated liver cirrhosis. Patients/Methods: Between May 2005 and Dec 2006, a total of 124 patients with hepatitis B virus-related liver disease underwent liver biopsy and LSM. Of these, 31 patients had definite clinical evidence of cirrhosis. Thus, 93 patients who did not fulfill the clinical criteria for liver cirrhosis were recruited in this study. The clinical criteria for liver cirrhosis were as follows: 1) history of overt complication of cirrhosis such as ascites, variceal bleeding, hepatic encephalopathy, or 2) platelet count <100,000/mm3 and ultrasonographic findings suggestive of cirrhosis such as blunted, nodular liver edge accompanied by splenomegaly (>10 cm). The cut-off value of LSM for the diagnosis of cirrhosis was set as 10.5 kPa. Results: There were 71 males and 20 females with a mean age of 40 years. The mean aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels were 36 and 46 IU/L, respectively. The mean platelet count, albumin, total bilirubin, and prothrombin time (PT) were 177,000/mm3, 4.5 g/dl, 0.8 mg/dl, and 96 sec, respectively. The median LSM score was 9.1 kPa (4.2–36.3). All the patients were divided into two groups by liver biopsy result; group A (cirrhosis, n=39) and group B (chronic hepatitis B, n=52). In comparison of two groups, the mean age of group A was significantly higher than group B (47 vs. 35 years, P<0.001). The platelet count and PT in group A were also statistically different from group B (147,000/mm3 vs. 201,000/mm3, P<0.001; 91% vs. 99%, P=0.02). The median value of LSM in each group was 11.8 kPa (6.8–36.3) and 7.6 kPa (4.2–28.4), respectively (P<0.001). In group A, the number of patients with LSM >10.5 kPa was 23 (sensitivity, 23/39=0.59). In group B, the number of patients with LSM ≤10.5 kPa was 41 (specificity, 41/52=0.78). The positive predictive and negative predictive value (NPV) was 0.68 and 0.72, respectively. The area under receiver operating characteristics (AUROC) curve was 0.78, whereas the AUROC of AST/ALT and APRI ([AST/upper normal limit]/platelet) was 0.54 and 0.74, respectively. Conclusion: LSM showed an acceptable diagnostic accuracy, especially high NPV, in the discrimination between chronic hepatitis B and compensated liver cirrhosis.

784 URINARY LIPOCALIN2 REFLECTS HEPATIC DYSFUNCTION IN PATIENTS WITH CHRONIC LIVER DISEASE

Jin-Wook Kim, Sook-Hyang Jeong; internal medicine, Seoul National University Bundang Hospital, Seongnam, South Korea

Lipocalins form a large family of small extracellular proteins with a binding property to small hydrophobic molecules and cell surface receptors. Lipocalin 2 (LCN2), also known as neutrophil gelatinase-associated lipocalin (NGAL), forms complex with matrix metalloproteinase-9 (MMP-9) and inhibits auto-degradation of MMP9. LCN2 / MMP-9 complex was shown to be present in the urine of breast cancer patients, suggesting its role in the progression of cancer. We hypothesized that urinary LCN2 would be increased in advanced cirrhosis and/or hepatocellular carcinoma (HCC) in which MMP-9 might contribute to the pathogenesis of disease progression. Urinary LCN2 was quantified by ELISA in patients with fatty liver (n=7), chronic HBV carrier / chronic viral hepatitis (n=24) and liver cirrhosis (n=5) with or without HCC and corrected for urinary concentration of creatinine. Urinary lipocalin2 level was significantly increased in patients with liver cirrhosis (30.1 ± 5.6 mg/mg creatinine) compared to fatty liver (2.7 ± 1.0) or non-cirrhotic HBV carrier / chronic viral hepatitis patients (6.7 ± 2.4) (P = 0.006, Fig. 1). Associated HCC tended to increase the level of urinary lipocalin2 levels in cirrhotic patients and real-time quantitative PCR showed increased LCN2 mRNA in HCC compared to background cirrhotic tissues. However, LCN2 level was not significantly different between HCC and non-HCC patients (13.4 vs. 11.9, p = 0.732). Serum albumin (r = -0.52), total bilirubin (r = 0.50), prothrombin time (INR; r = 0.34), Child–Pugh score (r = 0.56), and MELD score (r = 0.48) correlated significantly with urinary LCN2. AST and ALT did not show significant correlation with urinary LCN2. Among the non-invasive predictors of hepatic fibrosis, FORNS score (r = 0.29) and FIB-4 score (r = 0.35) significantly correlated with urinary LCN2. In multivariate analysis, hepatic encephalopathy, serum albumin and bilirubin were independent predictor or urinary LCN2 levels. In conclusion, urinary lipocalin2 increases as liver disease progresses from simple steatosis / chronic hepatitis to advanced liver cirrhosis and correlates with known indicators of hepatic dysfunction and fibrosis. We postulate that dynamic remodeling of hepatic extracellular matrix is associated with increased urinary excretion of LCN2 in patients with advanced chronic liver disease.

Background/Aim: Model for end-stage liver disease with incorporation of serum sodium (MELD-Na) was suggested to provide better survival prediction than MELD alone for patients with end stage liver disease in Western countries. However, there is no data verifying the usefulness of MELD-Na for predicting short term mortality of cirrhotic patients in Asian countries where the etiology and the course of chronic liver diseases may be different. This study was aimed to determine whether MELD-Na would be more accurate in the prediction of short term mortality than other prognostic models such as Child-Turcotte-Pugh (CTP) and MELD in an Asian country as well. Methods: Medical records of patients with liver cirrhosis who admitted at Korea University Ansan Hospital between January, 1996 and September, 2006 were retrospectively reviewed. Patients with hepatocellular carcinoma, chronic renal failure, serious cardiopulmonary disease, sepsis or other malignant tumors were excluded. The cumulative survival rates according to the respective scores of three prognostic models at admission were decided with Kaplan-Meier presumed values, and the differences of survival were verified with log rank test. Predictability on mortality for three months and one year were analyzed using the area under receiver operating characteristics (AUC). Results: Data from 355 patients (male, 266; female, 89) were analyzed. Mean age was 55.9 years old. Major causes of liver cirrhosis were alcohol (177 patients, 49.9%), chronic HBV infection (142 patients, 40.0%), and chronic HCV infection (20 patients, 5.6%). Miscellaneous causes (16 patients, 4.5%) included autoimmune hepatitis, nonalcoholic fatty liver disease, and primary biliary cirrhosis. Mean follow up period was 18.9 months. One hundred patients (28%) died during the study period. All of the three models showed significant differences in the cumulative survival rate according to the scores at admission (p<0.001). The AUC of CTP, MELD, and MELD-Na in predicting the three-months mortality were 0.828, 0.845, and 0.862, p<0.05) and the AUC of each score system for death within one year were 0.792, 0.800, and 0.831, respectively (p>0.05). The AUC of MELD-Na in predicting short term death was the highest, although not statistically significant. However, multivariate analysis showed that only MELD-Na was significantly related to three-month mortality among three prognostic models (p=0.012). Conclusion: It was shown that MELD-Na is more appropriate in predicting short term mortality, but larger scale studies are needed to confirm the superiority of MELD-Na to MELD or CTP in patients with liver cirrhosis.

786 LIVER INJURY IS ASSOCIATED WITH MORTALITY IN SICKLE CELL DISEASE

Jordan J. Feld1, Tammy Shields2, Mark T. Gladwin2, Mariana E. Hildesheim2, James S. Nichols2, David Kleiner3, T. Jake Liang1, Jay H. Hoofnagle1, Gregory J. Kato2, Theo Heller1; 1Liver Diseases Branch, NIDDK, NIH, Bethesda, MD; 2Vascular Diseases Branch, NHLBI, NIH, Bethesda, MD; 3Liver Diseases Branch, NHLBI, NIH, Bethesda, MD

Background: Sickle cell disease (SCD) is a blood disorder leading to progressive multi-organ damage. Although hepatic abnormalities have been described in SCD, it is unknown if they relate to disease outcome. Aims: To determine if markers of liver involvement affect survival in SCD. Methods: We evaluated a large cohort of well-characterized patients with SCD followed at the NIH. Cox proportional hazards regression was used to assess factors associated with mortality. Univariate and multivariate logistic regression were performed to determine factors associated with identified predictors of mortality. Results: A total of 247 patients (148F/99M) with a mean age of 36.2 (18-74) years were followed for a median of 26.7 (0.3-49) months. Twenty-two patients died during that period. One patient with hepatitis C infection and iron overload underwent liver transplantation. Liver parameters, markers of iron overload and factors previously identified to be associated with mortality in SCD (age, pulmonary hypertension, WBC and creatinine) were evaluated by Cox regression. By multivariable analysis, direct bilirubin (HR 2.6 95% CI 1.4-4.8, p=0.002) and log ferritin (HR 1.6 95% CI 1.1-2.5, p=0.018) were independently associated with mortality. Pulmonary hypertension and WBC contributed to the final mortality model but were not independently statistically significant. To determine factors associated with predictors of mortality, logistic regression was performed. By multivariable analysis, increasing number of blood transfusions, WBC and ALT associated with a serum ferritin above 1,000 µg/l while increasing inferior vena cava diameter, mean arterial blood pressure, AST and LDH were associated with an elevation of direct bilirubin. Interpretation/Conclusion: Serum ferritin and direct bilirubin are independently associated with mortality in SCD. Although ferritin reflects transfusion-related iron overload, it may also be a marker of liver inflammation. Elevation of direct bilirubin is associated with evidence of hepatic congestion. The additional association with markers of hemolysis suggests that the inability to handle increased bilirubin loads in the face of chronic congestion may indicate subtle but clinically important impairment of hepatic function. Monitoring of serum ferritin and direct bilirubin levels may be helpful in assessing prognosis in patients with SCD.

2Hematology Department, 2nd Propaedeutic Internal Medicine Clinic, Hippokration Hospital, Aristotle University of Thessaloniki, Thessaloniki, Greece

Introduction: Spur cell anemia (SCA) is a rare cause of hemolytic anemia in patients with advanced cirrhosis, more often alcohol-related. Diagnosis is made by the morphological appearance of red blood cells in peripheral blood smear. It is associated with bad prognosis and is considered reversible after liver transplantation. Aim: To evaluate the incidence of spur cell anemia in hospitalized patients with advanced cirrhosis and to correlate it with disease severity as well as overall survival.

Methods: From March 2004 to April 2006 all patients with advanced cirrhosis who were hospitalized for various conditions were examined for spur cells. Excluding criteria were: hepatocellular carcinoma at the time of examination, hemoglobinopathies, direct Coombs positive, chronic renal failure (not hepatorenal syndrome), sepsis, active bleeding and cirrhosis due to cholestatic liver disease. 48 patients, median age 66 years old (range 29-84) and male/female ratio 40/8 were included. The etiology of cirrhosis was: viral-17 patients (35.42%), alcohol-21 patients (43.75%) and cryptogenic-10 patients (20.83%). Patients were divided in two groups: patients without spur cells (Group A, n=26) and with spur cells (group B, n=22). Results: Overall 22 out of 48 patients (45.83%) had evidence of spur cells in blood smear. Seven out of 48 patients (14.58%) had >5% spur cells. The presence of spur cells was associated with more advanced liver disease (Child C 90.9% vs 62.5% and MELD score 24.5 vs 18 for group B vs A, p<0.001 respectively) and mainly alcohol-related (54.55 vs 34.62%). Patients with spur cells had lower hemoglobin level (8.8 vs 11.2 g/dL, p=0.001), higher bilirubin level (total/unconj-5.3 vs 3.78 vs 2.35/1.58 mg/dL, p<0.001), higher reticulocyte count (3.5% vs 1.6%, p<0.001), number of RBC transfused (12 vs 0, p<0.001) and shorter survival [90 vs 270 days, p<0.001]. When we compared patients with 1-5% (n=15) vs >5% spur cells (n=7), we found statistical difference in MELD score (21 vs 30, p=0.012), bilirubin level (total/unconj 4.4/3.3 vs 14.7/7.35mg/dL, p=0.026) and survival (150 vs 25, p=0.002). Three patients with spur cells underwent liver transplantation, one died during the operation from uncontrolled bleeding, one died 5 days later due to multigorgan failure and one is still alive with no spur cells detected in blood smear.

Conclusion: The presence of spur cells in not an uncommon finding in patients with advanced liver disease, however a poor outcome correlates with increasing number of spur cells. This entity is reversible only with liver transplantation.

Disclosures:
The following people have nothing to disclose: Themistoklis Vassiliadis, Sofia Vakalopoulou, Alexander Mpoumpounaris, Vasilis Perifanis, Dimitrios Gkisakis, Lemonia Mathiopoulou, Konstantinos Theodoropoulos, Nikolaos Grammatikos, Nikolaos Nikolaidis, Vasilina Garipidou, Olga Giouleme, Nikolaos Evgenidis.

THE IMPACT OF SERUM POTASSIUM CONCENTRATION ON MORTALITY FOLLOWING LIVER TRANSPLANTATION: A COHORT MULTI-CENTRE STUDY

Muhammad F. Dawwas1, James D. Lewsey2, Christopher J. Watson1, Alexander E. Gimson1; 1Hepatobiliary and transplant Unit, Addenbrooke's Hospital, Cambridge, United Kingdom; 2Public Health Research Unit, University of Glasgow, Glasgow, United Kingdom

BACKGROUND: Potassium plays a key role in human metabolism in both health and disease. The impact of recipient serum potassium concentration [K] on mortality following liver transplantation has not been previously described. METHODS In this cohort multi-centre study, we used Cox proportional hazards modelling to assess the effect of recipient [K], measured immediately before transplantation, on the survival of all adults with chronic liver disease who received a first single organ liver transplant in the United Kingdom and Ireland between March 1994 and June 2005 (n=5,262), adjusting for a wide range of recipient, donor and graft characteristics. RESULTS Post-transplant mortality significantly varied by [K], being highest among recipients with [K] of greater than 4.4mmol/L and lowest among those with [K] of 3.5-3.9mmol/L (log-rank test for trend: p<0.0001). Compared to those with [K] of 3.5-3.9 mmol/L (n=1,332, reference category), the overall 5-year risk-adjusted mortality was higher among hyperkalaemic ([K]>5mmol/L) recipients (n=477, HR 1.35 95%CI 1.07-1.72) and those with [K] of 4.5-5.5mmol/L (n=914, HR 1.40 95%CI 1.18-1.67). Compared to the reference category, the excess mortality was however confined to the first post-transplant year among recipients with [K] of 4.5-5.5mmol/L (≤90 days: HR 1.52 95%CI 1.15-2.00; 90days-1year: HR 1.72 95%CI 1.20-2.45) with no significant difference thereafter (HR 1.09 95%CI 0.81-1.46, p=0.6). This was also true for hyperkalaemic ([K]>5mmol/L) recipients (≤90 days: HR 1.28 95%CI 0.87-1.89, 90 days-1year: HR 2.04 95%CI 1.27-3.29; >1 year: HR 1.15 95%CI 0.75-1.75). In contrast, hypokalaemic ([K]<3.5mmol/L) recipients (n=318) and those with [K] of 4-4.4mmol/L (n=1,829) had similar risk-adjusted mortality at the above time-points.

CONCLUSIONS Recipient serum potassium concentration is an independent predictor of death following liver transplantation. This finding could be of clinical utility in the management, risk stratification, selection and prioritisation of appropriate candidates for transplantation among patients with end-stage liver disease.

COMPARISON OF CONVENTIONAL TESTS WITH THROMBOELASTOGRAPHY (TEG) IN ASSESSING BLEEDING RISK IN DECOMPENSATED CIRRHOSIS PATIENTS

Edward Xavier1, Sang-Hoon Park1,2, James Patrie4, Elizabeth E. Haspenheide1, Patrick G. Northup1, Abdullah M. Al-Osaimi1, Gail Macik2, Gary L. Manuel5, Paul Mintz6, Stephen H. Caldwell7, Daniel S. May1,3, Choong-Kee Park2; 1Division of Gastroenterology and Hepatology, University of Virginia, Charlottesville, VA; 2Internal Medicine, Division of Gastroenterology and Hepatology, Hallym University, Sacred Heart Hospital, Anyang-si, South Korea; 3Faculdade de Medicina, Universidade Federal da Bahia, Salvador, Brazil; 4Department of Health Evaluations, University of Virginia, Charlottesville, VA; 5Division of Hematology, University of Virginia, Charlottesville, VA; 6Special Coagulation Laboratory, University of Virginia, Charlottesville, VA

Background – Recent studies have raised questions about the International Normalized Ratio (INR) in estimating bleeding risk in cirrhosis. Thromboelastography (TEG – Haemoscope, Niles, Ill) is an automated measure of multiple parameters of hemostasis including rate of clot formation (r), which reflects clotting factor availability, alpha angle (α), which reflects assembly of fibrin monomers, maximum amplitude (ma), which reflects platelet function, coagulation index (CI), which reflects hyperviscosity, clot strength (G), and amplitude 3 minutes after ma (A) which reflects clot lysis. We assessed the utility of PT/INR vs. TEG in hospitalized cirrhosis patients. Methods – We evaluated 14 consecutive hospitalized cirrhosis patients (BF, age 54.3 ± 10.7) with PT/INR, platelets, and TEG. TEG was performed on recalculated citrated specimens (allows study within 2 hours of collection) by a single operator on a computerized device and allowed for run for at least one hour after achieving maximum amplitude. Results – Mean PT/INR was 2.0 ± 1.0 (1.1-5.1) and mean platelet count was 70,571 ± 38,790 (13,000-156,000). Mean and ranges of the TEG were for = 4.7 ± 1.8 (2.3-8.7), k = 2.7 ± 1.3 (1.0-6.3), a = 58.1 ± 15.3 (15.7-75.4), ma = 45.8 ± 15.9 (12.2-74.8), CI = -1.2 ± 3.4 (-7.3-4.2), G = 5.15 ± 3.61 (0.7-14.9), A = 39 ± 17 (0.1-6.5). We could not detect any association between INR and TEG although trends were evident for k and α (p<0.06). Platelet count was associated with a and ma (p<0.05) by regression. Each parameter was then compared for INR ≥ 1.5 (n=9) vs. INR < 1.5 (n=5). We discerned differences only in k (p=0.05) and ma (p<0.01) between these groups. One patient (INR = 1.4 and plt = 51,000) had intractable vaginal bleeding and evidence of hyperfibrinolysis by TEG (A=0.1), indicating normal maximal clot amplitude but rapid dissolution by 30 minutes. Another patient (INR=1.5, plt 36,000) had only mild defect by TEG (ma 44.4, ref=51-69 with normal r). He received prophylactic plasma for central line exchange by conventional practice and developed clinically evident transfusion-related acute lung injury (TRALI). Conclusion – Conventional tests (INR and platelets) failed to detect the most significant hemostatic defect that we encountered (hyperfibrinolysis in 1 of 14 patients (7%). Plasma use based on conventional parameters was associated with suspected TRALI in a patient whose TEG showed only mild platelet dysfunction. Our findings demonstrate the limitations of conventional measures of hemostasis in cirrhosis and the need for larger trials to define the potential role of alternative methods.

Heart rate variability (HRV) is a measure of the physiological fluctuation of the cardiac cycle over time. Decreased HRV has been reported in a variety of clinical settings associated with increased production of inflammatory cytokines and neuropsychiatric impairment (Griffin et al., 2005; Vigo et al., 2004). HRV is decreased in patients with cirrhosis (Fleischer et al., 2000) but its relationship to the impairment of neuropsychiatric performance, commonly observed in these patients, has not been explored. The aim of this study was to determine the relationship between HRV, hepatic encephalopathy (HE) and inflammatory cytokines, in patients with cirrhosis. Seventy-five patients (51 males; age [mean±SD] 55±9 yr; Child A 43, B 12, C 20) with biopsy-proven cirrhosis, were classified as neuropsychiatically unimpaired (n=37) or as having minimal (8) or overt (30) HE, using clinical (Conn et al., 1977), psychometric (Weissenborn et al., 2001) and EEG criteria (Amodio et al., 1999).

HRV was assessed by applying linear (SDNN [Niskanen et al., 2004]) and non-linear methods (SD1 and SD2 from Poincaré plots [Tulppo et al., 1996]; Sample Entropy [Richman et al., 2000]) to the R-R interval series on a five-minute ECG. Reference data were obtained from eight healthy subjects (3 males; 40±12 yr). Inflammatory cytokines (TNFα, IL6, IL10, IL12) were measured in a subgroup of 22 patients. Differences between normally [non-normally] distributed variables were examined by ANOVA/ANCOVA (age adjustment) [Kruskal-Wallis ANOVA]; post-hoc comparisons were performed using the Tukey [Dunn's] test. Factorial ANOVA was used to examine the interacting effects of hepatic/neuropsychiatric impairment on HRV. Correlations were tested using the Spearman's R. HRV was significantly decreased in the patients with cirrhosis on both linear (SDNN 19.4±9.5 vs. 36.2±11.3 p<0.01) and non-linear indices (SD1 11.3±7.8 vs. 23.4±12.1 p<0.05; SD2 31.8±15.5 vs. 56.1±11.8 p<0.001; Sample Entropy 2.25±0.61 vs. 2.90±0.33 p<0.001). HRV indices decreased in parallel with the degree of neuropsychiatric impairment (p<0.000) independently of the degree of hepatic dysfunction (SD2: Child F[2,66]=0.27 p=0.76; HE F[2,66]=4.8 p=0.01; Child*HE F[2,66]=0.42 p=0.79). Significant correlations were found between HRV and EEG/psychometric variables. Plasma levels of IL6 correlated significantly with both indices of HRV and neuropsychiatric performance. The changes in HRV and neuropsychiatric status observed in patients with cirrhosis are linked, most likely via a common pathogenic mechanism mediated by inflammatory cytokines. These data support the hypothesis that systemic inflammation plays a role in the genesis of HE.

INCREASED RESTING ENERGY EXPENDITURE (REE) IN CIRRHOSIS. RELATIONSHIP WITH BODY COMPOSITION AND INSULIN RESISTANCE

Cesar Prieto-de-Frias, Marian Conchillo, Marina Payera, Gema Frihbeck, Maria Jesús Gil, Carmen Mugueta, Bruno Sangro, José Ignacio Herrera, Mercedes Inarraiaegui, Félix Alegre, Javier Salvador, Jesús Prieto, Jorge Quiroga; Liver Unit. Dep. of Internal Medicine, Clinica Universitaria de Navarra, Pamplona, Spain; 2Biochemistry, Clinica Universitaria de Navarra, Pamplona, Spain; 3Endocrinology, Clinica Universitaria de Navarra, Pamplona, Spain

Aim: Factors influencing REE in cirrhosis are poorly understood. This study evaluated REE and its relationships with body composition, intermediary metabolism and its regulatory hormones and calorie intake in male cirrhotics. Patients and Methods: Forty-six male cirrhotic patients were evaluated (Child: A:17, B:20, C:9). REE was evaluated by indirect calorimetry and is expressed as % of the estimated normal value for each patient. Body composition was studied by air-displacement plethysmography (Bod-Pod). Serum Insulin, glycogen, adiponectin and leptin were measured by RIA. Calorie intake was estimated by a dietary questionnaire. Results: REE was normal (85-115% of theoretical value) in 18 patients (39%) and high (116-160%) in 28 (61%). Patients with increased REE exhibited as compared with those with normal REE: lower Child-Pugh index (p<0.05), lower total body fat (p<0.001), lower percent of body fat (p<0.003), higher percent of lean body mass (p<0.003), higher insulin resistance as evaluated by the HOMA index (p<0.01) and lower serum leptin (p<0.015). Calorie intake was reduced in both groups as compared with that expected for matched healthy subjects but intake deficiency was more severe in patients with normal REE (p<0.02). Conclusions: Hypercatabolism is present in 60% of male cirrhotics. These patients are characterized by less advanced disease, a lower fat mass-to-lean mass ratio, higher insulin resistance and a less severe undernutrition. These results suggest that cirrhosis is a hypercatabolic state even from early stages of the disease. This may be related to an abnormal utilization of fuel substrates. Further investigation is needed to define whether individual-specific dietary or pharmacological interventions would be of metabolic benefit in cirrhosis.

BENEFICIAL EFFECTS OF TIPS ON PARTIAL PORTAL VEIN THROMBOSIS (PVT) IN PATIENTS WITH CIRRHOSIS

Angelo Luca, Roberto Miraglia, Gianluca Marrone, Luigi Maruzzelli, Adele D'Antoni, Giovanni Vizzini, Bruno Gridelli, Jaime Bosch; 1Liver Unit. Dpt. of Internal Medicine, Clinica Universitaria de Navarra, Pamplona, Spain; 2Biochemistry, Clinica Universitaria de Navarra, Pamplona, Spain; 3Endocrinology, Clinica Universitaria de Navarra, Pamplona, Spain

PURPOSE: Partial PVT is a common finding in cirrhotic patients. In patients listed for liver transplantation (LT) the extension of PVT may be a contraindication for LT. Our study investigated the effect of TIPS in cirrhotic patients with partial PVT. MATERIALS AND METHODS: From January 2002 to January 2006, 166 consecutive cirrhotic patients underwent TIPS placement at a single transplant center. A total of 33 patients with partial thrombosis of main portal vein (MPV), and/or superior mesenteric vein (SMV), and/or splenic vein (SV) was included in this study. Luminal occlusion was estimated using a multidetector CT before and after TIPS creation (mean follow-up 22±14 months). Twenty-one patients received bare stent, 12 patients PTFE-covered stent. Patients with PVT ≥50% underwent mechanical thrombolysis using a balloon catheter. RESULTS: TIPS was placed in all patients without procedure-related complications. Portal pressure decreased from 24.4±6.0 mmHg to 8.9±4.2 mmHg (p<0.001). MPV thrombosis which was detected in 31 patients decreased from 49% (range: 10-90%) to 3% (0-20%) (p<0.001) after TIPS creation. SMV thrombosis which was detected in 20 patients decreased from 46% (range: 10-90%) to 5% (0-15%) (p<0.001) after TIPS. Two patients with SV thrombosis of 80% and 15%, had a complete resolution and no change, respectively. In overall 23 patients had a complete resolution of PVT, 8 patients had a marked reduction (PVT <20%), and 2 patients had no changes. Seventeen patients had PVT ≥50%; after TIPS placement, 12 patients had a complete resolution of thrombosis and five a significant reduction (<20%). A total of 30 episodes of TIPS stenosis occurred in 17 patients at the follow-up. TIPS stenosis rate was greater using bare stent vs. PTFE-covered stent (1.33 vs. 0.16 episodes/patients, p<0.001). Nine patients underwent LT 21±14 months after TIPS and none of them had PVT. No patient has been removed from the waiting list due to extension of PVT. Kaplan Mayer survival at 2-years was 90%. CONCLUSION: Our study showed that in cirrhotic patients with partial PVT, TIPS is safe and causes complete resolution or reduction of thrombosis. In patients eligible for LT, TIPS may avoid the extension of the clot and reduce the risk for LT. Additional studies should investigate if partial PVT can be a primary indication for TIPS placement.

IS VON WILLEBRAND FACTOR A PREDICTIVE PARAMETER FOR CLINICALLY SIGNIFICANT PORTAL HYPERTENSION IN PATIENTS WITH LIVER CIRRHOSIS?

Monika Homonick, Arnulf Feilitsch, Gregor Ulbrich, Thomas Reiberger, Alfred Gangl, Markus Peck-Radosavljevic; Internal Medicine III, Div. Gastroenterology and Hepatology, Medical University of Vienna, Vienna, Austria

Introduction: In patients with liver cirrhosis elevated levels of von Willebrand factor antigen (vWF-Ag) are found frequently. vWF-Ag plays an important role in primary haemostasis and development of thrombotic vascular obliteration is discussed as a possible mechanism leading to portal hypertension. Invasive measurement of hepatic venous pressure gradient (HVPG) is the current gold standard for the diagnosis of portal hypertension. We therefore investigated if vWF-Ag levels in plasma correlate with portal pressure, indicated by HVPG. Further, we investigated if vWF-Ag is a predictive parameter for clinically significant portal hypertension. Methods: Forty eight patients (mean age 55 y, 36 m and 12 w) with alcoholic, viral (chronic hepatitis C), and cryptogenic liver cirrhosis were included. Portal hemodynamics were assessed indirectly by measurement of HVPG, vWF-Ag levels were measured by ELISA. Results: Forty one patients had clinically significant portal hypertension (PH) (i.e. HVPG>or=10). In these patients HVPG was 19 mmHg (mean, 95%CI: 17-21 mmHg), and in seven patients without PH HVPG was 5 mmHg (mean, 4-6 mmHg). vWF-Ag was signifi-
cantly increased in patients with portal hypertension: 375% (334-417%) compared to vWF-Ag in patients without portal hypertension: 230% (173-288%); p<0.001. Further, HVPG correlated significantly with vWF-Ag (R=0.65; p<0.0001). Patients with vWF-Ag levels >300% had a markedly greater risk of PH (odds ratio: 15.3). Conclusion: In patients with liver cirrhosis vWF-Ag is elevated and can discriminate between patients with clinically significant portal hypertension and those without with a cut-off vWF-Ag >300%. This cut off of value for vWF-Ag level as a non invasive parameter indicating clinically significant portal hypertension has to be confirmed in an independent larger patient sample.

796 MOLECULAR MECHANISMS UNDERLYING MUSCLE LOSS IN CIRRHOTIC PATIENTS

Manuela Merli1, Federica Gentili1, Michela Giusto1, Olivero Riggo1, Maurizio Muscaritoli2, Silvia Iannuzzi2, Paola Costelli3, Andrea Bonetto3, Massimo Rossi3; 1Dip.di medicina clinica, università di roma “La Sapienza”, Rome, Italy; 2gastroenterology, università di Roma “La Sapienza”, Roma, Italy; 3Surgical Department, Università di Roma “La Sapienza”, Roma, Italy.

Liver cirrhosis (LC) is frequently accompanied by malnutrition and muscle loss (ML), which in turn negatively affect quality of life, morbidity and mortality. Increased protein degradation or decreased protein synthesis are mechanisms which may be involved in ML. Increased gene expression of MuRF and MAFbx, the so called “atrogins”, or of Myostatin (MSTN), a negative modulator of skeletal muscle growth, have been found to be associated with protein degradation in different clinical conditions. On the other hand depletion in the expression of Insulin Like Growth Factor-1 (IGF-1) may document an impairment in protein anabolism. The study was aimed at exploring the molecular mechanism underlying ML in CLF. Muscle biopsies from rectus abdominis were obtained intraoperatively in 12 patients undergoing orthotopic liver transplantation (LC) and in 4 well-nourished subjects undergoing elective surgery (C). Total RNA was extracted and m-RNA for atrogins (MuRF-1, MAFbx), MSTN, and IGF-1 was assayed (arbitrary units) by semiquantitative PCR. Patients were classified with anthropometry (Mid Arm Muscle Area : MAMA < 5th) and Subjective Global Assessment (SGA 0 or 1-2). Results are shown in Table 1. Overall, no significant differences were observed between LC and C in m-RNA levels. When patients were stratified according to nutritional status or ML, MuRF-1 tended to be increased but the difference did not reach statistical significance. These preliminary data suggest that the molecular pathways underlying ML in LC might be different from those involved in other chronic diseases, such as cancer, and deserve further research.

797 PARTICULATE MATTER AS POTENTIAL TRIGGER FOR ESOPHAGEAL VARICEAL BLEEDING IN PATIENTS WITH CIRRHOSIS OF THE LIVER

Bernhard Angermayr1, Werner Brannath2, Gregor Ulbrich3, Franz Koenig2, Wolfgang Spangl3, Markus Peck-Radosavljevic1; 1Gas- troenterology and Hepatology, Medical University Vienna, Vienna, Austria; 2Medical Statistics, Medical University Vienna, Vienna, Austria; 3Federal Environment Agency, Vienna, Austria.

BACKGROUND: Particulate matter (PM10), a consequence of air pollution, has recently been identified to have an impact on the etiology of several pulmonary and cardiovascular diseases. Recent studies have shown that exposure to PM10 is associated with oxidative stress, inflammatory responses, and endothelial dysfunction. These mechanisms have also been identified to play a role in the pathophysiology of esophageal varical bleeding in patients with the portal hypertensive syndrome. AIM: Aim of the study was to investigate a possible correlation of levels of particulate matter in the city of Vienna, Austria, and the incidence of esophageal varical bleeding in patients with cirrhosis of the liver. PATIENTS AND METHODS: All data of patients with varical bleeding were collected prospectively (May 2004–May 2006) within an European multicenter study investigating patients with cirrhosis and varical bleeding. Data of the current study were retrieved retrospectively from the database. All patients of the Viennese sample with cirrhosis and esophageal varical bleeding were included into the study. During the study period, the Viennese Emergency Medical Services were to transfer all patients with a suspected varical bleeding to the General Hospital. For the study period, daily levels of ambient air pollution parameters were provided by the Federal Environment Agency. These included levels of NO2, CO2, CO, PM10, O3, and air pressure. The data were analyzed by a multivariate logistic regression analysis with a nonlinear time trend (restricted cubic spline) as well as covariables to model the potential influence of the winter season (heating period), the day of the week, and holidays. RESULTS: 52 patients were included into the study. A significant correlation between PM10 levels and occurrence of varical bleeding was observed (p=0.014; odds ratio=1.018). On days with PM10 concentrations exceeding the maximum permissible limit (50μg/m3), the probability of varical bleedings was significantly increased (p=0.002, odds ratio 2.83). No such correlations were found for NO2, CO2, CO, O3, and air pressure. Probability for varical bleeding was independent from season, day of the week, and holidays. CONCLUSIONS: The incidence of varical bleeding in patients with cirrhosis and portal hypertension correlates with levels of PM10. An increase of 10μg/m3 PM10 approximately increases the probability of varical bleeding by 20%. On days with PM10 higher than the maximum permissible limit, the risk for varical bleeding is approximately 2-fold increased. PM10- and therefore air pollution- seems to be a hitherto unknown trigger for varical bleeding.

INCREDIBLE MORTALITY IN PATIENTS WITH PORTOPULMONARY HYPERTENSION: HAVE WE LEARNED THE LESSON IN THE MELD ERA?
Prasun K. Jhal, Thomas D. Schiano, Priya Grewal; DIVISION OF LIVER DISEASES, MOUNT SINAI MEDICAL CENTER, New York, NY

Background: Severe portopulmonary hypertension (PoPH) has a poor patient outcome with a decreased survival and is a contraindication to liver transplantation (LT). Patients with advanced liver disease appear to have a high mortality from PoPH. We sought to identify the survival of patients with PoPH based on the MELD score. Methods: Patients undergoing pre-LT evaluation in Mount Sinai Hospital from 2003-2006 were retrospectively analyzed for the presence of PoPH. The diagnosis of PoPH was established by the clinical diagnosis of portal hypertension and right heart catheterization showing mean pulmonary artery pressure (mPAP)>25 mmHg, pulmonary capillary wedge pressure<15 mmHg and pulmonary vascular resistance>240 dyne/sec/cm5. MELD score at initial presentation was calculated for each patient. Death or LT was considered as the primary outcome. In patients with PoPH, the outcome was compared between subjects having a MELD score of >15 and <15. The survival data for patients with PoPH and a MELD>15 were further compared with age and sex-matched patients who had MELD>15 without PoPH and did not undergo LT. Results: 52 patients fulfilled the criteria for the diagnosis of PoPH within the study period. The mean MELD score was 17 (6-35). The mean mPAP was 49 (26-80) and pulmonary vascular resistance was 560 (240-1300). PoPH was more common in female gender (F: M 1.7:1). The mean age of diagnosis was 48 yrs (18-74). Forty three (83%) had liver disease due to HCV or alcohol. Twenty two patients (41%) were excluded from the study in view of age<18 yrs, poor compliance to therapy or inadequate follow up. Out of 30 patients, 20 (66%) received treatment for pulmonary hypertension. With a mean follow up of 39 months, 12 patients are still alive, 3 were transplanted, and 15 patients died within a mean period of 11 (1-26) months of presentation. There was no difference in mPAP between the survivor and non-survivor groups (45.8 vs. 50.5 mmHg, p=0.37). Age, gender and drug therapy for PoPH did not differ between the two groups. Of the 15 patients who died, only 3 had MELD<15, compared with 12 with MELD>15. The number of patients without PoPH with MELD>15 who did not undergo LT was 964 (mean follow up 18 months). When they were compared with patients having MELD>15 with PoPH, there was a statistically significant difference in mortality (46% vs. 85%). Conclusions: Patients with PoPH with a MELD score>15 have a significantly increased mortality when compared with patients with lower MELD score.

PREVALENCE OF PORTAL HYPERTENSIVE GASTROPATHTY AT DIAGNOSTIC UPPER GI ENDOSCOPY
Gautam Mehta1, Abtehale Al-Hussaini2, Patrick Kennedy1, Jonathan Hoare2, Mark R. Thursz1; 1Department of Hepatology, St Mary’s Hospital, Imperial College London, United Kingdom; 2Department of Gastroenterology, St Mary’s Hospital, Imperial College London, United Kingdom

Background: Portal hypertensive gastropathy (PHG) is a common complication of portal hypertension. PHG has been reported to affect up to two-thirds of patients with cirrhosis and portal hypertension, with an increasing incidence in higher Child-Pugh grade. However, despite a consensus of specific, diagnostic endoscopic features from the New Italian Endoscopy Club (1), the frequency with which PHG is a presenting feature of portal hypertension remains undefined. Aims and Methods: The aim of this study was to determine the prevalence of PHG in an unselected population attending for diagnostic upper GI endoscopy in a tertiary endoscopy centre. Furthermore, the proportion of patients with no history of liver disease, in whom PHG was the first manifestation of portal hypertension, was determined. PHG was defined as a snake-skin or mosaic-like appearance of the gastric mucosa, with or without the presence of red point lesions, cherry-red spots and black-brown spots. Results: A total of 17320 upper GI endoscopies were performed between January 2001 and January 2007. PHG was diagnosed in 254 (1.5%) patients. Esophageal varices (EV) were present in 152 patients, and 102 patients had PHG with no evidence of EV. Of these 102 patients, 36 (35.3%) had no previous history of portal hypertension or liver disease. The indications for endoscopy in these 36 patients were: anemia (27.8%), abdominal pain (25.0%), dyspepsia (22.2%), dysphagia (11.1%), vomiting (5.6%), weight loss (2.8%), oesophagitis (2.8%) and hiccoughs (2.8%). The majority of patients with EV and PHG had a history of portal hypertension or liver disease. Conclusions: One-third of de novo cases of portal hypertension are diagnosed in patients without a history of underlying portal hypertension or liver disease. Despite these limitations, this study confirms that PHG remains a rare clinical entity for the general endoscopist. Nevertheless, physicians and endoscopists must be aware of the endoscopic diagnostic features of PHG, since de novo PHG at diagnostic upper GI endoscopy may be a common mode of presentation of portal hypertension and underlying liver disease. 1. Carpinelli L, Primignani M, Pretoni P, et al. Portal hypertensive gastropathy: reproducibility of a classification, prevalence of elementary lesions, sensitivity and specificity in the diagnosis of cirrhosis of the liver: a NIHC multicentre study. Ital J Gastroenterol Hepatol 1997;29:533-40.

COUNTRY STIFFNESS PREDICT THE PRESENCE OF HEPATOCELULAR CARCINOMA?
Sang Hoon Ahn1,2, Seung Up Kim1, Kwang Hyub Han1,2, Ju Hyun Lee4, Hyo Jin Yang1, Do Young Kim1,2, Yong Han Paik1,2, Kwan Sik Lee1,2, Byung Soo Kim1, Chae Yoon Chon1,2, Young Myoung Moon2; 1Department of Internal Medicine, Yonsei University College of Medicine, Seoul, South Korea; 2Liver Cirrhosis Clinical Research Center, Yonsei University College of Medicine, Seoul, South Korea; 3Brain Korea 21 Project for Medical Science, Yonsei University College of Medicine, Seoul, South Korea; 4Department of Internal Medicine, National Health Insurance Corporation Ilsan Hospital, Goyang, South Korea; 5Department of Internal Medicine, Kwandong University College of Medicine, Seoul, South Korea

Background/Aims: The degree of liver fibrosis is one of the strongest risk factors for hepatocellular carcinoma (HCC) development. Several studies have validated the correlation between stiffness and fibrosis, and a new noninvasive method—transient elasticity. 1. n vivo
er, hepatic and portal venous blood of 103 subjects whose hepatic disease classification spanned the spectrum from healthy controls to patients with type 2 HRS. Groups included healthy controls (N=6), organ donors (N=11), compensated cirrhotics (N=17), uncomplicated ascites (N=24), refractory ascites, (N=9), Type 2 HRS (N=19), and CRF without liver disease (N=17). Results. A progressive rise in plasma NOx and L-Arg, but not ET-1, was seen in decompensated cirrhosis as a function of renal insufficiency and worsening azotemia. The highest levels of NOx and L-Arg were observed in patients with type 2 HRS (P < 0.001 vs all groups). Patients with CRF had peripheral NOx levels significantly lower than patients with type 2 HRS, but significantly higher than healthy controls. There were no quantitative differences in NOx and ET-1 in blood collected from peripheral vs portal or hepatic veins. In general, plasma levels of L-Arg tended to follow NOx levels which were the closest when L-Arg was measured in portal vein. Univariate analysis showed significant correlations between Child-Pugh score, MELD score, and Platelet counts for NOx and L-Arg, but not ET-1. Conclusion. Patients with decompenated cirrhosis show progressive elevation in plasma NOx that correlates with the severity of renal dysfunction from compensated cirrhosis to type 2 HRS at the end of the disease spectrum. In our data, this occurred with only minor changes in ET-1 and was not a function of renal failure per se. These findings, from a large series of patients, support the hypothesis that unopposed NO vasodilation as a result of worsening liver disease is a major contributor to renal failure in patients with decompenated cirrhosis.

COVERED-STENT TIPS OFFERS A BETTER SURVIVAL FOR CIRRHOTIC PATIENTS WITH REFRACTORY ASCITES

Nelson Antonio Perez Gutierrez1, Sylvie Evrard2, Geert Maleux1, A. Mroue2, Olivia Le Maine2, Frederik Nevens1; 1Hepatology, UZ Gasthuisberg, KULeuven, Leuven, Belgium; 2Gastroenterology & Hepatopancreatology, Erasme Hospital, ULB, Brussels, Belgium

Background/aim: Transjugular intrahepatic portosystemic shunt (TIPS) is used to treat refractory ascites (RA). The self-expanded polytetrafluoroethylene covered-stent-graft (cs TIPS) gives a better long-term patency rate. Our aim was to study whether cs-TIPS might improve survival. Methods: We compared in a prospective cohort study from 1992-2006 in 222 consecutive cirrhotic patients with RA the long-term outcome of 126 patients with a non-covered stent TIPS (ncs-TIPS) versus 96 with a cs TIPS. Liver transplantation (OLT) and/or death were the end points of the follow-up. Results: The baseline characteristics were similar: age 55±11 years, alcoholic cirrhosis (73% ncs-TIPS/80% cs-TIPS), Child-Pugh (9±2.0 ncs-TIPS/9.2±1.3 cs-TIPS) and MELD (15±6 ncs-TIPS/15±4.9 cs-TIPS). Successful bridge to OLT was reached in 10% (n=13) of the ncs-TIPS after a median of 3.7 months vs. 20% (n=19) of the cs-TIPS patients after a median of 3 months. One year shunt dysfunction occurred in 49% (n=63) of the ncs-TIPS vs. 19% (n=18) of the cs-TIPS (P<0.0001) and post TIPS encephalopathy in 56% (n=70) of the ncs-TIPS vs. 22% (n=22) in the cs-TIPS group (however, 10 patients needed a reduction stent) (P<0.0001). The overall OLT free survival was better in the cs-TIPS (P=0.0071). The gain in survival in the cs-TIPS patients occurred especially if they had a baseline MELD score <16 (P<0.0001). The one year OLT free survival of patients with MELD score <16: ncs-TIPS [63% (n=44)] vs. [80%

801
INCREASED PLASMA NITRIC OXIDE AND L-ARGININE IN CIRRHOTIC PATIENTS WITH PROGRESSIVE RENAL DYSFUNCTION

Zeid Kayali1, Jason Hanson2, Pedro Baron2,1, Okekkouk Ojojogo3,1, Edson Franco3,1, Jason Smith3, Gregory Watkins4, David Smith4, Victor Lamin5, Thanh Hoang5, Meleah Mathahs5, Robert Sowers6, Kyle Brown5,6, Warren N. Schmidt5,6; 1Internal Medicine. Liver Transplant Program., Loma Linda University Medical Center, Loma Linda, CA; 2Biochemistry, Loma Linda University Medical Center, Loma Linda, CA; 3Surgery, Loma Linda University Medical Center, Loma Linda, CA; 4Radiology, Loma Linda University Medical Center, Loma Linda, CA; 5Internal Medicine. Gastroenterology and Hepatology, Yale, New Haven, Connecticut, USA; 6Internal Medicine. Gastroenterology and Hepatology, Veterans Administration Medical Center, Iowa City, IA.

Vasodilatation in the peripheral and splanchnic vasculature is a prelude to the development of ascites and azotemia. Nitric oxide (NOx), a potent vasodilator, and endothelin-1 (ET-1), a vasoconstrictor, have been reported to be elevated in cirrhosis, however, whether alterations in the plasma balance of these mediators correlates with the development of progressive renal dysfunction in human cirrhosis is unclear. The purpose of this study was to compare plasma levels of NOx, the NOx precursor L-Arginine (L-Arg), and ET-1 in splanchnic and post-hepatic circulation in patients with cirrhosis, decompensated liver disease, and HRS as compared with healthy controls and patients with chronic renal failure (CRF) without hepatic disease. Methods: Serum NOx, L-Arg and ET-1 were measured in the peripheral, hepatic and portal venous blood of 103 subjects whose hepatic disease classification spanned the spectrum from healthy controls to patients with type 2 HRS. Groups included healthy controls (N=6), organ donors (N=11), compensated cirrhotics (N=17), uncomplicated ascites (N=24), refractory ascites, (N=9), Type 2 HRS (N=19), and CRF without liver disease (N=17). Results. A progressive rise in plasma NOx and L-Arg, but not ET-1, was seen in decompensated cirrhosis as a function of renal insufficiency and worsening azotemia. The highest levels of NOx and L-Arg were observed in patients with type 2 HRS (P < 0.001 vs all groups). Patients with CRF had peripheral NOx levels significantly lower than patients with type 2 HRS, but significantly higher than healthy controls. There were no quantitative differences in NOx and ET-1 in blood collected from peripheral vs portal or hepatic veins. In general, plasma levels of L-Arg tended to follow NOx levels which were the closest when L-Arg was measured in portal vein. Univariate analysis showed significant correlations between Child-Pugh score, MELD score, and Platelet counts for NOx and L-Arg, but not ET-1. Conclusion. Patients with decompenated cirrhosis show progressive elevation in plasma NOx that correlates with the severity of renal dysfunction from compensated cirrhosis to type 2 HRS at the end of the disease spectrum. In our data, this occurred with only minor changes in ET-1 and was not a function of renal failure per se. These findings, from a large series of patients, support the hypothesis that unopposed NO vasodilatation as a result of worsening liver disease is a major contributor to renal failure in patients with decompenated cirrhosis.

803 PROGNOSTIC VALUE OF ALGORITHMS COMBINING FIBROTEST®/FIBROSURE® (FT) AND ASHTEST® (HT) IN COMPARISON WITH MELD AND PUGH PROGNOSTIC INDEXES IN PATIENTS WITH SEVERE CIRRHOSIS

Dominique Thabut1, Didier Lebreuc2,3, Frédéric Oberti4, Jean-Marc Perarnau5, Bertrand Condral,6 Hélène Barraud,7 Faouzi Saliba8, Nicolas Carbonell9, Philippe Renard10, Mona Munteanu1, Rachel Morra1, Djamilia Messous1, Richard Moreau2,3, Pascal Lebray1, Thierry Poynard1, APHP Hôpital Pitie-Salpêtrière, Paris, France; 2APHP Beaujon, Paris, France; 3INSERM, U773, Centre de Recherche Biomédicale Bichat-Beaujon CRB3, Hôpital Beaujon, Clichy, France; 4CHU Angers, Angers, France; 5CHU Tours, Tours, France; 6Hôpital Sainte Camille, Bry sur Marne, France; 7CHU Clichy, Clichy, France; 8APHP Hôpital Paul Brousse, Paris, France; 9APHP Hôpital St Antoine, Paris, France; 10CH Argenteuil, Argenteuil, France

Background. FT and HT have been validated as biomarkers of fibrosis and acute alcoholic hepatitis. The prognostic value of FT has been validated at 5 years only for chronic hepatitis C (Clin Chem 2006). Aim. It is clinically useful to combine diagnostic and prognostic markers for the short-term prognosis of patients with severe cirrhosis. We prospectively validated the prognostic value of FT and HT at 2 and 6 months and their combination with prognostic markers in a multicenter prospective randomized trial of pentoxifylline vs placebo. Methods. The usual baseline clinical and biochemical characteristics plus FT, MELD, Pugh, HT (only for alcoholic liver disease - ALD) were assessed. The most discriminant algorithms combining FT and independent biomarkers were constructed according to multivariate analysis for the 2- and 6-month-prognosis. The prognostic values of FT and HT alone or in combination with other biomarkers were assessed and compared with the standard prognostic markers (Pugh and MELD) using univariate (log-rank test) and multivariate prognostic analysis (Cox model), and area under the ROC curves (AUROCs) for predicting death at 2 and 6 months (mo). Results. A total of 224 patients were included, all Pugh C, age 55 years, 78% male, 84% alcoholic cirrhosis. The mortality was 20% (44/224) and 33% (75/224) at 2 and 6 months. Baseline Pugh was 11.3 (0.07) m(se), MELD 19.8 (0.6), FT 0.94 (0.06), and HT 0.62 (0.02). The best algorithms for all causes of cirrhosis combined FT, creatinine and natremia (FTprog). In the total cohort, the best AUROCs at 2 and 6 mo were for FTprog 0.82 (0.04) and 0.78 (0.03); this was equivalent to MELD 0.78 (0.04) P=0.38 and 0.70 (0.04) P=0.11, higher than FT 0.75 (0.06) P=0.07 and 0.64 (0.04) P=0.001, and higher than the Pugh score 0.63 (0.05) and 0.59 (0.04), respectively. Pugh was significantly lower than FTprog and MELD P<0.01. Sensitivity analysis showed that the results were the same after excluding patients with non alcoholic cirrhosis, hepatocellular carcinoma, and those treated or not with pentoxifylline or steroids. Among the 189 patients with ALD, the combination of HT slightly increased the prognostic value of the algorithm (regression coefficient Z value P=0.04) but without significant difference in the AUROCs. Cutoffs with Se>90% and Sp>90% permitted to identify a group (n=102) with 95% 2month survival (95%CI 91-99%), one (n=83) with 79% survival (95%CI 70-88%), and one (n=41) with 41% survival (95%CI 26-56%). Conclusion: Algorithms combining Fibrotest, creatinine and natremia have prognostic values at 2 and 6 months similar to those of MELD and better than Pugh in patients with severe cirrhosis.

804 MONITORING OF LOW MOLECULAR HEPARINS IN PATIENTS WITH LIVER CIRRHOSIS

Matthias Sichau1, Lars Bechmann1, Guido Gerken1, Knut Kroeger2, Philip Hilgard3; 1Gastroenterology and Hepatology, University of Essen, Essen, Germany; 2Angiology, University Hospital Essen, Essen, Germany

Background: The use of low molecular heparins (LMH) in patients with advanced liver diseases is frequently avoided, due to coagulopathy and therefore an enhanced risk of bleeding complications under the medication. However, many patients with impaired liver function are at enhanced high risk of thrombosis (immobilization, presence of HCC) or even have an indication for therapeutic anticoagulation (portal vein thrombosis). Therefore the aim of this study was to evaluate the safety and efficacy of low molecular weight heparin (LMH) in patients with liver cirrhosis and impaired liver function. Methods: 52 consecutive patients (28 males; 24 females) with proven liver cirrhosis and the clinical indication for prophylactic LMH treatment were included. Enoxaparin (40mg/d) was applied subcutaneously. Anti-Xa-activity was assessed on two consecutive, four hours after drug application. Severity of the liver disease was quantified using the Child-Pugh-criteria and correlated with the anti-Xa-activity and the occurrence of complications. Results: Three out of 52 patients suffered from endoscopically treatable variceal bleeding during LMH treatment, most likely unrelated to treatment. No patient died of complications. A negative correlation between Child score and anti-Xa-activity was observed (Child A = 0,24 ±0,08 p<0,05; Child B = 0,15 ±0,09 p<0,05; Child C= 0,18 ±0,09 p<0,05). Also, anti-Xa-activity and extent of ascites were negatively correlated. Conclusion: Prophylactic use of Enoxaparin in patients with liver cirrhosis is safe and does not increase the risk of bleeding. A decreased anti-Xa-activity in cirrhotic patients and a negative correlation with the degree of liver function impairment indicates that common doses of LMH might be too low in this subgroup of patients. Low levels of AT-III due to reduced hepatocellular synthesis in cirrhosis are the most likely cause of this observation and currently further investigated.

CIRRHOSIS

INTRODUCTION:

Cirrhotic patients admitted to the intensive care unit (ITU) have a poor survival. Previous studies have addressed the ability of both liver specific (MELD, Child-Pugh) and ITU disease severity and organ failure (SOFA, APACHE 11) parameters to discriminate between survivors and non-survivors. These studies have shown that SOFA is superior to MELD and Child-Pugh (CPS) score however to our knowledge the impact of cirrhosis aetiology on ITU mortality has never been evaluated.

PATIENTS AND METHODS:

A total of 524 autopsies were reviewed and three groups of patients were identified. 1. A total of 364 patients with advanced liver disease had undergone autopsy and 47 were excluded. In only 93(29%) patients were the clinical and post-mortem diagnoses in complete agreement. Discrepancy between pre-mortem clinical and postmortem pathological diagnoses. Agreement between pre-mortem clinical and postmortem pathological diagnoses. Agreement between pre-mortem and postmortem diagnoses were compared using the Goldman system. Studies with limited autopsy and missing clinical diagnoses were excluded. Results: A total of 524 autopsies were reviewed and three groups of patients were identified. 1. A total of 364 patients with advanced liver disease had undergone autopsy and 47 were excluded. In only 93(29%) patients were the clinical and post-mortem diagnoses in complete agreement. Major missed diagnoses included: gastrointestinal bleeding-73, superficial variceal bleeding with or without esophageal ulcer-50, gastritis/ulcers-8, intraperitoneal bleeding-6, diffuse bleeding-7, pneumonia-23, fatal acute pancreatitis-6. Unusual findings included death due to hemorrhage...

808 VWF FUNCTIONS, ADAMTS-13 ACTIVITY AND ANTIGEN LEVELS IN PATIENTS WITH LIVER CIRRHOSIS

Istvan Tornai1, Papp Maria1, Miklos Udvardy2, Jolan Harsfalvi2; 112nd Department of Medicine, University of Debrecen, Debrecen, Hungary; 2Clinical Research Center, University of Debrecen, Debrecen, Hungary

Introduction. Liver cirrhosis is one of the major causes of the acquired haemostatic disorders. There are a lot of alterations, which could result in a reduced haemostatic capacity, but many compensatory mechanisms have also been detected. Methods. Patients with cirrhosis of different origin (n=94; m/f:45/49; Child A/B/C: 40/44/16%) and healthy volunteers (n=57) were examined. Platelet poor plasma was obtained then stored at -80°C and tested within 1-2 weeks. Von Willebrand factor (VWF) antigen (VWF:Ag), ristocetin cofactor activity (VWF:RCo), collagen binding activity (CBA) and ADAMTS-13 antigen levels were 140±44 %, 144±42 % and 169±53 %, respectively. VWF:Ag (220±60 %), VWF:RCo (144±42 %) and CBA levels (169±53 %) were significantly elevated in patients with cirrhosis as compared to the control group. However, the functional activities were not that high as the antigen level. The VWF:RCo/VWF:Ag and the CBA/VWF:Ag ratios were significantly reduced as compared to the control, respectively (0.65 vs.0.94 and 0.77 vs.0.92; p<0.01). Both functional activities were reduced to the same extent, the CBA/VWF:RCo ratio was 1.17 (control: 1.04, p=NS). Multimeric distribution was characterized by the presence and significant elevation of all molecular weight fractions with the significant predominance of the low molecular weight fractions. The activity and antigen levels of ADAMTS-13 showed a high variability, both substantially elevated and low values. The plasma level of ADAMTS-13 activity in cirrhotic patients was 135±71 % and in controls 126±45 % (p=NS). The ADAMTS-13 antigen levels were 140±83 vs. 124±44 %. Discussion. Plasma VWF:Ag level and its functional activities were significantly elevated in patients with liver cirrhosis. However, the decreased activity/antigen ratios indicate a relative loss of function of the molecule. This is also suggested by the altered multimeric structure i.e. the reduced polymerization. These changes might be the consequences of endothelial perturbation in liver cirrhosis which results in the alteration of the endothelial synthesis of VWF. Bacterial infection, frequent in cirrhosis, may contribute to this. ADAMTS-13 probably has no significant role in the structural and functional alteration of VWF in patients with liver cirrhosis. Elevated VWF might compensate the defect in primary haemostasis.

809 RELATIONSHIP BETWEEN SEVERITY OF LIVER DISEASE AND RISK OF GALLSTONES IN MEN WITH CHRONIC HEPATITIS C: A CLINICOPATHOLOGICAL STUDY

Reena Khianey1,2, Anastasios A. Mihas1,2, H. Robert Lippman2, HoChong Gilles1, Lisa Pinseyn1, Douglas M. Heuman1,2; 1GI Section (111-N), McGuire VA Medical Center, Richmond, VA; 2Medicine, Virginia Commonwealth University, Richmond, VA

Background: Pigment cholelithiasis is common in patients with chronic liver disease and cirrhosis. Its pathogenesis is incompletely understood. Our specific aims were 1) to assess the relationship between liver histology and risk of gallstone disease in a relatively homogeneous population of men with chronic hepatitis C; and 2) to examine the role of demographic, viral, clinical and laboratory features as determinants of gallstone risk. Methods: We retrospectively analyzed data from two groups of male veterans with hepatitis C whose liver disease spanned the spectrum from normal to end-stage cirrhosis. Group A consisted of 493 male veterans with hepatitis C who underwent both liver biopsy and ultrasonography at our institution in anticipation of antiviral therapy. Liver biopsies were reviewed by two experts, and activity and fibrosis were scored according to Ishak. Group B included 548 additional male veterans with hepatitis C and established cirrhosis referred from outside institutions for consideration of liver transplantation. Findings: In men undergoing liver biopsy for hepatitis C, gallstone disease (gallstones on imaging or history of cholecystectomy) was present in 23%. Prevalence of gallstone disease increased with severity of hepatic fibrosis. Lowest prevalence was seen in patients with Ishak fibrosis stage 0-2 (15%), increasing at Ishak fibrosis stages 3 and 4 (27%, p<.01 compared to stage <2), and a further increase was seen at Ishak stages 5-6 (34%). Gallstone disease was associated with platelet count <130k (39% vs. 19%, p<.01) and with increasing splenomegaly (absent=18%, mild=30%, moderate to severe=40%, p=.014). Hemoglobin, erythrocyte indices and reticulocytes were similar in patients with and without gallstones. Gallstone prevalence did not vary with history of alcoholism, obesity or diabetes mellitus, was similar in whites and African-Americans, and was unrelated to hepatitis C genotype or viral load. Gallstone disease and fibrosis severity both increased with age, but age and fibrosis stage were independently associated with gallstones by logistic regression. In group B, prevalence of gallstones by CTP class was A=47 %, B=50 % and C=50 % (differences NS) and was not significantly associated with MELD or CTP score. Conclusions: Age, hepatic fibrosis, and presence of splenomegaly and thrombocytopenia are the key determinants of gallstone risk in men with
810 SURVIVALS OF HEPATIC ENCEPHALOPATHY: RELEVANCE TO ETIOLOGY AND INITIAL COMPLICATION OF CIRRHOSIS

Chang Wook Kim, Jong Young Choi, Won Young Tak, Sung Kyu Choi, Jeong Heo, Mong Cho, Jeong Won Jang, Seung Kew Yoon, Joon Yeol Han, Young Sok Lee, Chang Don Lee. 

Background/Aims: Despite numerous studies concerning natural history and prognostic factors of cirrhosis, there are few reports about epidemiology and prognostic factors focused on hepatic encephalopathy (HE) as well as the relationships between survival of HE and several factors such as initial complication of cirrhosis, etiology of cirrhosis, and model for end-stage liver disease (MELD). Methods: A total of 223 consecutive liver cirrhosis patients diagnosed as the first episode of HE with flapping tremor (1st HE) were included in this study from 4 medical centers of Korea from January 2001 to December 2003. Initial complication of cirrhosis is defined as first event of cirrhosis complication such as ascites, variceal bleeding, HE, and hepatocellular carcinoma (HCC) in his or her life. Survival times from 1st HE were calculated using the Kaplan-Meier method. The prognostic significance of variables such as demographic data, etiology of cirrhosis, clinical laboratory data, initial complication of cirrhosis, Child-Pugh (CP) score, CP classification, MELD score and MELD classification was analyzed using Cox regression model. MELD classification is categorized as MELD-A, MELD-B, and MELD-C according to MELD score (≤19, 20-39 and ≥40, respectively). Results: The major etiology of cirrhosis was virus such as HBV (61%) and HCV (11%). The median interval (median ± SE) between initial complication and 1st HE was 9.0 ± 1.9 months. The interval between first variceal bleeding and 1st HE was longer than intervals between other initial complications and 1st HE. The median survival time from 1st HE was 86 ± 29 months (37 ± 9 months if HCC cases were included). The 1 year, 3 years, survival rate after 1st HE was 71% and 56%, respectively. On univariate and multivariate analyses, etiology of cirrhosis, CP score and MELD classification remained independently significant for survival. HE associated with HBV showed low hazard ratio compared to HE associated with HCV (hazard ratio of HBV vs. HCV 3.813, 95% CI 1.439-10.10, p = 0.007). Conclusions: The median survival time (86 months) after 1st HE in HBV endemic area was longer than those of previous reports in non-HBV endemic area. Etiology of cirrhosis, CP score and MELD classification are the most important prognostic factors in patients with 1st HE. These findings suggest that survival of HE may be improved after anti-viral agent such as lamivudine has been available in HBV-endemic area.

Layla Hajjafar1,2, Mendel Singer2, Anthony Post1; 1Gastroenterology and Hepatology, Case Medical Center, Cleveland, OH; 2Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH

Study Aim: There is no gold standard treatment for refractory ascites in cirrhotics, so we conducted a cost-effectiveness analysis comparing transjugular intrahepatic portosystemic shunt (TIPS) vs. repeated large volume paracentesis (LVP) with albumin infusion in this population. Methods: We performed a decision analysis using a Markov model in a hypothetical cohort of identical 40 year old cirrhotics with newly-diagnosed refractory ascites. The two treatment modalities compared were TIPS and repeated LVP with albumin infusion. Patients failing one treatment were automatically switched to the other. Using Monte Carlo simulation, these patients were followed until death. Estimates of treatment outcomes were obtained from 3 randomized controlled trials (RCTs). Costs were determined by Medicare reimbursement and health state utilities were assigned based on previous data in the literature when available. Both costs and utilities were discounted at a rate of 3% per year. We calibrated our model to produce 1 and 2-year mortality rates consistent with those defined by the 5 RCTs in the literature: 38% and 50%, respectively for TIPS and 43.5% and 57%, respectively for LVP. Results: The incremental cost-effectiveness ratio (ICER) was $36,451 per additional quality adjusted life-year (QALY) for TIPS when compared to repeated LVP at a rate of 1.5 LVPs/month (refer to table). When compared to repeated LVP at a frequency of 1 LVP/month, the ICER increased to $52,335/QALY. Conclusion: TIPS is cost-effective in the treatment of refractory ascites when compared to repeated LVP with albumin infusion at a frequency of greater than 1 LVP/month.

814 PULMONARY DYSFUNCTION AND THE HEPATOMONARY SYNDROME (HPS) IN CIRRHOSIS: PREVALENCE AND EFFECTS OF OXYGEN INHALATION
Soren Moller1, Aleksander Krag2,1, Jan L. Madsen1, Jens H. Henriksen3, Flemming Bendsen1; 1Dept. Clinical Physiology 239, Hvidovre Hospital, Hvidovre, Denmark; 2Dept. Medical Gastroenterology 439, Hvidovre Hospital, Hvidovre, Denmark

Background/Aims. Circulatory and pulmonary complications with gas exchange abnormalities are common in patients with cirrhosis. The prevalence of the hepatopulmonary syndrome (HPS) is variably reported from 8 to 20% but its precise relation to the liver function is unclear. The aims of the present study were therefore 1. to assess the prevalence of the HPS in consecutive patients with cirrhosis in relation to patient characteristics and 2. during a 100% oxygen test, to assess the cardiopulmonary effects and peripheral oxygenation in patients and in matched controls. Patients and Methods. Fifty patients (19 women and 31 men) with alcoholic cirrhosis (Child class A/B/C: 18/21/11) and 12 healthy matched controls were entered in the study. All underwent haemodynamic and pulmonary investigations including measurement of lung diffusion capacity (TLCO), a contrast-enhanced echocardiography (CEE), and a lung scan with determination of the extrapulmonary shunt fraction (EPSF) to diagnose HPS. A 100% oxygen test was performed with the assessment of PaO2, the alveolar-arterial oxygen gradient (AaPO2), and peripheral transcutaneous oxygen tension (tcPO2). Results All patients had portal hypertension and a hyperdynamic circulation (p<0.05). The EPSF was normal in the controls. Five patients had an EPSF fraction above 6% and a positive CEE. Three of these patients had a PaO2 below 10.7 kPa giving a frequency of HPS of 6%. PaO2 was reduced below 10.7 kPa in 39% and AaPO2 above 2.7 kPa in 60% of the patients and PaO2 correlated with EPSF (r=0.31, p<0.05). TLCO was reduced in 72% of the patients and correlated significantly with markers of metabolic liver function (p=0.01), splanchnic haemodynamics (p=0.004) and systemic haemodynamics (p=0.006). After oxygen inhalation, the change in heart rate and MAP were smaller in the patients (p<0.02) and PaO2 and AaPO2 increased to only 75% of the level in the controls.
TERLIPRESSIN THERAPY FOR RENAL DYSFUNCTION AND HYponatREMIA IN PATIENTS WITH LIVER FAILURE

Emilia Prakoso1,2, Jade D. Jamias1, Martin W. James1, David J. Koorey1, Simone I. Strasser1, Geoffrey W. McCaughan1,2, Nicholas A. Shackel1,2; 1AW Morrow Gastroenterology and Liver Centre, Royal Prince Alfred Hospital, Sydney, NSW, Australia; 2Liver Immunobiology Laboratory, Centenary Institute, Sydney, NSW, Australia

Background: Indications for terlipressin use other than hepatorenal syndrome (HRS) and variceal hemorrhage are poorly defined. Therefore, we performed an analysis of terlipressin therapy for renal dysfunction and hyponatremia in patients with liver failure. Methods: A retrospective analysis was performed on all patients at a large single tertiary referral centre, who received terlipressin for a minimum of 24 hours. Biochemical response was defined as: (a) the return of creatinine to ≤133 µmol/L in HRS, (b) normalization of creatinine (≤110 µmol/L) in renal failure other than HRS, and (c) an increase in serum sodium level by 5 mmol/L from baseline in hyponatremia (Na <130 mmol/L) without renal failure. Results: Between August 2003 - February 2007, 85 patients (61 male, 24 female) with median age of 52 years (range 27-78) were treated with terlipressin. Seventy-six patients received 1 course of terlipressin, 6 received 2 courses, and another 3 received 3 courses (total terlipressin courses = 97). Indications for terlipressin were HRS1 (13), HRS2 (41), renal failure other than HRS (18), and hyponatremia without renal failure (25). Median duration of treatment was 6 days (range 1-60). Baseline MELD score was >25 in 79% of patients. Etiology of liver failure was mostly viral hepatitis (42%) and alcohol (41%). For all indications, terlipressin resulted in an overall improvement in creatinine from a median of 164 to 116 µmol/L (p<0.05) and an increase in serum sodium from a median of 128 to 134 mmol/L (p<0.05). Response rates for HRS, renal failure other than HRS and hyponatremia without renal failure were 43%, 39% and 76% respectively. There were 26 adverse events (19 pulmonary edema, 2 cyanosis, 3 chest pain, 1 livedo reticularis and 1 bleeding ischaemic gastric ulcers). After the initial terlipressin therapy, the follow-up duration was 27 days (range 1-1248). Thirteen (15%) patients underwent liver transplantation and 56 (66%) died including 2 who were transplanted. The 30-day survival rates were 31%, 52%, 31% and 67% for HRS1, HRS2, renal failure other than HRS and hyponatremia without renal failure respectively. Conclusions: Terlipressin therapy resulted in improved renal function and increased serum sodium in those with advanced liver failure. However, its use is also associated with significant side effects. This is the largest study to date of terlipressin use and the first to demonstrate the efficacy of terlipressin in treating hyponatremia without renal failure in advanced liver failure.

MONOCYTE HLA-DR EXPRESSION IS A PROGNOSTIC MARKER FOR MORTALITY IN PATIENTS WITH ACUTE ON CHRONIC LIVER FAILURE

Marie-Luise Berres1, Eray Yagmur2, Barbara Schmeyer1, Alexander Koch1, Ron Winograd1, Axel M. Gressner2, Christian Trautwein1, Hermann E. Wasmuth1; 1Medical Department III, University Hospital Aachen, Aachen, Germany; 2Department of Clinical Chemistry and Pathobiocchemistry, University Hospital Aachen, Aachen, Germany

Background: Acute on chronic liver failure (ACLF) is associated with a poor prognosis and an increased susceptibility to infections. Recently, we showed that monocyte HLA-DR expression is decreased in patients with ACLF compared to healthy controls and subjects with stable liver cirrhosis (Wasmuth et al. J Hepatol 2005; 42: 195-201). However, the prognostic value of HLA-DR expression has not been systematically investigated
of plasma VEGF and sVEGF R1 was observed in liver cirrhosis of various etiologies by ELISA. Results. The significant increase in growth factor and its soluble receptors: sVEGF R1 and sVEGF R2 levels in all cirrhotic patients were increased respectively to the degree of liver insufficiency. It was demonstrated through a significant positive correlation with Child-Pugh score: r=0.38, P<0.001 for VEGF and r=0.77, P<0.001 for VEGF R1. The similar relationship was observed in respect to MELD classification: r=0.41, P<0.01 for VEGF and r=0.56, P<0.001 for sVEGF R2. In conclusion, our study suggests that serum VEGF and VEGF R1 may reflect the hepatic function impairment in liver cirrhosis and seems to be associated with portal hypertension symptoms. Disclosures: The following people have nothing to disclose: Jerzy Jaroszewicz, Robert Flisiak

818 CIRCULATING VASCULAR ENDOTHELIAL GROWTH FACTOR AND ITS SOLUBLE RECEPTORS IN PATIENTS WITH LIVER CIRRHOSIS: POSSIBLE ASSOCIATION WITH HEPATIC FUNCTION IMPAIRMENT

Jerzy Jaroszewicz, Robert Flisiak; Department of Infectious Diseases, Medical University of Bialystok, Bialystok, Poland

Recent studies provided in vivo evidences of an increased angiogenesis in animal model of portal hypertension and cirrhosis which was linked to increased expression of vascular endothelial growth factor. The aim of present study was to evaluate the plasma concentration of VEGF and its receptors in liver cirrhosis of various etiologies and the possible association with the degree of liver insufficiency. Methods. Vascular endothelial growth factor and its soluble receptors: sVEGF R1 and sVEGF R2 were measured in plasma of 78 patients with liver cirrhosis of various etiologies by ELISA. Results. The significant increase of plasma VEGF and sVEGF R1 was observed in liver cirrhosis compared to healthy individuals (153.1±51.9 pg/mL, P<0.05; 279.8±34.3 vs. 105.1±5.9 pg/mL, P<0.001, respectively). On the contrary VEGF R2 plasma concentration was lower in liver cirrhosis then in control group. Differences in plasma VEGF as well as its receptors R1 and R2 were not significant in patients with liver cirrhosis of various etiologies. Plasma VEGF and foremost sVEGF R1 showed significant associations with biochemical indices of liver function. Among clinical parameters of liver dysfunction only ascites revealed significant association with plasma VEGF and sVEGF R1. Plasma sVEGF R1 and VEGF, but not VEGF R2 levels in all ascites vs no ascites (§) p<0.05 ; pre vs post TIPS (±) p>0.05

819 ACCURATE ASSESSMENT OF CARDIAC FUNCTION AND MYOCARDIAL FIBROSIS IN LIVER CIRRHOSIS BY CONTRAST-ENHANCED CARDIAC MAGNETIC RESONANCE

Manuela Merli1, Olivero Riggio1, Lorenzo Ridola1, Gabriele Lombardi1, Giorgio Pinto1, Adolfo Francesco Attili1, Marco Francone2, Carlo Catalano2; 1Gastroenterology, Università di Roma “La Sapienza”, Rome, Italy; 2Radiology, Università di Roma “La Sapienza”, Rome, Italy

Liver cirrhosis is associated with vasodilatation and hyperdynamic circulation affecting cardiac function. Contrast-enhanced Cardiac Magnetic Resonance (CMR) is a new diagnostic tool for the evaluation of cardiac volumes, systolic and diastolic function and is also able to detect myocardial fibrosis (MF). We investigated 22 cirrhotic patients (all males, 56 ± 7 yrs, Child-Pugh A/ B-C 7/15 patients: 9 without ascites, 13 with ascites [actual]). Nine patients were re-evaluated 7 days after elective Transjugular Intrahepatic Portosystemic Shunt (TIPS). Six healthy males matched for age were used as controls. CMR study (Siemens Avanto 1.5 T, Germany) including cine steady state free-presssure (SSFP) imaging and velocity encoded cine MR (VENC) sequences was performed in all patients. Delayed Enhancement (DE) acquisitions were used for MF detection. Left End Dyastolic (LEDV), and Systolic Volume (LESV), Cardiac Output (CO), E/A ratio, Ejection Fraction (EF%), and Systemic Vascula r Resistances (SVR) were calculated. Plasma Renin Activity (PRA) was also measured. Statistical Analysis: mean ± SD, “t” test for unpaired and paired data. Cirrhotic patients showed increased CO, and decreased SVR and Mean Arterial Pressure than controls. MF was detected in 3 patients (13%). The behaviour of cardiac parameters in patients with and without ascites and before and after TIPS are shown in Table 1. Patients with ascites showed a significant reduction in ESV and E/A ratio, while PRA was higher. Seven days after TIPS procedure CO, LEDV, E/A ratio and EF significantly increased, while SVR and PRA decreased. CMR allows an accurate assessment of cardiac function (particularly in volumes acquisition) in patients with liver cirrhosis and may be a useful in the evaluation of patients before and after TIPS procedure.

CLINICAL COURSE AND PROGNOSIS OF CULTURE-NEGATIVE NEUTROCYTIC ASCITES AND SPONTANEOUS BACTERIAL PERITONITIS

Nuria Cañete1, Eva Erice2, Isabel Cirera1, Anna Bargalló2, Rosa Maria Morillas2,Montserrat Garcia-Retortillo1, Susanna Coll1, Felip Bory1, Helena Masnou2, Maria Dolors Giménez1, Ricard Solà1, Ramon Planas2

1Liver Section, Digestive Service, Hospital del Mar, Barcelona, Spain; 2Liver Section, Digestive Service, Hospital Germans Trias i Pujol, Badalona, Spain

Spontaneous infections of ascitic fluid include the classical spontaneous bacterial peritonitis (SBP) and culture-negative neutrocytic ascites (CNNA), diagnosed when the ascitic fluid culture grows no bacteria, and the ascitic fluid polymorphonuclear cell count is >250 cells/mL. CNNA has been considered as a variant of SBP, with a similar short- and long-term course of patients with either condition. AIM: To assess the clinical course and prognosis of SBP and CNNA in patients prospectively followed up after their first ascites decompensation. PATIENTS AND METHODS: From August 1997 to December 2002, 263 consecutive cirrhotic patients who developed the first episode of ascites were prospectively followed for a median of 41±3 months. Analysis of ascitic fluid was performed in all patients presenting symptoms of infection or when their clinical condition deteriorated. Laboratory analysis of ascitic fluid included total and differential cell counts, protein levels and bacteria cultures obtained by bedside inoculation of 10 mL of ascitic fluid into culture blood bottles (BACTEC). RESULTS. Fifty-eight patients developed 83 episodes of ascitic infection, being community-acquired in 60 cases (72%). Forty-four episodes (53%) were CNNA and 39 (47%) culture-positive SBP. Escherichia coli was the most frequently isolated organism (25 cases), followed by Streptococcus (10), and Enterococcus, Klebsiella, Staphylococcus and Morganella (1 case each). At admission, hepatic and renal function in patients with CNNA were significantly better than those from SBP group as indicated by higher prothrombin index (62 vs. 49%; p<0.001) and serum albumin (33±0.9 vs. 29±0.9 g/L; p<0.02), lower incidence of encephalopathy (18 vs. 46%; p<0.05), as well as lower Child-Pugh score (8.9±0.3 vs. 10.1±0.3; p<0.01) and MELD score (13.3±1.1 vs. 18.9±1.2; p<0.001). Moreover, ascitic polymorphonuclear cell count was lower in CNNA group than in SBP group (1256±252 vs. 5513±1117 cells/mL; p<0.001), and ascitic fluid infection resolved more quickly in CNNA patients than in SBP patients (4.2±0.3 vs. 6.7±0.9 days; p<0.01). CNNA group had a lower incidence of infection-induced renal failure than SBP group (18.2 vs. 38.5%; p=0.04). Although hospital mortality was similar in both groups (27 vs. 41%; NS), there was a trend forward to a lower cumulative mortality at 1-year in CNNA group (34 vs. 57%; p=0.09). CONCLUSION: CNNA occurs mostly in cirrhotic patients with less severe disease and seems to have a better clinical course and prognosis than SBP.

The following people have nothing to disclose: Nuria Cañete, Eva Erice, Isabel Cirera, Anna Bargalló, Rosa Maria Morillas, Montserrat Garcia-Retortillo, Susanna Coll, Felip Bory, Helena Masnou, Maria Dolors Giménez, Ricard Solà, Ramon Planas
822 HISTOLOGICAL PREDICTORS OF OESOPHAGEAL VARICES: A RETROSPECTIVE SINGLE CENTRE STUDY

Titus Thomas1, Sindu Menon2, David Semeraro2, Gerry Mortimer1, Vincent Lai1, Andy S. Austin1, Jan G. Freeman1; 1Hepatology, Derby City General Hospital, Derby, United Kingdom; 2Histopathology, Derby City General Hospital, Derby, United Kingdom

Background: Clinically significant portal hypertension (CSPH) is defined as a hepatic vein portal gradient of >12mm of Hg and may be complicated by the development of oesophageal varices. Studies have suggested that small nodularity and septal thickness correlates with CSPH 1 and a histological sub-classification of cirrhosis has been suggested. Aims: The aim of this study was to determine if the nodule size and septal thickness on histology were predictive variables for endoscopic presence of oesophageal varices. Methods: Patients with established cirrhosis were randomly selected from an endoscopy and histology database. Biopsies were retrospectively reviewed by two operators (TT & SM) who were blinded to the presence or absence of varices on endoscopy. Nodules were classified as small, mixed or large based on width of the nodule in relation to biopsy size. The septal thickness was classified as thin, medium or thick. Results: Of the 95 slides reviewed, 8 were excluded as they did not have histologically established cirrhosis leaving 87 slides (Males: 54, median age: 53 years (IQR: 48-59)) for the final analysis. In 49% of cases the etiology was alcoholic liver disease. The median biopsy size was 15mm (IQR: 12-20) and the median number of portal tracts was 3 (IQR: 2-4). The number of patients with small, mixed and large nodules was, 34, 32, and 21 respectively and the number with thin, medium and thick septae was 44, 22, and 21 respectively. There was a significant correlation between both nodule size (Rho 0.2, 95% CI 0.002-0.40, two sided p=0.05) and septal thickness (Rho 0.51, 95% CI, 0.34-0.65, two sided p=0.0001) with the endoscopic presence of varices. However the correlation between small nodule size and endoscopic presence of varices was weak. Conclusion: Small nodule size and thick septae are predictors of the presence of oesophageal varices on endoscopy. Patients with the above histological variables should be clinically prioritised to have an early endoscopy. 1. Nagula S, Danpat J, Grossmann RJ et al. Histological- haemodynamic correlation in cirrhosis: a histological classification of the severity of cirrhosis Journal of Hepatology 2006; 44: 111-117

824 MEDICATION ADHERENCE TO BETA-BLOCKER THERAPY FOR PRIMARY PROPHYLAXIS OF ESOPHAGEAL VARICEAL HEMORRHAGE IN A VETERAN POPULATION

Katarina Greer1, Claudia O. Zein2; 1Department of Medicine, Case Western Reserve University, Louis Stokes Cleveland VAMC and University Hospitals of Cleveland, Cleveland, OH; 2Division of Gastroenterology and Hepatology, Case Western Reserve University-Louis Stokes Cleveland VAMC, Cleveland, OH

Background: Non-cardioselective beta-blockers (BB) are the mainstay of primary prophylaxis (PP) of esophageal variceal hemorrhage (EVH). BB decrease the rate of EVH and EVH-related mortality. BB are also associated with adverse effects and adherence to therapy can be a challenge. Aims: To assess BB adherence and discontinuation among veterans prescribed BB for PP of EVH. Methods: All patients with EV diagnosis seen by medication possession ratios based on pharmacy refill records. Inadequate adherence was defined as possession ratio < 0.75. Statistical analyses were performed. Results: 340 patients with EV were identified; 98 were excluded because of EVH before or at EGD. Of the remaining 242, 138 (57%) were on BB. Mean follow-up was 2.9 years. Inadequate adherence was recorded in 64/137 (47%) of subjects. Patients with inadequate adherence were more likely to have subsequent EVH compared to those adherent to therapy (Log rank test, p=0.001), and more likely to have EVH or die (combined outcome)(p=0.003, Figure). By Proportional Hazards Fit this association was independent of severity of liver disease and other variables. Conclusions: 1. Inadequate adherence to BB therapy for PP of EVH is frequent in the veteran population; 2. In this cohort, patients with inadequate adherence to BB had higher rates of subsequent EVH and death; 3. Studies to identify ways to improve adherence to PP in this population, as well as of possible preferential use of other PP modalities.

823 SERUM-ASCITES ALBUMIN CONCENTRATION GRADIENT (SAAG) MORE THAN 1.5 G/DL PREDICTS ESOPHAGEAL VARICEAL HEMORRHAGE

Pises Pisesponsa, Suthinee Sripotong, Taned Chitapanarux, Apinya Leerapun, Satawat Thongsawat, Ong-ard Praisontarangkul; Department of Internal Medicine, Chiang Mai University, Chiang Mai, Thailand

Background: Although serum-ascites albumin concentration gradient (SAAG) was strongly correlated with portal hypertension, the significance of SAAG to predict complications of cirrhosis was less well defined. We conducted a retrospective cohort study to determine the correlation of SAAG level and complications of cirrhosis, namely esophageal variceal bleeding (EVB), spontaneous bacterial peritonitis (SBP), and hepatic encephalopathy (HE). Methods: One hundred and eight cirrhotic patients with ascites and high SAAG (>1.1 g/dl) were included. The patients were divided into 3 groups according to the degree of SAAG: Group A (SAAG 1.1-1.49 g/dl), Group B (SAAG 1.5-1.99 g/dl), and Group C (SAAG > 2 g/dl) and complications of cirrhosis were reviewed. Results: Twenty-six patients (29%) were alcoholic cirrhosis. Among the three groups (A, B, C), EVB was found in 5.9% (2 of 34), 30.8% (12 of 39), and 34% (12 of 35) respectively (p=0.008). SBP was also found in 17.6% (6 of 34) 30.8% (12 of 39), and 14.2% (5 of 35) respectively (p=0.013), but there was no significant difference in the rate of HE occurrence. Conclusion: Complications of cirrhosis were associated with the degree of SAAG. Patients with SAAG value of > 1.5 g/dl are likely to have EVB. Thus, prompt primary prophylaxis may be warranted. However the prospective study in larger number of patients is needed to confirm these results.

Selective impairments of covert visual attention and movement preparation in minimal hepatic encephalopathy

Dennhardt Joel 2, St Louis Eric 2, Steven J. Luck3, Michael D. Voigt1; 1Internal Medicine, University of Iowa Hospitals and Clinics, Iowa City, IA; 2Department Neurology, University of Iowa, Iowa City, IA; 3Center for Mind and Brain and Department of Psychology, University of California-Davis, Sacramento, CA

Background/Rationale: Detecting cognitive impairment in cirrhotic patients is challenging until crude psychomotor slowing and impaired vigilance manifest in advanced stages. We utilized N2pc and lateralized readiness potential (LRP) event-related potentials (ERPs) to enable eloquent temporal characterization of disordered visual attention and motor preparation in minimal hepatic encephalopathy (MHE). Methods: We recorded ERPs from 10 MHE subjects and 10 age-matched controls. ERPs were recorded from standard 10-20 placements in subjects performing a feature-conjunction visual-search task. Data analysis compared ERP waves from equivalent channels ipsilateral and contralateral to the target for N1, N2pc, LRP, and P3 waves. Results: LRP latency was significantly delayed in MHE (MHE=774ms, control=609.6ms, p<.01). N2PC onset latency was also significantly delayed in MHE using the jackknife-based scoring method (MHE=268.8ms, Control=217.6, difference=51.2ms; Fc=3.24, p<.05). N1 and P3 latencies were not significantly different between MHE and control subjects. Conclusions: Specific impairments in visual attention and movement preparation underlie MHE, sparing stimulus registration and categorization, implying selective cerebral dysfunction from regional alteration of neurotransmission or deposition of hepatic neurotoxins. N2pc and LRP ERPs deserve further study as potential biomarkers for MHE.

Lasting amelioration in the clinical course of decompensated alcoholic cirrhosis with boost infusions of mobilized peripheral blood stem cells

Dimitrios Kapetanos1, Evangelia Yannaki2, Achilles Anagnostopoulos2, Angeliki Xagorari2, Fotis Iordanidis2, Ioannis Batis2, Panayotis Kaloyannidis2, Evangelia Athanasiou2, Georgios Dourvas2, Athanasios Fassas2, George E. Kits1; 1Gastroenterology Department, George Papanikolaou Hospital, Thessaloniki, Greece; 2Hematology Department-BMT Unit and Gene and Cell Therapy Center, George Papanikolaou Hospital, Thessaloniki, Greece; 3Pathology Department, George Papanikolaou Hospital, Thessaloniki, Greece

Background and aims: Liver transplantation is the only definite cure for decompensated cirrhosis, but donor livers are lacking and many patients die while waiting for transplantation. There is accumulating evidence that hematopoietic stem cells (HSCs) contribute to liver regeneration and infusion of autologous mobilized HSCs may be an alternative or bridging procedure until transplantation. We studied the safety and efficacy of infusions of autologous mobilized HSCs in patients with decompensated alcoholic cirrhosis while waiting for liver transplantation. Methods: Ten patients with decompensated alcoholic cirrhosis with at least 6 months’ abstinence were screened. Four patients were enrolled and the rest were excluded due to excessive splenomegaly and thrombocytopenia. G-CSF 10 µg/kg/day was administered for 4-5 days before HSCs were collected. When more than 10 CD34+ cells/µL were detected, leukapheresis started, with target CD34+ cell yield at least 5x106/kg. Three mobilization courses were performed and mobilized stem cells were collected and reinfused to the patients. Performance status, Child-Pugh and MELD score as well as hospitalizations due to complications of cirrhosis were recorded. Results: Two patients (P1, P2) completed the three cycles, the third (P3) is on the third cycle and the fourth (P4) on the second. The procedure was well tolerated without serious toxicities. P1 and P2 had no hospitalization during follow up of 30 and 41 months respectively, in contrast to repeated admissions before the treatment, due to complications of cirrhosis. The Child-Pugh score dropped 3 and 1 points and the MELD score 6 and 5 points respectively. P1 underwent liver transplantation 30 months after enrollment but he suffered cardiac arrest and died. P2 is on steady state 41 months after enrollment. P3 and P4 have improved disease indices and performance status, 5 months after the second and first cycle respectively. VEGF-ELISA in the serum of P1 and CD34 count in a liver biopsy of P2 suggested that hepatic angiogenesis, induced by peripheral blood stem cells (PBSCs) or by G-CSF, might contribute to the observed improvement. Another possible explanation is direct transformation of PBSCs to hepatocytes. Conclusion: Our preliminary results suggest that infusion of autologous PBSCs may convert decompensated cirrhosis to compensated and may serve as a bridge to transplantation.

827 PROTECTIVE EFFECTS OF ERYTHROPOIETIN IN RATS WITH CIRRHOTIC CARDIOMYOPATHY

Hongquan Liu, Annie Feng, Samuel S. Lee; University of Calgary, Calgary, AB, Canada

Background: Erythropoietin (EPO) is a major regulator of erythropoiesis. In addition, EPO receptor 1 (EPOR1) is found in rat heart. EPO can protect cardiomyocytes from ischemic injury, attenuate myocardial inflammation by suppression of tumor necrosis factor (TNFα) and improve cardiac contractile function. Similar to ischemic cardiomyopathy, cirrhotic cardiomyopathy shows decreased beta-adrenoceptors (β-AR) and decreased systolic and diastolic responses to stress stimuli. To date, no medical therapies have been shown to improve contractile function in cirrhotic cardiomyopathy. Therefore, it is crucial to explore possible new therapeutic agents for this condition. Methods: Rats were divided into 4 groups, sham control; sham + EPO; bile duct ligation (BDL); and BDL + EPO (n=6 in each group), and were studied 4 wk after surgery. EPO (1000 U/kg body weight every other day, i.p.) or equivolumic normal saline control injections were administered starting 10 days before the study date. Samples were collected for the measurement of TNFα, and EPOR1 expression. In separate groups of rats, isolated cardiomyocytes were subjected to contractile and relaxation function studies. Results: TNFα was significantly increased in BDL heart compared with sham control (345 ± 48 vs 250 ±18 pg/mg protein) and sham+EPO group (p<0.01). EPO significantly decreased TNFα expression in the BDL group (345 ± 48 vs 257 ± 32 pg/mg protein, p<0.01). There was no statistical difference between the sham control, sham + EPO and BDL + EPO groups. Western blot analysis showed that EPOR1 protein expression was significantly increased in the left ventricle from BDL compared with those from sham controls (P < 0.01). Isoproterenol-stimulated maximal systolic velocity in isolated cardiomyocytes was significantly decreased in cirrhotic rats compared with sham control [4.26 ± 1.09 vs 7.82 ± 2.27 µm/s, p<0.05). EPO significantly reversed the depressed contractility in the cirrhotic cardiomyocytes (4.26 ± 1.09 vs 8.26 ± 1.30 µm/s, p<0.01). Maximal diastolic velocity was also slower in cirrhotic rats compared with the sham group (2.21 ± 0.88 µm/s vs 5.53 ± 1.57, p<0.05). EPO corrected the diastolic velocity in BDL hearts (2.21 ± 0.88 vs 6.06 ± 0.88 µm/s, p<0.01). Conclusions: EPO receptors were increased in cirrhotic hearts. EPO treatment significantly decreased TNFα concentration and reversed the impaired systolic and diastolic function in cirrhotic cardiomyocytes. These results suggest that erythropoietin mediates at least part of its cardiotrophic effect by inhibiting the TNFα pathway, and may be a potential treatment for cirrhotic cardiomyopathy.

828 EFFECT OF LONG-TERM INHIBITION OF ACID GASTRIC SECRETION ON GASTRIC PH AND ON BACTERIAL TRANSLOCATION IN CIRRHOTIC RATS

Elisabet Sanchez1, German Soriano1, Beatriz Mirelis2, Begoña Gonzalez2, Carlos Guarnier1, Ingrid Ordas1, Joan Mones2, Carlos Guarnier1; 1Liver Unit, Hospital Sant Pau, Barcelona, Spain; 2Microbiology, Hospital Sant Pau, Barcelona, Spain; 3Gastroenterology, Hospital Sant Pau, Barcelona, Spain

Background: Bacterial translocation, as a consequence of intestinal bacterial overgrowth, plays an important role in the pathogenesis of bacterial infections in cirrhosis. Long-term inhibition of acid gastric secretion promotes intestinal bacterial overgrowth and could favour bacterial translocation. Aim: to evaluate the effect of long-term inhibition of acid gastric secretion on bacterial translocation in cirrhotic rats with or without ascites. Material and Methods: Cirrhotic rats with and without ascites induced by oral carbon tetrachloride were randomized to be treated with a daily subcutaneous injection of placebo, ranitidine (100mg/kg) or pantoprazole (8mg/kg) during two weeks. A control non-cirrhotic group were also randomized. The first day of the study (basal) and the previous day to the laparotomy a continuous 2 hour pH-metry under anesthesia was performed to evaluate the effect of antisecretory therapy. A laparotomy was performed to obtain samples of blood, mesenteric lymph nodes, ascites, pleural fluid, spleen, liver and cecal stools for culture. Results: Mortality was significantly higher in cirrhotic rats with ascites than in nonascitic cirrhotic rats (p<0.01) and in control rats (p<0.001) during the study, but no differences were observed in rats treated with placebo vs antisecretory drugs. Ranitidine and pantoprazole significantly increased gastric pH compared to rats treated with placebo (p<0.001). Administration of antisecretory drugs did not modify the incidence of bacterial translocation in nonascitic rats and control rats. In contrast, a higher incidence of bacterial translocation was observed in ascitic rats treated with ranitidine (7/11, p<0.05), pantoprazole (7/12, p=0.1) or any antisecretory therapy (14/23, p<0.05) compared to placebo treated ascitic rats (3/14) and to nonascitic rats treated with the same antisecretory drug (p<0.05, p=0.06 and p<0.01, respectively). Despite gastric pH previous to laparotomy was significantly higher in cirrhotic rats treated with pantoprazole than with ranitidine (p<0.001), the incidence of bacterial translocation was similar in both groups. Conclusions: Inhibition of acid gastric secretion increased acid gastric pH in control and cirrhotic rats with or without ascites, but the incidence of bacterial translocation only in cirrhotic rats with ascites. A similar incidence of bacterial translocation was observed in ascitic cirrhotic rats treated with any antisecretory therapy.

829 L-ORNITHINE PHENYLACETATE REDUCES ARTERIAL AMMONIA, IMPROVES BRAIN OSMOLYTES AND REDUCES BRAIN WATER IN A BILE DUCT LIGATED RAT MODEL OF CIRRHOSIS

Gavin A. Wright1, Nathan A. Davies 1, Lars M. Ytrebø 2, Vanessa Stadlbauer1, Ole-Martin Fuskvåg2, Claudia Zwingmann4, Stephen Hodgson3, Rajiv Jalan1; 1The Department of Medicine, The Institute of Hepatology, UCL, London, United Kingdom; 2The Department of Anaesthesiology, University Hospital of Northern Norway and University of Tromsø, Tromsø, Norway; 3The Department of Clinical Pharmacology, University Hospital of Northern Norway and University of Tromsø, Tromsø, Norway; 4Center of Research, Department of Medicine, University of Montreal, Montreal, QC, Canada

Introduction: Treatment of hyperammonemia and HE in cirrhosis are unmet clinical needs. In cirrhosis, the muscles can detoxify ammonia into glutamine. This concept has been exploited by the drug L-ornithine L-aspartate, but the glutamine produced regenerates ammonia in the gut and kidneys by the action of glutaminase. This study tests the hypothesis that L-ornithine-phenylacetate (OP) would reduce hyperammonemia by L-ornithine acting as a substrate for glutamine (Gln) synthesis (from ammonia) in skeletal muscle, and phenylacetate com-
bining with this Gln to form phenylacetylglutamine (PAG) which is then excreted in urine. **Methods**: Rats were studied 6 weeks after bile-duct ligation (BDL) or Sham-operation. The BDL rats were treated for 1 week with high protein/ammoniagenic diet. Three hours before termination, intraperitoneal administrations of either, phenylbutyrate (pro-drug; 0.3gm/Kg) or L-ornithine (0.3gm/Kg alone; 'OP' (0.3 gm/Kg of each) or placebo was given. Hourly arterial samples were collected for ammonia and urine for PAG. Samples collected at termination were measured for; Brain water (dry weight); Brain tissue osmolytes (1H-NMR spectroscopy); and muscle glutamine synthetase (GS) activity. **Results**: Compared to Sham-operated rats, BDL rats had significantly increased plasma ammonia (p<0.001) and glutamine/myo-inositol (Gln/mI) ratios (p<0.001); brain water content (p<0.01) and perivascular edema. Administration of OP to BDL rats significantly reduced plasma ammonia (2-way ANOVA, p<0.05) and brain water (p<0.05) versus the other 3 groups and ameliorated low-grade edema histologically. The Gln/mI ratio (p<0.01) was lowered to values not significantly different to Sham-operated rats which was not observed with L-ornithine or phenylbutyrate administration alone. These changes were associated with significantly increased urinary PAG and muscle GS activity (p<0.01 and p<0.05, respectively). **Conclusion**: The results show that OP reduces ammonia significantly in cirrhosis by increasing muscle ammonia detoxification and elimination of the ornithine related glutamine as urinary PAG. Also, by reducing plasma ammonia, OP leads to normalisation of brain osmolytes and brain water content suggesting a reduction of edema. These observations provide the rationale for further development of OP as a drug for clinical trials in patients with HE.

830 EVALUATION OF PULMONARY HYDROGEN SULFIDE GENERATION IN EXPERIMENTAL HEPATOPULMONARY SYNDROME (HPS)

Junlan Zhang1, Jo Morrison2, Jeannette Doeller2, David Kraus2-3, Bao Luo1, Liping Tang1, Joseph Barney1, Yongming Wang1, Michael B. Fallon1; 1Medicine, University of Alabama at Birmingham, Birmingham, AL; 2Environmental Health Sciences, University of Alabama at Birmingham, Birmingham, AL; 3Biology, University of Alabama at Birmingham, Birmingham, AL

**Introduction**: Hydrogen sulfide (H₂S) has emerged as a third endogenous gaseous signaling transmitter and a vasodilator, alongside nitric oxide (NO) and carbon monoxide (CO). Deficient hepatic H₂S production, due to a reduction in cystathionine γ-lyase (CSE) the main enzyme forming H₂S in peripheral tissues and vascular system, in experimental biliary cirrhosis (common bile duct ligation, CBDL) has recently been postulated to contribute to portal hypertension. CBDL animals also develop intrapulmonary vasodilatation and HPS and NO and CO contribute to this effect. However, the potential role of H₂S in the pulmonary vascular abnormalities of HPS has not been explored. **Aim**: To characterize pulmonary and hepatic CSE expression and H₂S generation in experimental HPS in relation to non-cirrhotic portal hypertension (partial portal vein ligation, PVL). **Methods**: Control, 1, 2, 3 and 4 week CBDL and 3 week PVL Sprague-Dawley rats underwent evaluation. The physiologic features of HPS were evaluated using ABGs and microsphere shunting. Western blot analysis and quantitative RTPCR were used to assess CSE protein and mRNA expression in lung and liver samples. H₂S generation in tissue homogenates were measured using a respirometer chamber and recorded with a polarographic H₂S sensor (PHSS) connected to a multichannel analyzer (Apollo 4000, WPI, Sarasota, FL). **Results**: CBDL animals, but not PVL animals developed physiologic alterations of HPS beginning within 2 wk after ligation. Pulmonary CSE expression decreased significantly within 2 wk relative to control and progressed over time (70% reduction in 4 wk CBDL vs control, p<0.05). These changes were accompanied by parallel reductions in lung H₂S generation (control and 4 wk CBDL as 4.6 ± 0.9 and 1.6 ± 0.2 pmol/sec/mg protein, p<0.05). The decrease in CSE expression and H₂S production also occurred over a similar time frame in CBDL liver. In contrast, PVL animals had no decrease in either CSE expression or H₂S production in lung or liver relative to control, despite a similar degree of portal hypertension. **Conclusions**: Both pulmonary and hepatic CSE expression and H₂S production decline in experimental HPS after CBDL, an effect not seen in non-cirrhotic portal hypertension where HPS does not develop. These findings indicate that the dramatic changes in H₂S production in experimental cirrhosis is not due to the development of portal hypertension and are not confined to the liver. Exploring the mechanisms and consequences of reduced H₂S production in cirrhosis and the possible role in experimental HPS may provide potential new therapeutic strategies.

831 POST-TRANSLATIONAL REGULATION OF SINOSUDBID ENDOTHELIAL CELL ENOS BY THE GPCR INTERACTOR, GIT1

Songling Liu1, Richard Premont2, Robert Schmalzigaug2, Xianjie Zeng1, Don C. Rockey1; 1Internal Medicine, UT Southwestern Medical Center, Dallas, TX; 2Medicine, Duke University Medical Center, Durham, NC

After liver injury, endothelial nitric oxide synthase (eNOS) activity is reduced in sinusoidal endothelial cells (SECs) and appears to result in reduction of nitric oxide (NO) synthesis, typical of portal hypertension. Previous studies of eNOS link post-translational abnormalities of Akt activation to GPCR signaling; therefore, we hypothesized that a GPCR kinase interacting protein (GIT1) might regulate eNOS activity. **METHODS**: SECs were isolated from normal or injured livers (BDL). eNOS, phospho-eNOS, and GIT1 expression were detected by immunoblotting. SECs were transduced with GIT1 cDNA and GIT1 siRNA. NO production was measured using the Griess reaction; a potential eNOS and GIT1 interaction was examined by immunoprecipitation. Adenovirus encoding GIT1 (1x10^15 pfu/kg) was transduced into SECs in vivo. **RESULTS**: Here, we report that GIT1 co-localizes and interacts with eNOS in SECs. GIT1 overexpression significantly increased NO production and enhanced Ser 1177 phosphorylation and Thr495 dephosphorylation without affecting total eNOS expression. The GIT1 and eNOS
interaction increased in response to ET-1. Importantly, the calcium/calcmodulin (CaM) inhibitor, W13, had no effect on GIT1 induced NO production, while inhibition of Src blocked GIT1 mediated eNOS phosphorylation and NO production (See Figure). GIT1 knockdown led to reduced NO production (normal SECs: 4.46±0.59, scramble siRNA:4.93±0.29, GIT1 siRNA:2.21±0.51, p<0.01 for control vs. GIT1 siRNA). After liver injury, both GIT1 expression and the GIT1-eNOS interaction were reduced. Finally, expression of GIT1 in injured livers normalized portal pressure. These data identify GIT1 as a novel post-translational regulator of eNOS in SECs.

832 LIVER ADAPTATION TO ISCHEMIA: NOVEL EVIDENCE FOR AN ALTERNATIVE ATP-GENERATING METABOLIC PATHWAY
Tom S. Chan1, Claudia Zwingmann1, Sven Gottschalk1, Valerie-Ann Raymond1, Peter Darby2, David Mazer2, Marc Bilodeau2; 1Centre de Recherche, CHUM, Montreal, QC, Canada; 2Department of Anaesthesia, St, Michael’s Hospital, University of Toronto, Toronto, ON, Canada

INTRODUCTION: Hepatocyte cell death and ensuing liver atrophy are observed in almost every chronic liver disease. These events can be reproduced experimentally in the left lateral and medial lobes of the liver by selectively occluding the left branch of the portal vein (LPVL). Using this model in the rat, we observed that cellular injury was preceded by a lag phase during which time cell death was absent. We hypothesized that this lag phase could be due to metabolic adaptations that were triggered to maintain the bioenergetic status of the ischemic liver. Using LPVL in male Sprague-Dawley rats, we studied metabolic changes in the ischemic lobe using high-resolution 13C and 1H NMR spectroscopy, HPLC, laser Doppler flow studies and oxygen tension measurements. RESULTS: Intrahepatic oxygen tension and blood flow were decreased almost immediately after LPVL. Despite this, the bioenergetic status of the liver was maintained for up to 6 hours as evidenced by only a marginal decrease in the ATP/ADP ratio. To investigate the flux of glucose-derived metabolites through the tricarboxylic acid (TCA) cycle, [U-13C]glucose was infused for 45 minutes before harvesting the tissue. Although total glucose levels were slightly increased, the fractional enrichment of intrahepatic glucose did not change at any time point studied. In comparison to the SHAM group, the entry of glucose into the TCA cycle was impaired as evidenced by a decrease in the incorporation of 13C-label into succinate (65±7%) (intermediate of the TCA cycle) and glutamate (49±13%) (derivative of the TCA cycle). Despite this observation, total succinate (127±14%) and total glutamate (119±12%) levels were markedly increased. In other words, the activity of the TCA cycle became less dependent on the metabolism of glucose. Furthermore, a significant decrease in the intrahepatic aspartate (80±4%) content was observed. CONCLUSION: Together, these results suggest that, in the presence of liver ischemia, ATP generation can be maintained by the transamination of aspartate into glutamate coupled with the metabolism of alpha-ketoglutarate into succinate, thus generating GTP which can be transphosphorylated into ATP (Weinberg et al. PNAS 97: 2826-2831). To our knowledge, this is the first reported evidence of this form of mitochondrial ATP generation in vivo. The maintenance of hepatic bioenergetics by this pathway may eventually be exploited to delay hepatocellular death in disease. This research was supported by a grant from the Canadian Institutes of Health Research (CIHR) and salary support from the CIHR, Canadian Association for the Study of the Liver and Fujisawa Inc.

833 REDUCED BRAIN CONCENTRATIONS OF A POTENT NEGATIVE ALLOSTERIC MODULATOR OF GABAERGIC TRANSMISSION IN HUMAN HEPATIC ENCEPHALOPATHY: A NOVEL EXPLANATION FOR "INCREASED GABAERGIC-TONE"
Samir Abboucha1, Wenlei Jiang1, Gilles Pomier-Layrargues2, Roger F. Butterworth1; 1Neuroscience Research Unit, CHUM (Hopital St-Luc), Montreal, QC, Canada; 2Liver Unit, CHUM (Hopital StLuc), Montreal, QC, Canada

Autopsied brain tissue from cirrhotic patients who died in hepatic coma contains increased concentrations of the neurosteroid allopregnanolone (Abboucha et al., Ann Neurol, 58:61-62, 2005). Allopregnanolone is a positive allosteric modulator of the GABA-A receptor with well established sedative properties. As part of a series of studies of neurosteroids in relation to the pathogenesis of hepatic encephalopathy (HE) in chronic liver failure, concentrations of dehydroepiandrosterone sulfate (DHEAS) were measured by radioimmunoassay in samples of frontal cortex obtained at autopsy from 11 cirrhotic patients who died in hepatic coma compared to an equal number of control subjects free from hepatic or neurological diseases at the time of death and who were matched for age, gender, and autopsy delay intervals. Patient material contained a significant reduction of DHEAS (5.81±0.88 µg/g tissue) compared to controls (9.70±0.79 µg/g tissue, p<0.01). Brain levels of DHEAS in four patients with chronic liver disease who died without HE (11.43±1.71 µg/g tissue), and in a patient who died in uremic coma (12.56±0.03 µg/g tissue) were within control range. In a separate series of experiments, DHEAS concentrations were found to be significantly reduced in CSF of rats following end-to-side portacaval anastomosis (PCA; 0.13±0.02 µg/ml) compared to sham-operated controls (0.21±0.03 µg/ml, p<0.01). In contrast to allopregnanolone, DHEAS is a potent negative allosteric modulator of GABAergic neurotransmission; reduced brain concentrations of DHEAS therefore have the potential to lead to a net stimulation of GABAergic neurotransmission; reduced brain concentrations of DHEAS therefore have the potential to lead to an increased GABAergic tone. Administration of Ro15-4513, a partial
834 THE SOMATOSTATIN ANALOGUE OCTREOTIDE INHIBITS ANGIOGENESIS AND VEGF EXPRESSION IN EARLY, BUT NOT LATE, STAGES OF PORTAL HYPERTENSION IN RATS. ROLE OF SOMATOSTATIN RECEPTOR SUBTYPE 2 DOWNREGULATION DURING THE EVOLUTION OF THE PORTAL HYPERTENSIVE SYNDROME

Marc Mejias, Ester Garcia-Pras, Jaime Bosch, Mercedes Fernandez; IDIBAPS, CIBEREHD, Hospital Clinic, University of Barcelona, Barcelona, Spain

Angiogenesis, the development of new blood vessels, is an important determinant of the pathophysiology of portal hypertension, contributing to the formation of portosystemic collateral vessels and the hyperdynamic splanchnic circulation associated to this syndrome. Somatostatin and its analogues, like octreotide, have been shown to be powerful inhibitors of experimental angiogenesis in vitro and in vivo. The purpose of our study was to determine the effects of octreotide on splanchnic neovascularization, expression of angiogenesis mediators, portosystemic collateralization and hemodynamics in portal hypertensive rats. The expression of the somatostatin receptor subtype 2 (SST2), which mediates the antiangiogenic effects of octreotide, was also assessed in mesentry from sham-operated rats and 4 and 7 days after induction of portal hypertension. Rats with portal hypertension induced by partial portal vein-ligation (PPVL) were treated with octreotide or vehicle during 4 or 7 days, starting immediately after PPVL. Splanchnic neovascularization (CD31 expression) as well as VEGF and SST2 expressions were determined by western blotting. Formation of portosystemic collaterals was measured by radioactive microspheres. Hemodynamic studies were performed by flowmetry. Octreotide treatment during 4 days significantly decreased splanchnic neovascularization and VEGF expression in portal hypertensive rats. Portal pressure and heart rate were also significantly reduced by the 4-days octreotide treatment, whereas portosystemic collateralization and splanchnic blood flow and resistance were not significantly modified. After one week of daily octreotide injection, starting on the day of PPVL, portal hypertensive rats escaped from octreotide therapy with regard to inhibition of angiogenesis. The only significant effect observed after 7-days octreotide treatment was a reduction in portal pressure. The mechanism underlying the escape phenomenon could be related to the finding that expression of the SST2 receptor decreased progressively during the evolution of portal hypertension. In conclusion, octreotide may be an effective therapy in early stages of portal hypertension by reducing splanchnic neovascularization, VEGF expression and portal pressure, but not in late stages most likely due to SST2 down-regulation during the progression of portal hypertension in rats.

Results: In cirrhotic rats CPG12177 decreases portal pressure, mainly caused by intrahepatic vasodilation, despite simultaneous splanchic vasodilatation. The additional application of propranolol blunted the splanchic blood flow and further decreased portal pressure. The selective blockade of beta-3-adrenoceptors by SR59230A led to a splanchic and hepatic vasoconstriction, and a slight decrease in portal pressure. The previous application of propranolol increased the splanchic vasodilatation and decreased markedly portal pressure. Discussion: Our data show for the first time that beta-3-adrenoceptor stimulation elicits intra- and extrahepatic vasodilatation with a drop in portal pressure. The combination with a non-selective beta-blocker (beta-1 and beta-2) further decreases portal pressure, suggesting that beta-1 and beta-2-adrenoceptor blockade together with beta-3 stimulation may have highest portal pressure lowering effect by decreasing portal inflow as well as hepatic resistance.

837 PORTAL HYPERTENSION TRIGGERS PERIPHERAL SIGNALS THAT INDUCES VASCULAR ENDOTHELIAL GROWTH FACTOR (VEGF) AND ENDOTHelial NITRIC oxide SYNTHASE (eNOS) EXPRESSION AT THE INTESTINAL MICROCIRCULATION IN CIRRHTIC RATS

Yasuko Iwakiri1,2, Juan G. Abraldes2, Omar Haq2,1, Supatsri Sethasine6, Mauricio Loureiro-Silva2, Roberto J. Groszmann1,2, 1Medicine, VA CT Healthcare System, West Haven, CT; 2Internal Medicine/Digestive Diseases, Yale University School of Medicine, New Haven, CT

Introduction: Portal pressure is an important factor that induces peripheral signals in different parts of the vasculature. Using a surgically induced model of portal hypertension in rats, it was shown that mild portal hypertension was enough to upregulate VEGF production and subsequent eNOS expression in the intestinal microcirculation. This upregulation of eNOS expression was partially reversed by the administration of VEGF receptor 2 blocker, suggesting that eNOS upregulation at the intestinal microcirculation was in part mediated by VEGF. In this study we hypothesized that the intestinal microcirculation may serve as an effector that senses changes in portal pressure in cirrhosis.

Thus we investigated how the severity of cirrhosis influences protein expression of VEGF and eNOS in intestinal microcirculation in cirrhotic rats. Methods: We generated rats (n=15) with different stages of cirrhosis using carbon tetrachloride (CCl4) inhalation in different duration: 6, 8, and 11 weeks, at which time points that rats were the beginning of, intermediate, and fully-established cirrhosis, respectively. Age-matched control rats (n=15) were also prepared as a control. Severity of cirrhosis was determined by portal pressure and Sirius red staining as a measurement of fibrosis. Results: Fibrosis was significantly increased at 8 weeks (3 %; microscopically: incipient cirrhosis) and 11 weeks (9 %; micronodular cirrhosis) of CCl4 treatment. Rats with 11 weeks of CCl4 inhalation developed ascites and showed significant increases in portal pressure (18.02±1.07 mmHg) and spleen weight (2.24±0.21 g), while those rats with 6 weeks (7.26±0.58 mmHg; 0.88±0.04 g) and 8 weeks (8.55±0.33 mmHg; 0.9±0.06 g) did not. At 11 weeks when portal hypertension was developed, both VEGF and eNOS expressions in the intestinal microcirculation significantly increased to 40 % and 3 folds (P<0.05), respectively, compared to the control group. Furthermore, rats with 11 weeks of CCl4 inhalation showed more than 2 fold elevated angiogenic cytokines such as TNF-alpha, Interleukin (II)-2, IL-6 and granulocyte-colony stimulating factor in the intestine, as evaluated by a cytokine array. These observations suggest that portal hypertension triggers peripheral signals at the intestine, which induces angiogenic cytokines and NO production, known mediators of complications observed in cirrhosis. Conclusion: Intestinal microcirculation senses the changes of portal pressure in cirrhosis and may serve as reservoir for angiogenic cytokines. The up-regulation of eNOS at the intestinal microcirculation contributes to the development of the hyperdynamic circulation in cirrhosis.

838 INHIBITION OF MYOSTATIN REVERSES THE LOSS OF SKELETAL MUSCLE MASS ASSOCIATED WITH IMPAIRED PROTEIN SYNTHESIS IN THE PORTACAVAL ANASTOMOSIS RAT

Srinivasan Dasarathy1, Sean Muc1, Prabhu S. Parimi2, Milan Dodig2, Satish C. Kalhan2, Arthur J. McCullough1, 1Department Of Gastroenterology and Hepatology, Cleveland Clinic Foundation, Cleveland, OH; 2Department of Pediatrics, MetroHealth Medical Center, Cleveland, OH

The portacaval anastomosis (PCA) rat is a model for skeletal muscle loss in human cirrhosis. Our previous data showed an increased expression of myostatin (inhibitor of skeletal muscle protein synthesis) and lower expression of myoD and proliferating cell nuclear antigen-PCNA (impaired satellite cell function). Satellite cells are myogenically committed precursor cells that maintain muscle mass. In the present study, we examined the functional consequences of these alterations by directly quantifying skeletal muscle protein synthesis and using follistatin, a myostatin antagonist. Methods: Male Sprague Dawley rats with an end to side portacaval anastomasis were compared with pair fed sham operated rats (n=5 each). At 2, 4 and 6 weeks after PCA, protein synthesis in the skeletal muscle was quantified using a flooding dose of labeled phenylalanine. Fractional synthesis rate (FSR) and synthesis of total skeletal muscle protein were quantified. The expression of myostatin, PCNA and myoD were quantified by real time PCR. The response to follistatin was examined in PCA and sham rats and compared with the response to vehicle alone. Results: PCA rats had significantly lower body weight, lean body mass, grip strength, and skeletal muscle weight and these changes were reversed with follistatin. The FSR of skeletal muscle protein in the sham rats increased while it did not change in the PCA rats. The FSR in the sham rats was higher than that in the PCA rats at week 2 and subsequently was similar in the 2 groups despite a lower muscle mass in the PCA rats. Therefore, the synthesis rate of the total skeletal muscle protein was lower in the PCA compared to sham rats at each of the times examined (p<0.05). The expression of myostatin was higher and that of PCNA and myoD were lower at 4 and 6 weeks after PCA. Discussion. Lower skeletal muscle mass in PCA rat was accompanied by an inability to mount an increased fractional synthesis rate response after surgery in contrast to that observed in the sham rats. This inappropriate compensatory response in the skeletal muscle protein compartment of the PCA rat contributes to the failure to gain skeletal muscle mass. The mechanism of this impaired compensatory protein synthetic response in the skeletal muscle was a consequence of an increased expression of myostatin as well as the lower myonuclear accretion as a result of impaired satellite cell function as evidenced by a reversal of
the alteration in skeletal muscle mass by follistatin. These observations are of clinical relevance in developing strategies to reverse skeletal muscle loss in human cirrhosis.

APELIN, A NOVEL CYTOKINE REGULATING INFLAMMATION AND ANGIOGENESIS, IS UPREGULATED IN DECOMPENSATED HUMAN CIRRHOSIS

Alessandro Principe1, Luis Ruiz del Arbol2, Pedro Melgar-Lesmes3, Manuel Morales-Ruiz4, Vicente Arroyo5, Wladimiro Jimenez2; 1Biochemistry & Molec. Genetics, Hospital Clinic, IDIBAPS, University of Barcelona, Ciberedh, Barcelona, Spain; 2Cardioangiology and Hepatology, Internal Medicine, University of Bologna, Bologna, Italy; 3Dept. of Gastroenterology, Hospital Ramon y Cajal, University of Alcala, Madrid, Spain

Apelin has recently been demonstrated to play a role in water homeostasis through the hypothalamic inhibition of ADH secretion. Several studies have also observed that this substance, expressed in a wide array of tissues, plays a role in inflammation and angiogenesis. In addition, apelin has been shown to be involved in ischemic heart disease and in intermediate metabolism regulation. Previous investigations demonstrated a close relationship between hepatic dysfunction and urinary excretion of apelin in experimental cirrhosis. In the present work we investigated whether the production of this peptide is also activated in patients with cirrhosis and portal hypertension. Two studies were performed. First, we assessed whether the concentration of apelin was higher in human blood during compensated cirrhosis. In the second study, we assessed mRNA expression of apelin and apelin receptor in different organs of cirrhotic rats with ascites to determine which tissue/s is/are responsible for the altered production of apelin in cirrhosis. Plasma concentration of apelin was measured in 64 patients with decompensated cirrhosis of different etiologies and in 10 individuals with no previous history of cardiovascular or chronic inflammatory disease and normal BMI. Apelin concentration was around three times higher in cirrhotic patients than in human controls (855±75 vs. 282±12 pg/ml, p<0.005). We then induced cirrhosis and ascites in 18 Wistar rats that were compared with 18 age matched control animals. Paralleling the results in human cirrhotics, apelin plasma concentration was significantly higher in cirrhotic rats than in control animals (1250±204 vs. 958±198 pg/ml, p<0.0001). Liver, lung, heart and kidney were extracted from both control and cirrhotic animals to assess apelin and apelin receptor mRNA expression by real-time PCR. Apelin gene expression showed a fourfold rise only in the liver (4.06±0.59 vs. 1.03±0.17 arbitrary units, p<0.0001), while no significant differences were found in any other organ. Interestingly enough apelin receptor mRNA levels were found to be almost 300 times higher in the liver of the cirrhotic animals than in controls (11.08±2.13 vs. 0.04±0.01 arbitrary units, p<0.0001), while a significant apelin receptor down regulation was observed in both heart (4.97±1.30 vs. 13.30±2.92 arbitrary units, p<0.05) and lung (43.53±14.28 vs. 91.82±13.74 arbitrary units, p<0.05). These results indicate that the hepatic apelin system is markedly and selectively activated in cirrhosis and suggest that this peptide could be involved in the angiogenic and fibrogenic processes occurring in this disease.

CARBON MONOXIDE REGULATES THE INTRAHEPATIC VASCULAR TONE IN NORMAL AND CIRRHOTIC RATS

Lien Van Langdeghem, Wim Laleman, Marcel Zeegers, Ingrid Vander Elst, Jos van Pelt, David Cassiman, Frederik NVeens; Hepatology, University Hospital Gasthuisberg, University of Leuven, Leuven, Belgium

Background/aim: Besides nitric oxide (NO), carbon monoxide (CO) produced by heme oxygenase isoforms (inducible HO-1 & constitutive HO-2) is involved in the regulation of the vascular tone of the systemic circulation. Our aim was to elucidate the role of CO in the vasoregulation of the hepatic microcirculation both in normal and thioacetamide (TAA) cirrhotic rat livers. Methods: Through immunohistochemistry (n=6) and Western blot (n=5), the topography and level of HO expression was examined. Total HO enzymatic activity (n=4) was measured spectrophotometrically. The contribution of CO vs NO in the regulation of the intrahepatic vascular resistance (IHVR) was evaluated in an in-situ liver perfusion model, using oxygenated human hemoglobin (HbO2) (a CO and NO intra- and extracellular trapping reagent) and methemoglobin (metHb) (a control tool that scavenges NO but not CO) (n=5). To further define the role of CO, the HO-inhibitor Zinc protoporphyrin IX (ZnPP-IX) and a CO-releasing molecule (COR-2) (n=5) were added to the liver perfusion system. Sensitivity of hepatic stellate cells (HSC) to CO-mediated relaxation was studied by a stress-relaxed-collagen-lattice model. Results: HO-1 was predominantly expressed in Kupffer cells, HO-2 in endothelial cells and hepatocytes. Western blot showed a decreased expression of both isoenzymes (HO-1 P<0.04; HO-2 P<0.001) in cirrhotic rat livers, which was confirmed by the HO activity assay (P=0.004). In normal rat liver, in-situ perfusion with HbO2 caused a strong elevation in IHVR, while metHb caused a significantly but smaller increase (P<0.05), suggesting an important role for CO in the intrahepatic microcirculation. The role of CO in the normal liver was further emphasized by a dose-related increase in IHVR after incubation with ZnPP-IX (P<0.001). The cirrhotic rat liver, basal IHVR was increased compared to control (0.22±0.01 vs 0.13±0.01 mmHg.min.mL-1, P<0.001). Administration of HbO2 and metHb caused similar small increases in IHVR, suggesting a smaller amount of hemodynamically important CO in cirrhotic rat livers. Perfusion with ZnPP-IX caused a similar pattern of increase in perfusion pressure as in normal rat livers (P=0.003). Perfusion with COR-2 attenuated the increased IHVR (P=0.016). In vitro, preincubation with COR-2 10-4M significantly decreased fetal calf serum (FCS)-promoted HSC contraction (P=0.013). Conclusion: These data suggest a role, probably mediated via HSCs, for CO in regulation of the normal hepatic and cirrhotic microcirculation, wherein reduced CO producing activity was associated with an increased IHVR.

AMMONIA AND HYPONATREMIA IMPAIR NEUTROPHIL FUNCTION BY INDUCING SWELLING AND IS MODULATED BY THE P38-MAPK PATHWAY

Debbie L. Shawcross, Gavin A. Wright, Vanessa Stadlbauer, Stephen Hodges, Rajiv Jalan; Liver Failure Group, Institute of Hepatology, University College London, London, United Kingdom

Background: Hyperammonemia and hyponatremia can affect cell hydration and are associated with increased risk of infection and mortality. Alteration in cell volume alters intracellular...
signalling through effects on p38-MAPK. Neutrophil phagocytic dysfunction and increased spontaneous oxidative burst (OB) in cirrhosis has been shown to be associated with increased infection risk and mortality (Hepatology 2007, in press). The aims of this study were to explore in vitro and ex-vivo, the effect of hyperammonemia and hyponatremia on neutrophil phagocytosis and OB, and determine the role of p38-MAPK. Methods: Neutrophils were isolated from whole blood of healthy volunteers and incubated with either 75µM ammonia or PBS (control group). Both groups were further challenged with hyponatremia (induced by buffering blood with PBS containing 124 mM sodium chloride) and/or the addition of p38-MAPK modulators. Phagocytosis was analysed by fluorescent activated cell sorting (FACS) using FITC-labelled E. coli and quantification of OB was determined using a test which measured the % of neutrophils producing reactive oxidants at rest and after stimulation with E. coli and analysed by FACS. In rats fed an ammonia-rich diet (HD) and controls, neutrophil phagocytosis and OB were analysed by FACS. Cell size was quantified by forward scatter on FACS. Results: In healthy isolated neutrophils, phagocytosis was impaired on incubation with ammonia (p<0.0005), hyponatremia (p<0.05) or both (p<0.05) compared to controls. These effects were abrogated by the addition of isoproterenol, a p38-MAPK agonist. Cell size increased by 2 +/- 0.4, 3.4 +/- 0.6 or 5.7 +/- 1.2% respectively, with ammonia, hyponatremia or both, compared to controls (p<0.02) and was abrogated by p38-MAPK agonist and exacerbated by the addition of SB203580, a p38-MAPK antagonist. In healthy unstimulated isolated neutrophils the resting OB was increased compared to controls (p<0.001). This was abrogated by p38-MAPK antagonist. In isolated neutrophils from HD rats we observed impaired phagocytosis (55.4 +/- 7 vs 82.7 +/- 3.3%; p<0.05) and increased resting OB (31.2 +/- 5.3 vs 8.1 +/- 1.9%; p<0.001) compared to naïves. Conclusion: Hyperammonemia and hyponatremia impair neutrophil phagocytosis by inducing cell swelling in which the p38-MAPK pathway plays an important role. We hypothesise that p38-MAPK is activated by cell swelling which acts as an osmoregulator, thereby reducing swelling. However, activation of p38-MAPK also induces spontaneous OB which can be reversed with a p38-MAPK inhibitor. Prompt treatment of hyperammonemia and hyponatremia may prevent neutrophil dysfunction and reduce infection risk.

842 KUPFFER CELL (KC) ACTIVATION BY BETA-GLYCANS: GUANYLATE CYCLASE AND HEME OXYGENASES (HO) COUNTERACUTE INCREASE OF PORTAL PRESSURE (PP)

Christian J. Steib, Markus Bystron, Christine Opelz, Josef M. Härtl, Ingrid Liss, Burkhard Göke, Manfred Bilzer, Alexander L. Gerbes; Medizinische Klinik II, Klinikum Grosshadern, Munich, Germany

Introduction: Recently we have shown that KC activation increases PP in normal and fibrotic livers via thromboxane A_2 [DOI: 10.1016/j.jhep.2007.03.019]. PP is the interplay of vasoconstrictors and vasodilators. Therefore we now investigated the role of the vasodilating NO and CO condition on PP after KC activation. Methods: Livers of male Sprague-Dawley rats were perfused for 100 minutes. KC were selectively activated by infusion of Zymosan (150 µg/ml). L-NAME (0.3 mM), NS 2028 (1.0 µM), and 8-Br-cGMP (50 µM) were administered to Zymosan-treated livers. CO generation was blocked by ZnPP IX (1 µM). Zymosan/ZnPP IX administration was combined with CO (2.5 µM), 8-Br-cGMP (50 µM), Indomethacin (50 µM), BM 131.77 (20 µM), Glutathione (2 mM) or Catalase (150 U/ml) to elucidate mechanisms limiting PP increase by HO. Thromboxane B_2, the stable degradation product of thromboxane A_2 was measured in effluent perfusate by RIA.

Results: (±SD) Activation of KC by Zymosan resulted in a transient increase of (PP, cm H_2O) from 4.0±0.8 to maximally 19.2±3.1 followed by a long-lasting elevation until end of perfusion (6.6±0.7) (p<0.05). The inhibition of NO-synthase by L-NAME or the inhibition of soluble guanylate cyclase by NS 2028 further raised the initial increase of PP. This could be abolished by 8-Br-cGMP indicating the NO-cGMP-pathway as important vasodilating mechanism following KC activation. Inhibition of HO by ZnPP IX caused a significant (p<0.05) amplification of initial (24.4±2.6) and prolonged increase of PP (14.1±1.4) in Zymosan-treated organs. Interestingly, CO prevented prolonged increase (11.7±0.9) by cGMP-independent mechanisms. Indomethacin, the thromboxane A_2 receptor antagonist BM 131.77 and also the antioxidants glutathione and catalase prevented maximal and long-lasting increase of PP about 60-80% in Zymosan/ZnPP- treated livers. In order to test the pathway of reactive oxygen species and thromboxane we measured hepatic efflux rates of thromboxane B_2 upon Zymosan infusion. Indeed the amplification of PP by ZnPP was accompanied by increased hepatic efflux rates of thromboxane B_2: 1.997±1.43 (Zymosan) vs. 4.500±529 pg/min x g liver (Zymosan/ZnPP). Interestingly, the additive infusion of glutathione or catalase lowered efflux of thromboxane B_2 significantly (1.443±243 and 1.351±265). Conclusion: NO restricts the initial PP increase after KC activation by guanylate-cyclase mediated cGMP. CO from heme degradation limits the initial and the long lasting increase of PP after KC activation by cGMP-independent mechanisms. Interestingly, reactive oxygen species from KC is blocked by HO leading to lowered thromboxane B_2 efflux which terminates increase of PP.

843 UPREGULATION OF RHOA- AND RHO-KINASE-EXPRESS AND RHO-KINASE ACTIVITY IN LIVERS FROM RATS WITH CCL4-INDUCED MICRONODULAR CIRRHOSIS

Martin Hennenberg, Jonel Trebicza, Andreas Eckhardt, Tilman Sauerbruch, Jörg Heller; Department of Internal Medicine I, University of Bonn, Bonn, Germany

Background: In cirrhosis, increased resistance of the intrahepatic vasculature and intrahepatic hyperresponsiveness to vasoconstrictors contributes to portal hypertension. We have previously shown that upregulation of RhoA and Rho-kinase and a subsequently increased Rho-kinase activity critically participate in the development of increased intrahepatic vascular resistance in rats with secondary biliary cirrhosis after bile-duct occlusion [Gut2006;55(9)]. Moreover, Rho-kinase activity is increased in livers from patients with alcohol-induced cirrhosis [Gut2006;55(9)]. In contractile cells, the small monomeric GTPase is activated by vasoconstrictors through G-protein coupled receptors. RhoA in turn activates Rho-kinase, which mediates vasoconstriction via inhibition of myosin-light-chain phosphatase. Here, we investigated the expression of RhoA and Rho-kinase, as well as Rho-kinase activity in livers of rats with CCl4-induced micronodular cirrhosis. Methods: Micronodular cirrhosis in male rats was induced by chronic application of CCl4. Livers from cirrhotic rats and non-cirrhotic controls
were shock-frozen and homogenized. Expressions of RhoA and Rho-kinase were studied by Western-blot analysis of liver homogenates. Rho-kinase activity in liver homogenates was assessed as phosphorylation of the Rho-kinase substrate, moesin (Thr-558), by Western-blot analysis with a site- and phosphospecific antibody. Results: Expression of RhoA and Rho-kinase were upregulated in livers from CCl4-rats, compared to livers from non-cirrhotic rats. Levels of phospho-moesin (Thr-558) were increased in homogenates of cirrhotic livers, compared to non-cirrhotic controls. Conclusion: Upregulation of RhoA and Rho-kinase expression, and increased Rho-kinase activity obviously contribute to increased intrahepatic vascular resistance in cirrhosis of different etiologies.

EFFECTS OF BILE ACIDS ON PULMONARY MICROVASCULAR ENDOTHELIAL CELL PROLIFERATION: IMPLICATIONS FOR EXPERIMENTAL HEPATOPULMONARY SYNDROME (HPS)
Liping Tang1, Junlan Zhang1, Bao Luo1, Yongming Wang1, Joseph Barney2, Michael B. Fallon1; 1Medicine, Gastroenterology-Hepatology, University of Alabama at Birmingham, Birmingham, AL; 2Medicine, Pulmonary/Allergy/Critical Care, University of Alabama at Birmingham, Birmingham, AL

Introduction: HPS occurs in 10-30% of patients with cirrhosis and increases mortality. Preliminary studies support that angiogenesis may be an important pathophysiologic process in experimental HPS induced by biliary cirrhosis (CBDL) which is not found in non-biliary cirrhosis (thioacetamide, TAA) where HPS does not develop. Whether circulating bile acids contribute to angiogenesis in CBDL animals is not known. Aim: To evaluate the effects and mechanisms of bile acids on endothelial proliferation in pulmonary microvascular endothelial cells.

Methods: Plasma bile acid concentrations were measured in CBDL and TAA cirrhosis and the effects of CBDL plasma on in vitro angiogenesis was assessed by measuring capillary tube formation on Matrigel. The effects of CDCA (100µM) on endothelial proliferation (MTT assay, 24hrs) and specific signaling pathways were assessed in rat pulmonary microvascular endothelial cells (RPMECs, VEC Technologies, Inc.).

Results: Plasma bile acid concentrations (µM, mean ± SE) were significantly increased in both 3 wk CBDL and 8 wk TAA cirrhosis relative to control (control 17 ± 3.4, CBDL 124 ± 8.4, TAA 35 ± 5.2, both p < 0.05). The addition of plasma from 3 wk CBDL animals significantly stimulated RPMEC tube formation, an effect not seen with the addition of control plasma. CDCA triggered a dose dependent increase in endothelial cell proliferation in RPMECs (2.1 ± 0.35 fold-control, p< 0.05). This effect was accompanied by an increase in VEGF expression (mRNA 2.9 ± 0.4 fold-control, protein 2.5 ± 0.6 fold-control, p< 0.05) and phosphorylation of Flik-1 and Akt. The proliferative response could be inhibited by VEGF neutralizing antibodies, a Flik-1 kinase inhibitor (SU1498) and by wortmannin (Akt inhibitor). Similar effects on VEGF expression and endothelial cell proliferation were also seen with GW474064 and accompanied by increased SHP mRNA levels (2.6 ± 0.4 fold-control, p< 0.05) supporting that the effects were in part FXR-dependent. However, time course analysis demonstrated that Akt phosphorylation occurred within 1 hour after CDCA administration and prior to upregulation of SHP supporting that the effects were in part FXR-independent.

Conclusions: Plasma bile acid levels are increased in experimental HPS and plasma from CBDL animals stimulates endothelial tube formation in vitro. In RPMECs, CDCA increases VEGF expression and Akt-dependent endothelial cell proliferation that is in part FXR-dependent. In addition, CDCA appears to have rapid FXR-independent effects on Flik-1 and Akt activation. These results support the hypothesis that circulating bile acids may contribute to the pulmonary angiogenic response in experimental HPS.

PROTEIN MICROARRAY STUDY REVEALS TOXIN-SELECTIVE CYTOKINE PROFILES IN EXPERIMENTAL ACUTE LIVER FAILURE: BENEFICIAL EFFECTS OF MILD HYPOThERMIA AND N-ACETYLCYSTEINE
Chantal Bémeur, Javier Vaquero, Paul Desjardins, Roger F. Butterworth; Neuroscience Research Unit, CHUM (Hospital SirLuc), Montreal, QC, Canada

Hepatic encephalopathy and cerebral edema are serious neurological complications of acute liver failure (ALF). The precise pathophysiologic mechanisms responsible for these complications have not been fully established but recent studies suggest the involvement of proinflammatory cytokines. In order to address this issue, protein array technology was used to investigate changes in the expression profile of 62 pro- and anti-inflammatory cytokines and related chemokines and growth factors in mice with ALF due to toxic liver injury. Male C57BL6 mice were treated with azoxymethane (AOM) (100µg/g; i.p.) or aceniamophen (APAP) (300µg/g; i.p.); control mice received an equal volume of saline. At equivalent stages of ALF, determined by measurement of serum transaminases and verified post-mortem by histopathology (hematoxylin-phloxine-saphron staining of paraffin-embedded liver sections), mice were killed and blood drawn for cytokine measurement. AOM-treated comatosc mice manifested significant brain edema (measured by a sensitive gravimetric technique) and increased expression of a wide range of cytokines including interferon-gamma (IFN-γ), interleukins (IL-1β, IL-3, IL-4, IL-5, IL-6, IL-10, IL-12, IL-17), tumor necrosis factor-alpha (TNF-α) as well as monocyte chemoattractant proteins MCP-1 and MCP-5. Cytokine profiles from APAP-treated mice showed some similarities but also major differences from those associated with AOM-induced ALF (in particular with regard to the interleukins IL-1β, IL-5 and IL-6). Treatment of AOM mice with mild hypothermia (35°C) or N-Acetylcysteine (NAC) (1,200 mg/kg; i.p.) led to reduced hepatic damage and improvement in neurological function (brain edema prevention). Both hypothermia and NAC led to selective attenuation in expression of IFN-γ, IL-10, IL-12 and IL-17. Hypothermia caused additional decreases in expression of IL-3, IL-4 and IL-6. These findings demonstrate that 1) Cytokine profiles in ALF due to toxic liver injury are both selective and toxin-dependent; 2) Treatment such as mild hypothermia or NAC have distinct actions on cytokine expression profiles in ALF. These findings suggest that novel treatment strategies using anti-cytokine or immunoneutralization therapy aimed at reduction of hepatic injury or stimulation of hepatic regeneration may need to target cytokines specific to the etiology of the ALF. MECHANISM OF B19-INDUCED ACUTE FULMINANT HEPATIC FAILURE: PARVOVIRUS B19 HELICASE-INDUCED DNA DAMAGE LEADS TO APOPTOSIS IN PRIMARY HEPATOCYTES AND HEP G2 CELLS

Stanley J. Naides1, Violetta Kivovich1,2, Brian D. Poole2,4, Leona Gilbert2,3

1Immunology, Quest Diagnostics Nichols Institute, San Juan Capistrano, CA; 2Cell and Molecular Biology Graduate Program, Pennsylvania State University, Hershey, PA; 3Department of Biological and Environmental Sciences, University of Jyväskylä, Jyväskylä, Finland; 4Department of Arthritis and Immunology, Oklahoma Medical Research Foundation, Oklahoma City, OK

PURPOSE: Parvovirus B19 can cause hepatic enzyme elevation, clinical hepatitis, and acute fulminant liver failure (AFLF).

BACKGROUND: B19 causes a restricted infection in non-erythroid cells (e.g., primary hepatocytes and Hep G2) with expression of nonstructural protein (NS1) but not viral capsid proteins. NS1 is a superfamily 3 helicase, typical of small DNA viruses, that plays a key role in initiation of viral genome replication. In hepatocytes, we demonstrated B19-induced apoptosis was mediated by caspase 9 and caspase 3 activation. We used an enhanced green fluorescent protein (eGFP) fusion protein system to confirm the role of NS1 in apoptosis in primary hepatocytes and Hep G2 cell lines, and to identify its molecular mechanisms.

METHODS: NS1 was cloned into an inducible plasmid or baculovirus expression system, and eGFP/NS1 or parental eGFP was expressed in the presence of inducer. Western blotting was performed with anti-GFP polyclonal rabbit antiserum. Apoptosis induction was detected with annexin V-Alexa-fluor 594. NS1 was immunoprecipitated with anti-GFP polyclonal antibody and protein-G agarose beads. Cellular DNA was labeled with α32P-dTTP. Antibodies specific for the single strand DNA recognition protein, replication protein A (RPA), or proliferating cell nuclear antigen (PCNA) were used in colocalization experiments. Poly(ADP ribosyl) polymerase (PARP) activity was determined by western blotting. Apoptotic subcellular particles were collected through filtration, and total protein or anti-GFP immunoprecipitate was examined on western blots. RESULTS: eGFP/NS1 expressed in either the plasmid or baculovirus system precipitated from purified subcellular apoptotic bodies contained NS1 fusion protein. CONCLUSIONS: B19 NS1 forms bulky adducts with cellular DNA, nicks cellular DNA, and induces apoptosis through DNA repair pathways that lead to mitochondrial stress. B19 may persist in tissues, including liver. Expression of NS1 in hepatocytes may lead to hepatic dysfunction, including acute fulminant hepatic failure through cell loss by apoptosis.

INCIDENCE OF BACTERAEMIA AND OUTCOMES IN PATIENTS WITH ACUTE LIVER FAILURE

Constantine J. Karvellas1, Fred Pink1, Mark McPhail2, Timothy J. Cross3, Georg Auzinger1, William Bernal1, Elizabeth Sizer1, Ian Eltringham2, Julia Wendon1

1Institute of Liver Studies, King’s College Hospital, London, United Kingdom; 2Department of Medical Microbiology, King’s College Hospital, London, United Kingdom

INTRODUCTION: Patients with acute liver failure (ALF) are susceptible to infections secondary to multiple immunological deficits and the high dependence of care required. Previous studies have demonstrated a high incidence of infection, early bacteremia (day 3) and significant attributable mortality. Methods: Data collected prospectively and entered onto a dedicated physiology database for all patients admitted to a specialist liver intensive care unit (LICU) was retrospectively examined for the period January 2003 to July 2005. The incidence and outcomes of bacteremia was examined in patients with ALF. Results: 206 patients were defined with ALF; 72 (35%) suffered bacteremia (BALF) on 133 occasions (163 isolates). In contrast, 134 patients had no bacteremia (NBALF). Aetiology of ALF was not different between the two groups and equal numbers fulfilled King’s College hospital criteria for transplant (BALF 54% vs NBALF 51%). Gram-positive organisms were observed in 44% of isolates, gram-negatives in 52% and candida in 4%. Median time to first bacteremia was 10 (7-16) days. On admission BALF patients had higher SIRS score (2 vs 1, p<0.001). No differences were seen for other biochemical markers on admission. While in LICU, BALF patients had higher degrees of encephalopathy (HE) (maximum HE grade >2: 81% vs. 63%, p=0.008). They also had greater requirements for hemofiltration (RRT) (92% vs. 65%), mechanical ventilation (100% vs. 77%) and significantly longer LICU stays (26 vs. 7 days, p<0.001 for all). Numbers undergoing transplant (OLT) were BALF=26% and NBALF=36% respectively (p=NS). Survival to hospital discharge was not different between the two groups (62% vs 64%). Subgroup analysis for those undergoing OLT (BALF=26%, NBALF=33) and medical management (non-OLT) (BALF=46%, NBALF=101) was performed. In the OLT and non-OLT subgroups, admission SIRS score, requirement for RRT, ventilation and length of stay in LICU were all significantly greater in BALF patients (p<0.05 for all). For the total group, multivariate analysis demonstrated OLT (OR 4.0) and maximum HE grade <3 (OR 5.4) to be important determinants of survival (p<0.001 for both); bacteremia was not significant (p=NS). Significant predictors of bacteremia were maximum HE grade >2 (OR 1.6), admission SIRS score > 1 (OR 2.7) and requirement for RRT during LICU stay (OR 8.9, p<0.02 for all). Conclusion: In this study bacteremia was observed later than reported previously. Bacteremia was associated with increased SIRS markers on admission, an increased requirement for organ support and increased length of LICU stay, but did not significantly impact on mortality.

848 CEREBRAL HYPEREMIA AND INTRACRANIAL HYPERTENSION INDUCED BY CO-ADMINISTRATION OF ENDOTOXIN AND AMMONIA IN THE RAT ARE MEDIATED BY CYCLOOXYGENASE

Hans R. Pedersen1,2, Helmer Ring-Larsen3, Fin Stolze Larsen1; 1Hepatology, Rigshospitalet, Univ Copenhagen, Copenhagen, Denmark; 2Department of Pharmacology and Pharmacotherapy, Faculty of Pharmaceutical Science, University of Copenhagen, Copenhagen, Denmark

Background/Objective: Systematic inflammation and hyperammonemia acts synergistically in increasing cerebral blood flow (CBF) and intracranial pressure (ICP). The aim of this study was to determine if the increase in CBF and ICP seen after co-administration of lipopolysaccharide (LPS) and ammonia, can be prevented by inhibition of cyclooxygenase (COX) and by the unspecific anti-inflammatory hormone dexamethasone. Methods: Fifty-four male Wistar rats, 6 in each group, were divided into the following groups: Saline + saline; LPS (2 mg/kg) + saline; LPS + indomethacin (10 mg/kg); LPS + diclofenac (10 mg/kg); LPS + dexamethasone (2 mg/kg) in experiment A. Experiment B included the following groups: LPS + ammonium acetate (NH3) (140 μmol/kg/min) + saline; LPS + NH3 + indomethacin; LPS + NH3 + diclofenac and LPS + NH3 + dexamethasone. ICP was monitored via a catheter placed in cisterna magna, while the changes in CBF were recorded by laser Doppler flowmetry. Results: LPS with and without NH3 induced an increase in 6-keto-prostaglandin-F1α (6-keto PGF1α) together with a concomitant rise in CBF and ICP. Indomethacin and diclofenac both significantly prevented the increase in ICP by LPS alone, and with the addition of NH3 the increase in both CBF and ICP. There was no increase in the plasma 6-keto PGF1α concentration. Dexamethasone only reduced the LPS induced increase in ICP, and partly the 6-keto PGF1α plasma concentration. Conclusion: Cerebral cyclooxygenase seems of central importance for development of cerebral hyperemia and high ICP during systemic inflammation and hyperammonemia.

849 ACETAMINOPHEN THERAPEUTIC MISADVENTURE: A PROSPECTIVE STUDY

Alexandre Louvet1,2, Benoît Quesnel1, Jeanne Boitard1, Sébastien Dharancy, Faustine Wartel, Valérie Canva, Pierre Deltenre1, Philippe Mathurin1,2; 1Hepatology, Hôpital Hôtel-Dieu, Lille, France; 2INSERM U 795, Lille, France

Development of severe acute liver failure (SAF) related to acetaminophen use at therapeutic dose (≤60g/day) as the so-called “acetaminophen therapeutic misadventure (ATM)”, was reported in 1 registry but never evaluated in a prospective cohort. Aims: I/ describe and compare prospectively SAF-ATM to SAF with acetaminophen overdose (SAF-AO) II/ confirm the deleterious impact of chronic drinking in SAF-AO. Methods: All patients admitted for SAF (PT<50%) were asked for daily dose and duration of acetaminophen and alcohol intakes. SAF-ATM was defined as: a) acetaminophen use at therapeutic dose (≤4 g/day) together with a concomitant rise in CBF and ICP. Indomethacin and diclofenac both significantly prevented the increase in ICP by LPS alone, and with the addition of NH3 the increase in both CBF and ICP. There was no increase in the plasma 6-keto PGF1α concentration. Dexamethasone only reduced the LPS induced increase in ICP; and partly the 6-keto PGF1α plasma concentration. Conclusion: Cerebral cyclooxygenase seems of central importance for development of cerebral hyperemia and high ICP during systemic inflammation and hyperammonemia.

850 BRAIN CORTEX ACCUMULATION OF GLUTAMINE CORRELATES WITH LACTATE–PYRUVATE RATIO IN PATIENTS WITH ACUTE LIVER FAILURE

Peter N. Bjerring1, Hans-Jørgen Frederiksen2, John Hauergaard3, Fin Stolze Larsen1; 1Hepatology, Rigshospitalet, Univ Copenhagen, Copenhagen, Denmark; 2Anesthesia, Rigshospitalet, Copenhagen, Denmark; 3Neurosurgery, Rigshospitalet, Copenhagen, Denmark

Aims/Objectives: The pathogenesis of brain edema and high intracranial pressure (ICP) in acute liver failure (ALF) is not fully understood, but it is suggested that accumulation of glutamine compromises mitochondrial function within the brain parenchyma. The aim of this study was to test if cerebral glutamine concentrations is associated with a rise in the lactate concentration and the lactate-pyruvate ratio in patients with ALF. Methods: By using in vivo brain microdialysis technique together with ICP monitoring in 13 ALF patients (8 F / 5 M; median age 46 (range 18 to 66) years) the extracellular concentrations of lactate, pyruvate and glutamine were measured together with ICP and cerebral perfusion pressure. Results: The median cerebral glutamine concentration was 4396 (range 1011-9712) μmol/l, lactate 2.15 (1.1-4.45) mmol/l, pyruvate 101 (43-255) μmol/l and the lactate to pyruvate ratio 21.3 (15.8-40.1). No correlation was found between the glutamine and the lactate levels. A correlation of glutamine concentration and lactate-pyruvate ratio was found (r=0.89, p<0.05). In patients with a glutamine concentration above 6 mmol/l the lactate to pyruvate ratio was higher than compared to those patients with a glutamine concentration below 6 mmol/l (p=0.02). ICP was 20 (2-28) mmHg and cerebral perfusion pressure 72 (56-115) mmHg. Conclusion: Our results show that...
cerebral accumulation of glutamine correlates to the lactate-pyruvate ratio in patients with ALF, which indicates impairment of mitochondrial function as cerebral perfusion pressure was sufficient.

Disclosures: The following people have nothing to disclose: Peter N. Bjerring, Hans-Jørgen Frederiksen, John Hauerberg, Fin Stolze Larsen

851 CONTRIBUTION OF MICROGLIAL ACTIVATION TO HEPATIC ENcephalopathy AND BRAIN EDEMA IN EXPERIMENTAL ACUTE LIVER FAILURE: BENEFICIAL EFFECT OF MINOCYCLINE

Wenlei Jiang, Paul Desjardins, Roger F. Butterworth; Neuroscience Research Unit, CHUM (Hospital St-Luc), Montreal, QC, Canada

Encephalopathy and brain edema are serious complications of acute liver failure (ALF). The precise pathophysiologic mechanisms responsible have not been fully elucidated but a previous report (Hepatology 44:366A, 2006) provided evidence that brain-derived proinflammatory cytokines are involved. However, these findings have so far failed to lead to new therapeutic approaches in ALF management. In order to address this issue, we investigated the effects of the anti-inflammatory drug minocycline on the progression of hepatic encephalopathy and brain edema in rats with ALF resulting from hepatic devascularization (portacaval anastomosis followed by hepatic artery ligation). ALF rats were administered saline or minocycline (22.5mg/kg) on days 2, 1 and day 0 of surgery. ALF rats were sacrificed at precoma (loss of righting reflex) and coma (loss of corneal reflex) stages of encephalopathy along with their appropriate sham-operated controls. Minocycline-treated animals were sacrificed in parallel with saline-treated comatose rats. IL-1β in serum and brain was measured by ELISA. IL-1β mRNA in the brain was assessed by real-time PCR. Microglial activation was analyzed by immunohistochemistry using anti-OX42 antibody. Minocycline delayed the onset of coma and significantly reduced brain water content (sham vs. ALF-saline vs. ALF-minocycline: 78.09±0.11% vs. 80.78±0.09% vs. 79.38±0.15%; p<0.001). Minocycline treatment also attenuated the increase of IL-1β protein in serum (sham vs. ALF-saline vs. ALF-minocycline: 15.5±2 pg/ml vs. 66±6 pg/ml vs. 27±2 pg/ml; p<0.001), together with IL-1β mRNA expression (sham vs. ALF-saline vs. ALF-minocycline: 49.2±6.7 vs. 178±25 vs. 51±13; p<0.001) and IL-1β protein (sham vs. saline vs. minocycline: 4.3±0.4 ng/g protein vs. 8.4±0.8 ng/g protein vs. 2.7±0.7 ng/g protein; p<0.001) in cerebral cortex of ALF animals. Furthermore, induction of OX42 immunoreactivity observed in the frontal cortex of ALF rats was suppressed by minocycline treatment. These findings demonstrate that minocycline treatment delays the onset of precoma and coma in experimental ALF due to suppression of microglial activation and decreased IL-1β expression in brain. These results further support a role for brain-derived cytokines in the pathogenesis of brain edema and its complications in ALF and suggest that minocycline may be beneficial in their prevention. [Funded by CIHR and CASL, Canada]

852 EVIDENCE OF ENDOTOXIN TOLERANCE AND SEVERELY IMPAIRED T-HELPER 1 RESPONSE IN ACUTE HEPATIC FAILURE

Charalambos G. Antoniades, Philip A. Berry, Ivana Carey, Astrid Scalori, Julia Wendon, Diego Vergani; King’s College Hospital, Institute of Liver Studies, London, United Kingdom

Introduction: Both acute(ALF) and acute on chronic liver failure (AoCLF) are associated by monocyte deactivation and immunoparesis, characterised by diminished monocyte HLA-DR expression and elevated serum levels of interleukin-10 (IL-10). This phenomenon has striking similarities with the endotoxin tolerance model described in septic shock where impaired antigen presentation is of pathogenic importance. Aim: To determine monocyte pro-and anti-inflammatory cytokine profile following endotoxin challenge and assess immune responses to a panel of recall antigens in acute hepatic failure. Methods: TNF-α and IL-10 secretion was evaluated using Elispot in peripheral blood mononuclear cells (PBMC) at baseline and after stimulation with lipopolysaccharide (LPS) in 20 patients with acute hepatic failure (AHF), 8 ALF and 12 AoCLF, and compared them with 14 healthy controls. Th1 specific responses were evaluated by IFN-γ Elispot in peripheral blood mononuclear cells (PBMC) at baseline and after stimulation with a panel of recall antigens (tetanus toxoid antigen [TTAg], purified protein derivative [PPD], a peptide pool of viral epitopes [CEF]) in 20 AHF and compared to 14 healthy and 28 pathological (HCV infected) controls. Results are expressed as median of specific spot forming cells/10⁶ PBMC [spSF/10⁶ PBMC]. Results: IL-10 secretion was higher in AHF patients compared to healthy controls following LPS challenge (529 vs 77.5, p<0.001). After LPS stimulation no significant change in TNF-α secretion was detected (83 vs 61, p=0.9), while there was a highly significant increase in IL-10 secretion compared to unstimulated cells (205 vs 529, p<0.001). There was an inverse correlation between TNF-α and IL-10 secretion following LPS challenge, the monocytes with the highest IL-10 response having the lowest TNF-α secretion (r=-0.6, p=0.014). Following exposure to TTag, PPD, and CEF there was no significant increase in IFN-γ secretion in AHF from baseline (TTag 0.75 vs 9.4, PPD 0.75 vs 0, CEF 0.75 vs 0, p=NS). IFN-γ production following TTag exposure was significantly reduced in AHF when compared to that seen in pathological (9.4 vs 155, p<0.001) and healthy controls (9.4 vs 300, p<0.001). Conclusion We have identified an endotoxin tolerant monocyte phenotype in patients with acute hepatic failure, characterised by an anti-inflammatory cytokine secretion profile in response to microbial stimuli. This is also associated with severe impairment in mounting a Th1 response against tetanus toxoid, a reflection of defective antigen presentation. These findings strongly support monocyte dysfunction as a pathogenic event in the immunoparesis of acute hepatic failure.

Disclosures: The following people have nothing to disclose: Charalambos G. Antoniades, Philip A. Berry, Ivana Carey, Astrid Scalori, Julia Wendon, Diego Vergani
853 EVALUATION OF THE BIOMARKER, DIMETHYLARGININE SCORE-ISCHEMIA MODIFIED ALBUMIN RATIO (DASIMAR) TO IDENTIFY RISK OF PROGRESSION TO ACUTE ON CHRONIC LIVER FAILURE AND MORTALITY (ACLF) IN PATIENTS WITH DECOMPENSATED CIRRHOsis

Rajeshwar P. Mookerjee1, Nathan A. Davies1, Neil Dalton2, Rajiv Jalan1; 1Institute of Hepatology, University College London, London, United Kingdom; 2Wellchild Laboratories, St Thomas Hospital, London, United Kingdom

With increasing recognition of the disease entity acute on chronic liver failure (ACLF), and limited management options available when patients evolve to multi-organ failure, there is a clinical need for early biomarkers identifying patients with decompensated cirrhosis at risk of progressing to ACLF and mortality. Recently we described the prognostic value of dimethylarginines and a dimethylarginine score (DAS) in decompensated liver disease, and its association with hepatic inflammation. This study aimed to assess the additional utility of ischaemia modified albumin ratio- IMAR (reflecting oxidative injury corrected for albumin variability in liver disease) combined with DAS in defining outcome in decompensated alcholic cirrhosis. Plasma acquired 48 hours after admission from 52 decompensated alcoholic cirrhotic patients (bilirubin >85μmol/L; increasing ascites and creatinine <150μmol/l) managed with supportive therapy, was analyzed for asymmetric and symmetric dimethylarginines (fragmentation specific stable isotope dilution electrospray tandem mass spectrometry) and IMAR (modified albumin-cobalt binding assay with correction for albumin concentration). Patients were characterized by histology and inflammatory indices and studied prospectively to determine development of organ failure (defined by need for organ support, ACLF). 28 patients developed ACLF. 13/28 died (9 from renal failure and 4 from sepsis, with progression to multi-organ failure). DASIMAR was not only significantly greater in ACLF patients vs. non-ACLF (table below) but also in non-surviving ACLF patients compared to survivors: 2.7±0.1 vs. 4.1±0.4, p<0.001. Whilst DAS correlated with inflammation and renal function as previously described, IMAR correlated with severity of liver disease (r =0.54, p<0.0001) and portal pressure (r =0.44, p<0.01). The DASIMAR score had a significant predictive utility for outcome in ACLF patients: AUROC of 0.92±0.05 and 95% confidence intervals 0.82-0.99; sensitivity of 92% and specificity of 80%. In conclusion, addition of IMAR to a previously described DAS score is a good marker of outcome in patients with decompensated liver disease. DAS and IMAR encompass different elements key to the development of ACLF (liver failure, renal dysfunction, inflammation and severity of portal hypertension). Further validation of DASIMAR as a biomarker may be useful in guiding intervention in ACLF.

854 BLOOD LACTATE AS A PREDICTOR OF POOR PROGNOSIS IN ACUTE LIVER FAILURE IN ACETAMINOPHEN OVERDOSE

Caroline M. Bates, Narendra Kochar, Janice S. Davidson, Peter C. Hayes, Kenneth Simpson; Scottish Liver Transplant Unit, Royal Infirmary of Edinburgh, Edinburgh, United Kingdom

Introduction Hyperlactataemia is considered an indicator of poor prognosis in acute liver failure due to acetaminophen overdose. The Kings College Hospital (KCH) criteria have been modified in the United Kingdom to incorporate admission and post resuscitation lactate levels in this aetiology. Patients with a lactate greater than 3.5mmol/l 24 hours post overdose or greater than 3.0mmmol/l following fluid resuscitation fulfil a separate criterion for poor prognosis and can be listed for super-urgent orthotopic liver transplant (OLT). Aim To assess the sensitivity and specificity of the lactate criteria when applied to patients admitted to the Scottish Liver Transplant Unit (SLTU). Methods We retrospectively analysed all admissions to SLTU between 1st June 2004 and 31st May 2007 with a diagnosis of acetaminophen overdose. The initial lactate level on admission and a second sample following fluid resuscitation were recorded. We analysed the sensitivity and specificity of these lactate levels in relation to poor prognosis compared with KCH criteria. Results 96 patients were admitted within this 36 month time period with a diagnosis of acetaminophen overdose. The initial lactate level on admission in the remaining 69 patients was 3.8 mmol/l (range 1.1-19.53mmol/l). 37 patients had a lactate >3.5 mmol/L, 22 patients survived (2 fulfilled KCH criteria) and 15 died (13 fulfilled KCH criteria). The sensitivity of initial lactate for predicting death from FHF was 88%, but specificity was only 58%. KCH criteria were 88% sensitive and 94% specific for predicting death. 3 patients within the lactate <3.5mmol/l group subsequently fulfilled KCH criteria, 2 died. 32 patients had a second lactate value, post admission following fluid resuscitation (median time 12.2 (4.4– 27) hours). Within this group 20 patients had a post resuscitation lactate > 3.0mmol/l, 8 of these patients survived (median lactate 3.72 (3.03- 14.61) mmol/l). 2 of the 8 fulfilled KCH criteria. 12 patients died (med lactate 7.07 (3.03–16.86) mmol/l, 11 of these patients fulfilled KCH criteria. Post resuscitation lactate >3.0mmol/l proved 100% sensitive but only 60% specific for predicting death in predicting mortality in acetaminophen overdose. Conclusion The incorporation of lactate into poor prognostic criteria may reduce the time to listing for OLT. In our experience lactate lacks the specificity to be the sole criterion for listing for liver transplantation in acetaminophen overdose. KCH criteria remain sensitive and specific in predicting poor prognosis.

855 ELAD® CELLULAR AND SYSTEM PERFORMANCE IMPROVEMENTS

John Brotherton2, Dar He2, Shapour Asslani2, Michael Millis1; 1Dept of Sugery, University of Chicago, Chicago, IL; 2Vital Therapies, Inc, San Diego, CA

One of the concerns with immortalized human hepatocytes has been the robustness of the metabolic pathways. As evidence mounted that the pathways expressed were dependant on the conditions the cells were exposed to, effort was placed on opti-
mizing the metabolic function, by modifying the materials and conditions. METHODS: C3A cells were inoculated into improved polysulfone hollow fiber cartridges with 0.2 micron pores and allowed to grow to confluence. Oxygen delivery and culture media were optimized, with pH and temperature maintained at physiologic conditions. Standard metabolic assessments were performed and compared to the cartridges utilized in the Phase 1 and 2 clinical trials. RESULTS: See Table below CONCLUSIONS: The metabolic growth and maintenance conditions that the C3A cells are exposed to and the physical characteristics of the hollow fiber cartridge utilized significantly affect the metabolic repertoire of the cells. The improved metabolic characteristics may have significant affect on the level of metabolic support provided by the ELAD System. The new system with improved metabolic characteristics is currently in a randomized, multi-center clinical trial assessing the safety and efficacy of the ELAD System for acute decompensation of chronic liver disease

**ELEVATED SERUM α-NH₂-BUTYRATE:LEUCINE RATIO MAY PREDICT SPONTANEOUS SURVIVAL IN PEDIATRIC ACUTE LIVER FAILURE**

David Rudnick1, Dennis Dietzen1, Ross Shepherd1, Yumirle P. Turmelle1, Song Zhang2, Robert Squires2, Pediatric Acute Liver Failure Study Group The 2; 1Washington University School of Medicine, St. Louis, MO; 2University of Pittsburgh Medical Center, Pittsburgh, PA

Up to half of pediatric acute liver failure (PALF) patients do not survive without liver transplantation; however, early identification of those unlikely to recover spontaneously is challenging. The establishment of the PALF Study Group offers opportunities to test novel strategies that could improve prediction of clinical outcomes in this serious, often fatal condition. Clinical experience suggests that recovery from ALF depends on the ability of the liver to regenerate. Based on this, we hypothesize that molecular markers characteristic of regeneration in the rodent partial hepatectomy (PH) model might have utility as markers of liver regeneration in PALF patients, and thus permit more reliable identification of patients likely to recover spontaneously.

**Methods:** Results of comprehensive amino acid analysis on liver and plasma recovered from mice 6 hours after PH were compared to those from non- and sham-operated mice (3-6 mice per group). Amino acids that were elevated in mice subjected to PH were measured in sera from PALF patients and compared to clinical outcomes. For this analysis, the initially-collected serum samples from 20 randomly selected patients in each of two outcomes groups were analyzed. Outcomes groups included spontaneous survival and death or transplantation. There were no significant differences in age, gender, initial encephalopathy grade, diagnosis, or number of positive King’s College criteria between groups. **Results:** α-NH₂-adipic acid (AAA) and α-NH₂-butyrate (AAB) were identified as elevated in liver and plasma from mice subjected to PH compared to control animals (Table). Analyses of PALF sera showed greater AAB in patients who survived without transplantation (29.2±5.9 µmol/l) compared to those who were transplanted or died (13.9±3.2, p=0.03). The AAB to leucine ratio (AAB:LEU) was also higher in spontaneously surviving PALF patients (0.29±0.03) than in the other group (0.14±0.03, p=0.01). 80% (12 of 15) of patients with AAB:LEU>0.21 survived without transplantation compared to only 32% (8/25) with a ratio<0.21 (p=0.008). **Conclusion:** These data show that the serum AAB:LEU ratio may predict outcomes in PALF patients. Further large scale, prospective studies should be done to assess the utility of this novel candidate diagnostic tool in the management of acute liver failure.

**ADMISSION LEVELS AND EARLY CHANGES IN SERUM IL-10 ARE ASSOCIATED WITH POOR OUTCOME IN ACUTE LIVER FAILURE AND ACUTE-ON-CHRONIC LIVER FAILURE**

Philip A. Berry, Charalambos G. Antoniades, William Bernal, Munther Hussain, George Auzinger, Elizabeth Sizer, Diego Vergani, Julia Wendon; Institute of Liver Studies, Kings College Hospital, London, United Kingdom

Background: The degree of immunoparesis contributes to prognosis in acute liver failure (ALF) and acute-on-chronic liver failure (AOCLF). The anti-inflammatory cytokine IL-10 is thought to mediate this phenomenon. Although levels of the pro-inflammatory cytokines IL-6 and TNF-α have been examined, the significance of IL-10 levels has not been studied. Aim: We investigated the prognostic value of admission IL-10 levels and their evolution during the early phase of treatment in intensive care, in comparison to the pro-inflammatory cytokines IL-6 and TNF-α. Method: Cytokine levels (IL-10, -6 and TNF-α) were measured within 48 hours of admission in 51 ALF and 39 AOCLF patients admitted to an intensive care environment. Follow-up measurements were obtained a median of 2 days later, in 35 patients, 15 of whom died within 30 days or required liver transplantation. Results: Levels of all measured cytokine were significantly increased in patients with a poor outcome. IL-10 outperformed TNF-α and IL-6 in the prediction of poor outcome in the whole cohort (AUROC 0.73 vs 0.66 and 0.72). IL-10 performed optimally in the subgroups with ALF (0.80 vs 0.63 and 0.70) and acetaminophen induced ALF (0.92 vs...
0.67 and 0.81). IL-6 performed best in the cirrhosis subgroup. Levels of all cytokines rose significantly in the 15 non-surviving or transplanted patients at subsequent measurement; IL-10 by a factor of 2, TNF-α by 2.6 and IL-6 by 1.13. No significant changes were seen in the surviving patients. In the ALF subgroup with poor prognosis only TNF-α changed significantly (x 2.4), and in the cirrhosis group only IL-6 changed significantly (x 1.6), although a ten-fold rise in IL-10 was seen. Conclusion: The magnitude of the anti-inflammatory response at admission, and its evolution during the early phase of treatment, predicts outcome as well as the pro-inflammatory response in acute hepatic syndromes, and supports a vital role for this immunological phenomenon in the outcome of these patients.

**858 FOLLOW-UP OF PATIENTS WITH SEVERE ACUTE LIVER DISEASE USING AN ON-LINE 13C METHACETIN BREATH TEST: A NEW TOOL FOR DECISION MAKING IN CLINICAL HEPATOLOGY**

Gadi Lalazar, Tomer Adar, Yaron Ilan; Liver Unit, Hadassah Hebrew University Medical Center, Jerusalem, Israel

Decision making in the treatment of patients with severe acute liver disease is based on several clinical and laboratory parameters. Currently used parameters, including clinical assessment, serum liver enzymes, synthetic function and serum ammonia levels, lack the ability to accurately assess liver function. Frequent determination of liver function is of importance in the follow-up of patients with severe acute liver disease, including those with fulminant hepatic failure. The BreathID® continuous online 13C methacetin breath test (MBT) enables accurate assessment of the metabolic function of the liver. Aim: To assess the role of the MBT for follow-up in patients with severe acute liver disease. Methods: 15 patients (9 males and 6 females, ages 14-60) with severe acute liver disease, diagnosed with autoimmune hepatitis (5), acute HIV (1), acute HBV (1), drug induced liver injury (4, 2 due to paracetamol) and neoplastic disease (1), were followed-up with 13C MBT during the acute phase of their illness. MBT was performed after an 8 hour fast and ingestion of 75mg methacetin. The correlation between standard follow-up parameters, including clinical assessment, serum liver enzymes, synthetic function, serum ammonia levels; and breath test scores including the PDR peak (percentage 13C dose recovered), CPDR30 and CPDR60 (cumulative PDR at 30 and 60 minutes, respectively) was assessed. Results: Clinical improvement and normalization of biochemical parameters were detected by progressive improvement of 13C MBT scores. In ten patients improvement was detected using MBT 1–3 days earlier than any of the conventional parameters. This was demonstrated by an early positive trend (slope) in breath test values. A model of recovery based on exponential function (1-const.*exp(time_from_baseline/time_constant) for MBT returning to normal metabolic function; and (1+const.*exp(time_from_baseline/time_constant) for blood test value decrease and return to normality, was used to extract the time to recovery. CPDR60 reached normal values within an average 4.5 days compared with 22.8, 12.8, 8.9 and 40.3 for ALT, AST, INR and Bilirubin, respectively. Conclusions: Assessment of liver function by the BreathID® 13C MBT is a rapid, non-invasive follow-up tool in acute liver disease of diverse etiologies. This data suggests that, while correlating with standard parameters, the MBT serves as a more sensitive decision making tool for follow-up of these patients in the setting of severe acute liver disease.

**859 EARLY PREDICTION OF OUTCOME OF ACUTE LIVER FAILURE USING BEDSIDE MEASUREMENT OF INTERLEUKIN-6**

William Bernal, Georg Auzinger, Elizabeth Sizer, Julia Wendon; Liver Intensive Therapy Unit, Institute of Liver Studies, London, United Kingdom

Background. Identification of patients with acute liver failure (ALF) with a poor prognosis who would benefit from liver transplantation remains sub-optimal. Current selection criteria are limited by low sensitivity and by late identification of LT candidates; additional prognostic markers are needed to improve prediction of outcome. Circulating levels of Interleukin-6 (IL-6) show highly significant differences between survivors and non-survivors of ALF and may now be rapidly and accurately measured at the bedside using point-of-care (POC) testing. In a cohort of patients with ALF and using POC testing we prospectively examined the clinical correlates of IL-6 and evaluated its potential for use in the early and rapid prediction of outcome. Patients and Methods. 56 patients with ALF admitted to a transplantation ICU were studied. 40 had ALF from acetaminophen-induced hepatotoxicity and 16 from non-acetaminophen causes. Median age was 36 years (inter-quartile range 27-44), encephalopathy grade 3 (1-4), INR 4 (2.9-6), Bilirubin 75 µmol/l (53-127), arterial lactate 4 mMol/l (2.2-8.7) and creatinine 169 µmol/l (94-262). IL-6 was measured within 24 hours of admission in whole arterial blood using a bedside semi-quantitative lateral flow immunoassay (Milenia Quickline IL-6). Statistical testing utilised non-parametric testing and receiver-operating characteristic (ROC) techniques. In assessment of prognostic value, analysis was performed without the inclusion of patients who underwent LT as ‘non-survivors’. Results. 11 patients died, 19 underwent LT and 26 survived with medical management alone. Median IL-6 was 100 to 300 pg/ml (100 to 300-200 to 1000) and correlated with arterial lactate (Spearman r=0.431, p<0.001) and requirement for vasopressors (r=0.528, p<0.001). IL-6 was higher in non-survivors (>300 pg/ml) than medical survivors (100-300 pg/ml). Excluding LT patients, area under the ROC was 0.83 (95%CI 0.66-1); 0.884 (0.74-1) in acetaminophen and non-significant in non-acetaminophen patients. The optimal threshold value for identification of non-survivors was 300 pg/ml. Applied to the whole cohort, excluding LT patients, 8/9 (89%) with >300 pg/ml and 3/28 (11%) <300 pg/ml died (p<0.0001). In acetaminophen patients 6/7 (86%) >300 pg/ml and 2/24 (8%) <300 pg/ml died (p<0.0005); sensitivity was 0.75, specificity 0.96, accuracy 0.9, negative predictive value (NPV) 0.91 and positive PV 0.86. Conclusion. Bedside testing of IL-6 provided a rapid and apparently accurate early assessment of prognosis in patients with ALF. Its predictive accuracy was greatest in patients with acetaminophen-induced disease in whom further study is warranted.
860 PATIENTS WITH SEVERE HEPATIC ENCEPHALOPATHY HAVE DIFFERENT PATTERNS OF RECOVERY OF NEUROCognitive DYSFUNCTIONS

Deanna Oliver1, Fatma Barakat1, Meghan Carlson1, William Perry1, Jan Stange2,1, Tarek Hassanein1; 1University of California, San Diego, San Diego, CA; 2University of Rostock, Rostock, Germany

Patients with severe Hepatic Encephalopathy (HE) who regain consciousness after correcting the precipitating event are judged as improved based on level of consciousness. Information regarding the degree of recovery of Neurocognitive functions from the presenting HE is unknown. We monitored neurocognitive recovery of patients presenting with severe HE grades 3 & 4 by evaluating attention-concentration, visuosconstruction, simple and complex computations, and verbal memory. The aim was to determine if patients with HE grades 3 & 4 recover in a similar path from their hepatic encephalopathy.

Methods: A prospective trial of MARS & SMT for patients with HE grades 3 and 4 was conducted. Data of subjects who responded and did not receive a liver transplant were analyzed. Patients were assessed using the Hepatic Encephalopathy Scoring Algorithm (HESA) for the first 5 days. HESA is an adaptation of the West Haven Criteria. Results: 14 subjects (10 MARS, 4 SMT) had sustained improvement in their HE by at least two grades over 5-day study period without liver tx. Mean age was 50 ± 13 years. 7 patients had HE Grade 3. All patients began the study with 100% impairment. Grade 3 and 4 patients responded similarly, but poorly in testing for Amnesia of recent events. However, in testing for Slow Responses, Shortened Attention Span and Complex Computations, Grade 4 patients had no recovery of functioning while Grade 3 patients did (Table 1). Grade 3 patients had more recovery of their Construction Ability and Simple Computations compared to Grade 4 patients. Both groups had the greatest recovery in their hepatic encephalopathy.

861 β-CATENIN ACTIVATION IS CRITICAL FOR HEPATIC REGENERATION AFTER ACUTE LIVER FAILURE

Udayan Apte1, Gang Zeng1, Benjamin Cieply1, Klaus Kaestner2, Satdarshan P. Monga1; 1Department of Pathology, University of Pittsburgh School of Medicine, Pittsburgh, PA; 2Genetics, University of Pennsylvania School of Medicine, Philadelphia, PA

Acute liver failure (ALF) remains a disease with limited treatment options. Improved prognostic in this otherwise fatal condition has been associated with spontaneous liver regeneration indicating therapeutic relevance of ‘regenerative’ therapies. Here, we report activation of the Wnt/β-catenin pathway to be essential for liver regeneration following ALF. ALF was induced in the mice by acetaminophen overdose, which is also the leading cause of liver failure in the Western countries. A non-lethal dose of acetaminophen in mice, which induces both liver injury and regeneration, led to rapid activation of β-catenin secondary to GSK-3β down-regulation and dissociation of the metastable complex. Administration of lethal dose of acetaminophen, which is associated with lack of regeneration, led to failure of β-catenin activation. β-Catenin conditional knockout mice that lack CYP2E1, when treated with acetaminophen following CYP2E1 induction, failed to exhibit liver regeneration. Retrospective examination of biopsies from ALF patients from acetaminophen overdose identified high correlation between nuclear/cytoplasmic β-catenin and spontaneous liver regeneration and vice versa. Further analysis suggested that β-catenin immunohistochemistry on patient biopsies could predict spontaneous regeneration with a positive predictive value and specificity of 100% and sensitivity of 55%. These data affirm the role of β-catenin in liver regeneration after ALF and suggest therapeutic and prognostic significance of this observation.

The following people have nothing to disclose: Udayan Apte, Gang Zeng, Benjamin Cieply, Klaus Kaestner, Satdarshan P. Monga

862 CEREBRAL BLOOD FLOW AUTOREGULATION IN EXPERIMENTAL LIVER FAILURE

Thomas J. Dethloff1, Gitte M. Knudsen2, Finn Stolze Larsen1; 1Dept Hepatology, afd. 2.12.1, Copenhagen University Hospital Rigshospitalet, Denmark, Copenhagen Ø, Denmark; 2The Neurobiology Research Unit, Copenhagen University Hospital Rigshospitalet, Denmark, Copenhagen, Denmark

In acute liver failure (ALF) alterations in cerebral blood flow are common features, which increase the patients’ risk for neuronal damage due to hypotension. It is well-known that the cerebral blood flow (CBF) autoregulation is impaired in ALF, but the pathophysiological mechanism remains obscure. The purpose of this study was to determine, which of the components of liver failure accounts for this impairment of CBF autoregulation. Four different rat models were chosen, each representing different aspects of ALF: galactosamine (GIN) intoxication versus 90% surgical hepatectomy (PHx90) was applied to examine the effects of liver necrosis versus shear reduction in functional liver mass. A model of porta-caval shunting (PCA) assessed the effects of shunting of portal blood (and hence toxins) into the systemic circulation. Combining the PCA model with ammonia infusion provided information about the additional effects of hyperammonemia. The CBF autoregulation was impaired in both the GIN and PHx90 groups (p<0.0001 compared to control group). By contrast, despite high arterial ammonia, high cerebral glutamine concentration, and significantly increased CBF and ICP, autoregulation was intact in the PCA and PCA+NH3 groups (vs. control: p= 0.16 and p=0.91).

Disclosures:
The following people have nothing to disclose: Deanna Oliver, Fatma Barakat, Meghan Carlson, William Perry, Jan Stange, Tarek Hassanein
Increased water content of the brainstem (PCA vs. control \( p=0.041 \); PCA+NH3 vs. control \( p=0.002 \)) or cerebellum (PCA+NH3 vs. control \( p<0.001 \)) did not affect CBF autoregulation. In conclusion, liver necrosis, porta-caval shunting of blood and hyperammonemia do not impair CBF autoregulation, whereas reduced functional liver mass is associated with loss of CBF autoregulation.

**Impaired autoregulation (autoregulatory plateau phase) in experimental ALF.** In healthy animals CBF is independent of CPP (horizontal plateau phase) while a sloped plateau reveals an impaired autoregulation.

863

**AN HLA-DR EXPRESSING MONOCYTE INFILTRATE AND AN ABUNDANCE OF IL-10 TRANSCRIPTS CHARACTERIZE THE LIVER OF ACUTE LIVER FAILURE**

Charalambos G. Antoniades, Philip A. Berry, Munther Hussain, Maria Serena Longhi, Alberto Quaglia, Julia Wendon, Diego Vergani; King's College Hospital, Institute of Liver Studies, London, United Kingdom

Introduction Central to the immunoparalysis in acute liver failure (ALF) is monocyte deactivation, characterised by a reduction in the percentage and absolute number of monocytes expressing the HLA-DR molecule. This reduction and concomitant elevations of circulating levels of both pro-(TNF-α) and anti-(IL-10) inflammatory cytokines, are strongly associated with severity of acute hepatic injury and predict poor outcome. It is not known whether the profound depletion of immunocompetent, HLA-DR expressing monocytes is confined to the periphery or reflects intra-hepatic events. Aim: To compare monocyte/macrophage HLA-DR expression, pro- and anti-inflammatory cytokines in the liver and peripheral blood of patients with ALF. Methods: The macrophage specific CD68 marker, HLA-DR, TNF-α and IL-10 were detected by single epitope immunohistochemistry in serial paraffin-embedded explanted liver sections from 11 ALF patients. Peripheral total monocyte count was determined using Coulter counter and peripheral blood monocyte HLA-DR (mHLA-DR) was determined, 24 hours before transplantation in all 11 ALF and compared to 59 pathological controls with compensated cirrhosis (CLD group) by flow cytometry after staining 50µl fresh blood labelled with monoclonal antibodies for HLA-DR and CD14. mHLA-DR expression is given as % and total number of HLA-DR positive monocytes. Hepatic TNF-α and IL-10 gene expression was determined in 7 out of 11 explanted liver frozen tissue samples using specific primers real-time (rt) PCR. Results All 11 ALF explant specimens were characterised by a large infiltrate of CD68 positive macrophages concentrated in areas of centrilobular necrosis, the majority of these cells strongly expressing of HLA-DR (figure). This contrasted with the findings in the periphery where a profound reduction in median mHLA-DR % (11.6% vs 71%, p<0.001) and total number of HLA-DR expressing monocytes (0.06 x 10⁹/L vs 0.36 x 10⁹/L, p<0.001) was found when compared to pathological controls. Hepatic gene expression of TNF-α and IL-10 was concentrated in areas of necrosis with that of IL-10 (18±2.5) being significantly higher than of TNF-α (3.6±2.0, p=0.021). Conclusion Our data show that in the liver of ALF there is an abundance of HLA-DR expressing intra-hepatic macrophages in striking contrast to their paucity in the periphery; illustrating the dichotomy between local and systemic immune responses during systemic inflammation. The high hepatic IL-10 expression suggests a concomitant anti-inflammatory cytokine profile that could partly explain the IL-10 induced systemic immunoparalysis observed in ALF.

Disclosures: The following people have nothing to disclose: Charalambos G. Antoniades, Philip A. Berry, Munther Hussain, Maria Serena Longhi, Alberto Quaglia, Julia Wendon, Diego Vergani
tality in animals and rescued 90-100% mice, p<0.001. Conclusions: Acute liver failure associated with toxic injury may be the result of profound perturbations in the ATM signaling pathway. Despite extensive liver injury in this situation, hepatic support through transplantation of suitable cells in an appropriate extrahepatic location, such as the peritoneal cavity, will have therapeutic potential. This animal model will have multiple uses in defining the cell therapy potential of various cell populations, including stem cells, as well as other potential interventions for acute liver failure.

865 PRECLINICAL ASSESSMENT OF HEPAHOPE BIOARTIFICIAL LIVER SYSTEM

Sung-Soo Park1, Yoon-Kyong Yang1, Young-Im Lee1, Jaeho Jung1, Delai Zhao1, Young Park1, Hyoun Yoon1, Jun-Seok Park1, Jennifer Tam1, Chintya Ganda1, Hyung-Taek Lee1, Sunny Yang1, Charles Grupper1, Robert G. Gish2, Brendan McGuire3, Angela Panoskaltsis-Mortari4, Dong Jin Suh2, Han Chu Lee3, James Ferguson5; 1HepaHope, Irvine, CA; 2California Pacific Medical Center, San Francisco, CA; 3University of Minnesota, Minneapolis, MN; 4University of Ulsan, Seoul, South Korea; 5ISIS services, Berkeley, CA

Acute liver failure (ALF) is one of major cause of death worldwide. HepaPheresisTM System (HepaHope BiArtificial Liver System containing 2 bioreactors each with ~75g porcine liver slices) was designed to treat such liver failure patients as a potential life-saving alternative. Designated pathogen free, transgenic hCD46 swine from Mayo Clinic were utilized as liver sources. In vitro and in vivo studies were conducted to demonstrate the safety and efficacy of the HepaPheresisTM System for human clinical trial. In vitro studies underwent to evaluate the safety and performance of the HepaPheresisTM System. Human plasma was used to mimic clinical condition. The liver slices in HepaPheresisTM System were proved to be functioning by clearing lidocaine and diazepam and accumulating their metabolites (Dimethylxylidine, temazepam and nordiazepam). Up to 60% of ammonia was cleared with conversion to blood urea nitrogen. HepaPheresisTM System did not activate porcine endogenous retrovirus (PERV) in liver slices. GLP long term (3 weeks) and short term (3 days) safety studies were conducted to test the safety of HepaPheresisTM System by using canines (16 dogs) which were grouped into treatment (with liver slices) and control (without liver slices). All animals showed no significant clinical complications. Biomarkers, physiologic, coagulation and immunologic parameters were in normal range in both control and treatment groups. PERV was not detected in treated canine serum by RTqPCR. In vivo efficacy study was performed by using combined surgical (two stage de-vascularization) and ammonia induced canine ALF model. 10 dogs were arranged to treatment, control and sham group. ALF Scoring system was applied to evaluate reliable liver failure status (liver damage, hepatic encephalopathy and coagulopathy). Based on survival time measured from the end of the HepaPheresisTM System treatment to the death of animal, the treatment group animals survived 3 to 6 times longer than control and sham animals. Other biomarkers especially ammonia were lower in treatment group than sham and control groups. Treatment animals showed decreased intracranial pressure during the BAL treatment and delayed onset of increased intracranial pressure after treatment. The series of studies showed the safety of HepaPheresisTM System. There was no PERV activation during in vitro study and no significant complication in canine treatment. Efficacy of HepaPheresisTM System was demonstrated by ammonia and drug metabolism in vitro study and survival benefit in canine ALF model.

866 ACTIN FREE GC GLOBULIN: A RELIABLE MARKER OF OUTCOME IN ACUTE AND ACUTE ON CHRONIC LIVER FAILURE

Andrew J. Portal, Matthew Bruce, Mark Austin, Constantine J. Karvellas, Mark McPhail, Elizabeth Sizer, Georg Auzinger, Julia Wendon, William Bernal; Institute of Liver Studies, Kings College Hospital, London, United Kingdom

Introduction Gc globulin, a component of the actin scavenger system has previously been shown to be a useful marker of prognosis in acute (ALF) and acute on chronic liver failure (AoCLF) in a retrospective cohort from this institution. We measured actin free (and therefore biologically available) Gc Globulin (Af-Gc), and prospectively assessed its use in ALF and AoCLF patients admitted to a liver intensive therapy unit. Methods Af-Gc was measured in 40 consecutive patients with ALF and 28 with AoCLD within twenty four hours of admission. ALF patients were subdivided into true acute liver failure (tALF; ie with encephalopathy, n=22) or acute hepatic dysfunction alone (AHD; n=18). Af-Gc was measured using sandwich ELISA (AntibodyShop®). Biochemical, physiological and outcome variables were recorded. Results are expressed as median and interquartile range (IQR). Transplantation was considered equivalent to death. Results In ALF patients, Af-Gc values were significantly lower in patients with tALF as opposed to those with AHD (15.1 (2.1-38.9) vs 53.2(27.9-87.7); p<0.001) and also in patients who were listed or fulfilled transplant criteria compared to those that did not (10.4 (2-34.4) vs 53.2 (27.9-87.7); p<0.001; sensitivity 82%; specificity 78%). Af-Gc was significantly higher in those with AoCLF when compared to ALF (59.4mg/L (39.1-105.1) vs 27mg/L (5.3-57.7); p<0.001). In AoCLF patients, Af-Gc correlated with MELD score (r=0.65; p<0.001). Af-Gc was significantly lower in patients requiring filtration (45.6mg/L (21.1-62.1) vs 68.8 (56.3-110.4); p<0.02) and also in those did not survive to 30 days (40.2 (21.1-61.3) vs 68.6 (58.6-68.6); p<0.005). Af-Gc values < 55.6mg/L (AUC
867 INTEGRATED METABONOMIC INVESTIGATION IN THE MODEL OF LIVER INJURY AND REGENERATION INDUCED BY CCl4 IN RATS

Athina Zira1,2, Stamatios E. Theocharis1, Soren Engelsen3, Ioannis Stamoulis1, Ioanna Andreadou2, Emmanuel Mikros2; 1Department of Forensic Medicine and Toxicology, Medical School, National and Kapodistrian University of Athens, Athens, Greece; 2Department of Pharmaceutical Chemistry, School of Pharmacy, National and Kapodistrian University of Athens, Athens, Greece; 3Department of Dairy and Food Sciences, Royal Veterinary and Agricultural University of Copenhagen, Copenhagen, Denmark

The Metabonomic approach in toxicological studies is used to detect and quantify changes in the levels of metabolites as a response of living systems to toxicity. In the present study NMR based metabonomics, combined with pattern recognition techniques, was applied in order to study metabolic alterations in liver tissue extracts and plasma of rats intoxicated by CCl4. Acute liver injury was induced in adult male Wistar rats by intraperitoneal administration of CCl4 (1 ml/kg BW). The animals were sacrificed at 0 (controls) and at 12, 24, 36, 48, 60 and 72 h after CCl4 administration. Liver tissue and blood samples were collected from all animals for 1H-NMR spectroscopic analysis, estimation of biochemical parameters and histopathological examination. NMR spectra were segmented in 0.04 ppm regions and integrated. The data were analyzed using Principal Component Analysis (PCA) to maximize information recovery. Spectroscopic and biochemical data correlate with histopathological analysis verifying that the maximum of the toxic insult occurred at 24 h post-CCl4 administration, followed by a regenerative process later on. Differences in the levels of glucose, glycogen, lactate, alanine and choline were observed in the aqueous soluble liver extract between controls and CCl4 treated subjects. The lipid soluble liver extract revealed an overall increase in the lipids during the toxic phase compared to controls, gradually regaining the control levels at 72h. Alterations in the levels of glucose, lipoproteins, lactate and formic acid in plasma were also noted. PCA of liver tissue extracts and plasma samples revealed a distinct separation between animals under toxic insult and those at the regenerative state and the control group was totally separated from the CCl4-treated animals. These results suggest that 1H-NMR based metabonomics when applied in a rat model of acute liver injury can distinguish the toxic insult from the regenerative state. Alterations in the levels of metabolites in both liver and plasma reflect changes in energy usage and in metabolic pathways.

868 ANATOMICAL LOCATION OF ACUTE LIVER INJURY DETERMINES THE BONE MARROW RESPONSE TO LIVER INJURY

Eleanor S. Gilchrist1, Catherine Payne1, Kay Samuel2, Patricia Lee1, Philip N. Newsome1, John Plevris1; 1Hepatology, University of Edinburgh, Edinburgh, United Kingdom; 2John Hughes Bennett Laboratories, University of Edinburgh, Edinburgh, United Kingdom

It has been demonstrated by many groups, including our own, that haematopoietic stem cells are mobilised into the peripheral blood (PB) in liver injury. The chemokine SDF-1 has a role in this. However, there are reports in which mobilisation is not seen. We postulated that anatomical location of liver injury may be a factor. We compared two models of acute liver injury in NOD/SCID mice. 4 mice were injured with carbon tetrachloride (CCl4) (0.3 ml/kg) and sacrificed at 24 hours. 4 mice were treated with 70mg/kg phenobarbital daily for 4 days and then with a single dose of 50mg/kg cocaine. They were sacrificed at 24 hours. 4 control animals were used. PB, bone marrow (BM) and liver were collected from each animal. CD34+ cells were counted in both PB and BM. The gradient hypothesis suggests that haematopoietic stem cells migrate along an SDF-1 concentration gradient. We measured SDF-1 concentrations in BM supernatant, plasma and liver homogenate from these animals by ELISA. Similar degrees of injury were obtained in both injury groups, as determined by ALT (>6000iu/µl). CCl4 produced a peri-central injury; cocaine a peri-portal injury. There was an increase in PB CD34+ cells in the cocaine group compared to control (mean 1.32% vs. 0.206% monocytes). In addition, there was an increase in BM CD34+ cells seen in the cocaine group (mean 7.097% vs. 4.72% monocytes). These increases were not seen in the CCl4 group. In control animals the BM/plasma SDF-1 ratio was 0.13ng/mg total protein/0.01ng/mg = 13, whilst in cocaine injury it was 0.31ng/mg/0.26ng/mg = 1.2. This represents a near reversal of the BM/plasma SDF-1 gradient and may account for the increase in PB CD34+ cells seen above. A smaller gradient reversal was seen in CCl4 (0.1/0.06=1.7), but in the absence of an increase in BM CD34+ cells (4.93%), there was no increase in PB CD34+ cells (0.05%). There was a decrease in liver SDF-1 concentrations in cocaine injury (0.0098 ng/mg protein, control 0.037 ng/mg), borne out by diminished staining intensity for SDF-1 by immunohistochemistry. There was no change in the CCl4 group. We postulated that peri-portal injury in the cocaine injured group might cause bile duct injury, resulting in decreased liver SDF-1, but Feulgen staining did not confirm excess apoptosis. Conclusions 1) Anatomical location of liver injury (peri-portal vs. peri-central) determines bone marrow response in NOD/SCID models of acute liver injury. 2) Reversal of the BM/ PB SDF-1 gradient with an increase in plasma SDF-1 is associated with stem cell mobilisation in our model of peri-portal injury. 3) Intra-hepatic SDF-1 plays a minor role in stem cell recruitment in our model.

Renal Failure in Acute and Acute on Chronic Liver Failure: A Role for Novel Renal Biomarkers?

Andrew J. Portal¹, Mark Austin¹, Matthew Bruce¹, Constantine J. Karvellas¹, Funmi Awopetu², Ray Sherwood², Elizabeth Sizer¹, William Bernal¹, Georg Auzinger¹, Michael Heneghan¹, Julia Wendon¹, ¹Institute of Liver Studies, Kings College Hospital, London, United Kingdom; ²Department of Biochemistry, Kings College Hospital, London, United Kingdom

Introduction Renal failure is common in acute (ALF) and acute on chronic liver failure (AoCLF). Novel renal biomarkers have been pioneered but have not yet been examined in this patient cohort. We report our experiences of two such markers, Neutrophil Gelatinase Associated Lipocalin (NGAL) and Cystatin C (Cys C), in acute and acute on chronic liver failure. Methods Blood and urine samples were collected within 24 hours of admission to a specialist liver intensive care unit. Novel biomarkers were compared with standard markers of renal function. Serum Cys C was measured by immunonephelometry and NGAL by sandwich ELISA (urine (uNGAL) and plasma (pNGAL), AntibodyShop®). Biochemical and physiological data was collected prospectively over the first 5 days of admission. Renal dysfunction was defined as the need for renal replacement therapy (RRT) or by reduced estimated glomerular filtration rate (eGFR<60). Results are expressed as median and interquartile range. Results In both ALF (n=40) and AoCLF (n=28) patients, pNGAL correlated significantly with day 1 serum creatinine (sCr) r=0.54 (p<0.001), day 1 urine output r=-0.53, (p<0.001), day 3 urine output (r=-0.54, p<0.001). Cys C had similar correlations. uNGAL had strong correlations with sCr (r=0.72, p<0.001) and with eGFR (r=0.77, p<0.001) on day 3. Day 3 values of both pNGAL and uNGAL were significantly higher in patients requiring RRT, as were day 5 pNGAL values in those needing RRT. No significant differences were observed for Cys C. Receiver operator characteristic curves (ROC) showed pNGAL predicted the need for RRT on days 3 and 5 (Day 3: pNGAL AUC 0.84 [0.73-0.94], p<0.001 vs sCr AUC 0.77 [0.64-0.90], p<0.001. Day 5: pNGAL AUC 0.72 [0.57-0.88], p=0.02 vs sCr /Cys C/eGFR not significant). For ALF patients, uNGAL correlated very strongly with day 3 need for RRT (r=0.70, p=0.02), urine output (r=0.85, p<0.001) and eGFR (r=0.83, p<0.001). Both uNGAL and pNGAL were significantly higher in acetaminophen induced ALF than non acetaminophen ALF (uNGAL 374ng/ml (155->500) vs 42ng/ml (5-205) respectively, p=0.02; pNGAL 296ng/ml (199-458) vs 158ng/ml (60-338) respectively, p=0.03). This reflected the higher incidence of renal impairment in the acetaminophen group (95% vs 40%, p=0.02). Admission uNGAL and pNGAL were associated with the need for RRT on day 3 of admission (uNGAL AUC 0.9 [0.71-1.1], p=0.05; pNGAL AUC 0.83[0.69-0.98], p=0.002). Conclusions Plasma and urine values of NGAL represent promising markers of early renal impairment in liver disease. Further investigation may clarify the pathological processes by which renal failure occurs in liver disease.

Staged Algorithm for Activating Living Donor Liver Transplantation for Acute Liver Failure in Adults

Michal Carmiel-Haggai¹,², Richard Nakache²-³, Riki Keidar²-⁴, Patric Sorkin², Nimrod Adi², Ran Oren¹,², Menahem Ben-Haim²-³, ¹Department of Gastroenterology & Liver Disease, Tel-Aviv Sourasky Medical Center, Tel-Aviv, Israel; ²Organ Transplantation Unit, Tel-Aviv ‘Sourasky’ Medical Center, Tel-Aviv, Israel; ³Surgery B, Tel-Aviv ‘Sourasky’ Medical Center, Tel-Aviv, Israel; ⁴Social Work Services, Tel-Aviv ‘Sourasky’ Medical Center, Tel-Aviv, Israel; ⁵Intensive Care Unit, Tel-Aviv ‘Sourasky’ Medical Center, Tel-Aviv, Israel

Background and Aims: Organ scarcity is a major problem worldwide. Facing a patient with acute liver failure (ALF), waiting time is a devastating factor which correlates with high mortality rate. In this report we present an algorithm used to activate a living donation (LD) for a patients with ALF. Patients and Methods: Data of all patients admitted to ICU between 1/2002 and 3/2007 that were diagnosed with ALF and fulfilled King’s criteria for liver transplantation was collected. For patients who were listed as status one, a simultaneous search for LD was started among close family members, aged 18-50, who express their wish to donate. Potential donors underwent medical, psycho-social and imaging evaluation. Upon completion the most appropriate potential donor was presented for final approval by an ethic committee. Even though LD was found and approved, the patient was still waiting for a cadaveric donation (CD). Only when grade III encephalopathy occurred and the patient was sedated, ventilated and no CD was found, LD was performed within 12-24 hours. Waiting time was calculated from listing to transplantation or death. Critical waiting time was referred to the period patient was intubated. Results: Twenty six patients [17 women], aged 1.5-58 years (median 30) with ALF, fulfilled King’s criteria for liver transplantation with an average MELD score of 43 (range 17-58). Sixteen families were informed of a possible need for LD, and 65 potential donors from 13 families started an active evaluation. Nineteen had completed evaluation, 5 of them eventually were declined. Nine potential donors were approved for 9 patients. Eleven patients recovered without transplantation (42%). Twelve underwent liver transplantation (46%); 7 had LD and 5 received CD (2 had an approved potential LD, 2 were transplanted during evaluation of LD and one with no potential LD). Three patients died while waiting (12%): none of them had a potential LD. Critical waiting time was longer for patients who died without transplantation compared with patients transplanted with LD or CD (8.3 vs 2.1 (p<0.001) vs 1.6 (p=0.005) days, respectively). All living donors had an excellent recovery with no major complications. Three months patients and graft survival were 100% for recipients of LD, and 80% for recipients of CD (over median follow up of 42 months (3.5-55 months). Conclusions: Ethical debate of LD for adult’s ALF exists. Nevertheless, the use of a cautious algorithm which provides a safety net of LD may minimize the impact of luck in finding an organ when critically needed. It may reduce waiting-time mortality rate and potentially improves patient’s outcome.

THE RATIO OF COMPUTED TOMOGRAPHY-DERIVED LIVER VOLUME / STANDARDIZED LIVER VOLUME IS A USEFUL PROGNOSTIC FACTOR OF ADULT ACUTE LIVER FAILURE

Yoshiyuki Yamagishi, Hitotsubu Saito, Shinichiro Tada, Hirotoshi Ebinuma, Masahiro Kikuchi, Yoshihiro Hori, Shinzou Kata, Toshifumi Hibi; Division of Gastroenterology & Hepatology, Department of Internal Medicine, School of Medicine, Keio University, Tokyo, Japan

[Background and Aim] Acute liver failure (ALF) is still one of fetal diseases. Since cadaverous liver transplantation is rarely performed by religious reasons in Japan, living donor liver transplantation (LDLT) is usually done for progressive ALF cases. Because a living donor is always a healthy volunteer, prognostic markers are needed to decide whether the patient really needs transplantation. King's College Hospital (KCH) criteria and The Model for End-Stage Liver Disease (MELD) score are famous and useful. Liver atrophy not included in these criteria seems to be one of poor prognostic factors. The aim of this study was to determine whether liver atrophy is a useful poor prognostic marker for ALF. [Methods] Computed tomography-derived liver volume (CTLV) of 30 adult ALF patients treated in our institution was calculated at the time of diagnosis. Their standardized liver volume (SLV) was also calculated using the formula shown in the previous report (Urata, et al. Hepatology 1995). Patients were divided into two groups; group A, 13 patients recovered from ALF without surgical procedure; group B, 17 patients died due to liver failure or underwent LDLT. The CTLV/SLV ratios of two groups were compared. Actual liver weight (ALW) was measured in 14 cases when LDLT or autopsy was performed and compared to their latest CTLV. [Results] The CTLV/SLV ratio was significantly correlated with the ALW/SLV ratio (p<0.001, r²=0.959). The mean CTLV/SLV ratio of group A and B was 1.019±0.182 and 0.757±0.240, respectively (p<0.01). Receiver operating characteristic curve analysis of this showed a good diagnostic potential [area under curve=0.86, p<0.05]. The statistical difference between group A and B was mostly significant (p=0.0002) at the probability cut-off point 0.80 of the CTLV/SLV ratio with 76.5% sensitivity and 92.3% specificity. In the factors of KCH criteria, jaundice duration prior to hepatic encephalopathy (p<0.05) and serum total bilirubin levels (p<0.01) were significantly different between the groups. No significant difference was noted in etiology, age, PT-INR. There were significantly more cases having more than three factors of KCH criteria in group B (p<0.05). There was not the significant difference about MELD score. Multiple logistic regression analysis identified that the CTLV/SLV ratio was an only independent predictor (p<0.05, OR=22.1, 95%CI=1.83-234). [Conclusion] The CTLV/SLV ratio is very useful procedures to objectively estimate liver atrophy and to predict the prognosis of adult ALF cases. A patient with the CTLV/SLV ratio under 0.80 is predicted to have poor prognosis, and transplantation should be considered as soon as possible.

A NEW GENOTYPE OF HEPATITIS C VIRUS ORIGINATING FROM CENTRAL AFRICA

Donald Murphy1, Jasmine Chamberland1, Raymond Dandavino2, Erwin Sablon3; 1Laboratoire de santé publique du Québec, Institut national de santé publique du Québec, Sainte-Anne-de-Beaupré, QC, Canada; 2Service de néphrologie, Hôpital Maisonneuve-Rosemont, Montréal, QC, Canada; 3Infectious Diseases Unit, Innogenetics, Ghent, Belgium

The characterization of hepatitis C virus (HCV) variants from different parts of the world has shown that they can be classified into 6 genotypes. Their distributions differ geographically. Genotypes 1, 2 and 4 display significant genetic diversity in Africa while genotypes 3 and 6 show high genetic diversity in southern Asia. On the other hand, genotype 5 is comprised of only one subtype and its origin remains to be established. We have identified three variants (QC69, CS101285 and CS101300) that cluster together but do not classify within the 6 genotypes of HCV. In order to better characterize these variants and to study their evolutionary relationships with the other genotypes, the entire coding region sequence of QC69 and partial coding region sequences of CS101285 and CS101300 were determined. QC69 was isolated from a patient residing in Canada while CS101285 and CS101300 were obtained from patients residing in Belgium. However, all three patients originated from the Democratic Republic of Congo where they are believed to have been infected. QC69 contained an open reading frame of 3013 amino acids. It showed 33.4% to 35.5% nucleotide and 28.1% to 31.0% amino acid divergence with genotypes 1a-H77, 2a-HCJ6, 3a-NZL1, 4a-ED43, 5a-EUH1480 and 6a-EUHK2. Phylogenetic analysis based on complete coding region sequences (Figure) shows that QC69 forms a branch distinct from other genotypes confirming that it constitutes a novel HCV genotype. Additional analysis performed on individual gene regions indicates a closer relationship between genotype 6c and genotype 2 variants analogous to the relationship observed between genotype 1 and 4 variants. This analysis also showed that QC69 was not produced as a result of recombination events between known genotypes. Further epidemiological studies based on coding region sequences are required to determine the prevalence and spread of this genotype in Africa. The finding of a new genotype in Central Africa will contribute in elucidating the origin of the worldwide HCV epidemic. We propose that these three isolates be classified as genotype 7 of HCV.

OUTBREAK OF A NEW HEPATITIS C VIRUS SUBTYPE (SUBTYPE 1M) IN A HEMODIALYSIS UNIT

Stephane Chevaliez1, Rozenn Brillet1, Jean Sehonou2, Laetitia Barbotte1, Jean-Michel Pawlotsky1; 1Henri Mondor Hospital, University of Paris 12, Creteil, France; 2Hubert Kutuku Maga Hospital, Cotonou, Benin

Nosocomial transmission, especially in the hemodialysis setting, is one of the most frequent causes of hepatitis C virus (HCV) infection worldwide. We describe an outbreak of a new HCV genotype 1 subtype in a hemodialysis unit, illustrating how new HCV genotypes may spread in the developing world and further.

METHODS: The 64 patients undergoing regular renal dialysis in the hemodialysis unit of Hubert Kutuku Maga Hospital in Cotonou, Benin (Africa) have been tested for the presence of anti-HCV antibodies and HCV RNA. Two HCV genomic regions, located within the non-structural 5B and the core-E1 coding regions, have been PCR-amplified and sequenced in all cases at the French National Reference Center for Viral Hepatitis B, C, and delta. Genetic and phylogenetic analyses have been performed to assess the genetic relatedness between the strains, in order to evaluate the frequency of between-patient transmissions in the context of hemodialysis.

RESULTS: 19 hemodialysis patients out of 64 (29.7%) were HCV-infected; 17 of them were infected with HCV genotype 1, one with genotype 2 and one with genotype 3. Among the 17 patients infected with genotype 1, 4 (23.5%) were infected with subtype 1i, one with subtype 1b, and 12 (70.6%) could not be subtyped. The 4 patients infected with genotype 1i clustered together and distinctly from other reference genotype 1 strains, suggesting between-patient transmissions in the hemodialysis unit. In the 12 patients that could not be subtyped, the sequences were analyzed by a variety of distance-based, parsimony, and maximum-likelihood methods and evidence was sought for consistent phylogenetic grouping together and distinctness from other subtypes. All studied HCV strains were closely related together and segregated into one monophyletic cluster with high bootstrapping values, suggesting nosocomial transmission in the hemodialysis unit. Furthermore, these strains differed from all of the known HCV genotype 1 subtype nucleotide sequences (1a to 1l) by 16-26% in the NS5B region and 24-33% in the core-E1 region. Since the cluster members diverged from subtypes 1a to 1l by more than 15% of their nucleotide sequence, they could be assigned a new, provisional subtype designation: subtype 1m.

CONCLUSION: We report a high prevalence of nosocomial transmission of HCV in a hemodialysis unit in Benin, Africa. We identified a new subtype of HCV genotype 1, provisionally designated as subtype 1m, that was heavily transmitted among the regular hemodialysis patients. This study witnesses how new subtypes of HCV genotypes may be transmitted though nosocomial routes in the developing world before further spreading.

HEPATITIS C VIRUS RNA IS DETECTED IN CERVICOVAGINAL FLUIDS OF MENSTRUATING WOMEN, IN A MENOPAUSAL WOMAN WITH BLOODY CERVICOVAGINAL FLUID, BUT NOT IN WOMEN WHO HAVE HAD Hysterectomy

Chia C. Wang1, Linda Cook2, Sarah Holte1, Meighan Krows1, Arthur Bagabag2, Rawing Ng2, Keith Jerome1,2; 1Medicine, University of Washington, Seattle, WA; 2Virology, Fred Hutchinson Cancer Research Center, Seattle, WA

OBJECTIVE: Sexual transmission of hepatitis C (HCV) accounts for approximately 20% of new infections. Nevertheless, the presence of HCV RNA in the female genital tract has not been extensively examined; in 3 published cross-sectional studies, 19-25% of women of childbearing age had detectable HCV RNA. We sought to define the prevalence of female genital tract HCV RNA shedding in a prospective study of pre- and post-menopausal women.

METHODS: Women with untreated chronic HCV and detectable serum HCV RNA were enrolled. Menstrual status and history of hysterectomy were recorded. Women inserted two Dacron swabs into their vaginas every morning as they would a tampon, placed the swabs into dry cryovials, and stored them immediately in their home freezers for 18-56 consecutive days. Menstruating women indicated menstruation dates. HCV RNA and hemoglobin were detected in cervicovaginal fluids using real-time RT PCR and spectrophotometry, respectively. Statistical analyses were performed using nonparametric tests and generalized estimating equations taking into account repeated measures.

RESULTS: 16 women were enrolled; median age was 50 (range 27-59). Seven women were menstruating, 6 were menopausal, and 3 had had hysterectomies. Baseline serum VL was 6.43 (range 5.17-7.36 log10 IU/ml) and did not differ by menstruation or hystereCTomy status. Menstruating women were more likely than menopausal women to have HCV RNA detected in cervicovaginal fluids on at least one day (86% versus 16%, p=.02). For menstruating women, detection of HCV RNA was more likely during menstruation (OR= 56.4, 95% CI (23.0,138.3)) or when hemoglobin was detected in cervicovaginal fluids, even when menstruation was not occurring (OR= 35.4, 95% CI (12.2,102.6)). The median quantity of HCV RNA detected in cervicovaginal fluids in menstruating women was 4,631 (range 231-69,580 IU/ml). Only 1 menopausal woman had HCV RNA detected in cervicovaginal fluids; she also had hemoglobin detected on 8 days during the 56 day sample collection period.

CONCLUSIONS: In women with chronic hepatitis C, HCV RNA detection in cervicovaginal fluids is associated with menstruation or the detection of hemoglobin on non-menstruation days. HCV RNA was not detected in women who had had hysterectomies, suggesting that the presence of the cervix plays a role in HCV RNA genital tract shedding in women. The quantity of HCV RNA detected was low, supporting the epidemiologic finding that HCV is not efficiently transmitted sexually. These findings highlight the fact that HCV is primarily a blood-borne virus, and may have implications for menstruating women with chronic hepatitis C.

HEPATITIS C TESTING, CARE AND TREATMENT: EVOLUTION OVER TEN YEARS IN FRANCE

Christine Meffre1, Elisabeth Delarocque-Astagneau1, Corinne Pioche1, Frédéric Dubois2, Françoise Roudaut-Thoraval2, Dominique Guyader3, Christine Silvain3, Yann Le Strat4, Jean Claude Desenclos1
1National Institute for Public Health Surveillance (InVS), Saint-Maurice, France; 2Social Security Health Centre (IRSA), La Riche, France; 3University Hospital, Créteil, France; 4University Hospital, Rennes, France

With a prevalence of Hepatitis C virus antibodies (anti-HCV) of about 1% in the population in 1994, hepatitis C was considered as a serious public health issue by French health authorities that consequently implemented a national prevention and control program in 1999. To assess its impact we set up two surveillance systems to 1) monitor trends in anti-HCV screening (Rena-VHC) and 2) to follow up epidemiological-clinical characteristics of HCV patients newly referred for care and treatment in hepatology centres (Pôles-de-Référence) and conducted a population based prevalence survey in 2004. We present the change over time of several key indicators. We used four data sources. Two were national cross sectional population-based serosurveys of French adult metropolitan residents that collected risk factors and awareness of HCV infection. Serum samples were tested for anti-HCV and HCV RNA. The third was Rena-VHC, based on 159 laboratories spread all over France that report number of performed anti-HCV tests, number of positive tests, age and sex of positive diagnosed persons. The forth was Pôles-de-Référence which relies on 26 hepatitis C reference centres and describes clinical and epidemiological characteristics of newly referred patients, including circumstances of anti-HCV testing, risk exposure for HCV transmission, HCV RNA serum status and severe liver disease (cirrhosis, hepatocarcinoma).

From 1994 to 2004, the awareness of an anti-HCV seropositive status increased from 24% to 57% (95%CI: 43-71). In 2004, awareness was 93% (95% CI:77-98) for persons with history of injection drug use and, 67% (95% CI: 41-85) in case of transfusion <1992. From 2000 to 2005, Rena-VHC showed a 45% increase of overall anti-HCV performed tests and a significant decrease in the proportion of positive tests (p<0.0001, X2 linear trend). From 2001 to 2005 in Pôles-de-Référence, routine medical check-up was increasingly reported as a reason for anti-HCV screening (41% vs 52%) whereas screening in case of risk factors declined (25% vs 17%). The proportion of patients at first referral in the year of screening decreased slightly (49% vs 43%) and proportion of patients with cirrhosis (Metavir score F4) remained stable (11%). Our analysis of four sources of information indicates convergent results which suggests that the hepatitis C program was effective, particularly in increasing the proportion of HCV patients screened. However the decrease of positive tests with an increase of overall tests suggests an excess of screening of persons at low risk. The screening strategy needs to evolve to better and more timely identify those at risk of HCV infection for earlier intervention.

INJECTION DRUG USE, SOCIAL NETWORKS AND HEPATITIS C: UNDERSTANDING THE BEHAVIOURAL AND IMMUNOVIROLOGICAL FACTORS LEADING TO TRANSMISSION - THE NETWORKS II STUDY

Margaret E. Hellard1, Campbell Aitken2, Mandvi Bharadwaj2, Scott D. Bowden2
1CEPHR, Burnet Institute, Melbourne, VIC, Australia; 2Department of Microbiology and Immunology, University of Melbourne, Melbourne, VIC, Australia

Hepatitis C virus (HCV) infection affects an estimated 180 million people worldwide, and causes 50–76% of liver cancers and two thirds of liver transplants in the developed world. The burden of disease and costs attributable to HCV-related chronic liver disease will grow due to complications of cirrhosis and hepatocellular carcinoma in ageing chronically-infected cohorts and as new HCV infections arise. It is imperative that research efforts focus on ways to prevent new HCV infections to reduce the global burden of disease. In Networks II study we established a longitudinal IDU cohort study; 251 IDUs are followed for two years. Networks II enables us to study HCV transmission (naïve, recurrent and superinfection) and behavioural and immunological determinants of this and HCV clearance using a social network approach where the relationship between the IDUs is studied. Recruitment commenced in Melbourne, Australia in July 2005. Every three months participants completed a questionnaire about sexual, injecting and other risk behaviour, network data, and provided a blood samples. Blood tests included HCV antibody, HCV RNA, genotype and molecular sequencing. Samples were also HLA typed and then tested for HCV specific CD8+ T cell response using minimal T cell epitopes. We describe the results for the first year of the study. The traditional (naïve) incidence in our cohort to date is 29.1% per annum (95% CI 17.5, 48.3) and 79.2% (95% CI 23.5, 245.4) in IDUs injecting for less than one year. The incidence of reinfection was 50.6% (33.3, 76.9) and of superinfection 20.8% (12.9, 33.4). A key driver of HCV infection was having all members of your network HCV-infected whereas the number of injecting partners and the level of needle-sharing were less important when measuring disease transmission. We identified 39 persistently HCV RNA negative people who injected with >=1 RNA-positive partner, and six who recently injected with a needle used by >=1 RNA-positive partner; this suggests they possess innate resistance or develop protective immunity. Our immunological data suggest that IDUs who clear HCV maintain functionally potent memory CD8+ T cells that are highly cytotoxic and produce antiviral cytokines (IFNg and TNFa); conversely, CD8+ T cells from IDUs with persistent HCV infection are functionally downregulated with compromised cytotoxic and cytokine secreting capacity. The results of Networks II thus far have advance understanding of the dynamics and immunovirology of HCV infection transmission. It is our expectation that the study will provide further insights that will contribute to HCV prevention intervention strategies and vaccine development.

Purpose: People with chronic hepatitis C (HCV) may face barriers to accessing health services. The aims of this study were to determine the extent to which perceived barriers may complicate HCV care and to examine the relationship between barriers and socioeconomic (SES) factors. Methods: One hundred and twenty eight (n=128) patients referred for HCV at two hepatology centers completed instruments on a laptop computer during one of their first two clinic visits. The Barriers to Care Scale (BACS), a 12-item scale with 4 subscales developed for HIV patients, was modified for this study. Items were rated on a 4-point scale, ranging from 1 (No problem) to 4 (Major Problem) to indicate the extent to which each barrier made it difficult to access HCV care. Nonparametric tests were used to explore associations between SES and BACS subscales.

Results: The majority of participants were male (55%), Caucasian (81%), married (53%) with a mean age of 46 years. SES characteristics were as follows: Working full or part-time (70%); Household income of < 40K (56%); No insurance (11%); Traveled over 30 minutes to clinic (54%); and Lack of self-transportation (21%). The greatest barriers rated by participants were lack of personal financial resources, lack of HCV knowledge in their community, and feeling stigmatized for having HCV. Long distance to a hepatitis facility and lack of professionals competent in HCV care were also highly rated as barriers to HCV care (See Table 1). The following associations were found between BACS subscales and SES factors: 1) Distance was a barrier for unemployed patients (p=.04) and patients without self-transportation (p=.006); 2) Community stigma was greater for women compared to men (p=.04); and 3) Personal resources were a barrier for unmarried patients (p=.001), patients without private insurance (p=.007), and patients without self-transportation (p=.000). Conclusions: HCV patients perceive numerous barriers to accessing HCV care, which are related in part to SES factors. These data must be considered when designing interventions to increase access to care for HCV patients.

878 BARRIERS TO HEALTHCARE ACCESS AMONG CHRONIC HEPATITIS C PATIENTS

K. G. Reddy, Rohit Satoskar, Helen S. Te, Nancy Reau, Smruti R. Mohanty, Amanda DeVoss, Katherine Wherity, Donald M. Jensen; Medicine, Center for Liver Diseases, University of Chicago, Chicago, IL

BACKGROUND: Although hepatitis C (HCV) is common in the United States, the majority of patients are ineligible for clinical trials due to rigorous enrollment criteria and do not undergo standard treatment due to comorbid medical conditions and adherence failure. The majority of trials available in the U.S. are targeted at treatment naive genotype 1 HCV infected patients. AIM: To determine the candidacy of treatment naive HCV infected patients for HCV clinical trials referred to a tertiary referral center. METHODS: Using a hepatitis C registry database, we reviewed 230 consecutive new patients referred with a positive HCV antibody by ELISA to The University of Chicago Center for Liver Diseases between April 1, 06 and March 31, 2007. HCV infection was confirmed with PCR for HCV RNA and genotype status was identified. A retrospective chart review of treatment naive genotype 1 HCV infected patients using computerized records was performed to determine: patients’ demographic data, presence of advanced or concomitant liver disease and comorbidities. Both eventual standard of care HCV treatment and reasons for HCV study exclusion were recorded. RESULTS: Of the 230 patients, 128 (55.7%) were treatment naive genotype 1 HCV infected patients. The other 102 patients were: previously treated (n=68), other genotypes (n=22), unknown genotypes (n=3) or were HCV PCR negative (n=9). Of the 128 naive genotype 1 patients, 9 (7.0%) were enrolled in clinical trials and 17 (13.3%) were started on standard Peg-IFN based HCV therapy. Reasons for trial exclusion include: declined trial (n=26, 25.5%), decompensated or concomitant liver disease (n=18, 17.6%), malignancy in the last 5 years (n=14, 13.7%) renal insufficiency (n=13, 12.7%), ongoing alcohol abuse in the last 6 months (n=11, 10.8%), illicit substance use in the last 12 months (n=8, 7.8%), psychiatric illness (n=8, 7.8%), HIV (n=7, 6.9%), lost to follow up (n=6, 5.9%), cardiopulmonary issues (n=6, 5.9%) and uncontrolled diabetes (n=3, 2.9%). Seventeen (16.7%) had more than one criteria for study exclusion. Of the 17 on standard treatment, 12 (70.1%) had exclusion criteria for clinical trials. CONCLUSIONS: 1) Rigorous enrollment criteria of current clinical trials precludes most HCV infected patients referred to tertiary care referral centers. 2) The most common reasons for trial exclusion from treatment naive genotype 1 studies include: treatment refusal, decompensated or concomitant liver disease, malignancy and renal insufficiency, respectively. 3) Further studies should be done to determine feasibility of expanding enrollment criteria of future clinical trials.

879 ROLE OF CYP2D6*4 AS A GENETIC MARKER FOR FAST FIBROSIS PROGRESSION RATE IN CHRONIC HEPATITIS C: VALIDATION OF A PILOT STUDY IN LARGE COHORT

Sigal Fishman, Guy Rosner, Philippe Hallon, Hava Peretz, Guillaume Penaranda, Moshe Leshno, Zamir Halpern, Ran Oren; 1gastroenterology and hepatology, Tel Aviv Sourasky Medical Center affiliated to Sackler medical school of Tel Aviv University, Tel Aviv, Israel; 2Alphanbo laboratories Marseilles 13006, Marseille, France; 3Clinical Biochemistry laboratory, Tel Aviv Sourasky Medical Center affiliated to Sackler medical school of Tel Aviv University, Tel Aviv, Israel

BACKGROUND: Fifteen to twenty percent of chronic hepatitis C (HCV) patients progress during their life time to end stage liver disease and it crucial to identify them preemptively in order to give them a suitable treatment. However, markers of fibrosis progression rate are not available, yet. A recent pilot study has demonstrated an association between CYP2D6 polymorphism and fibrosis rate AIM: The aim of our study was to verify our preliminary data in a larger cohort and to determine whether CYP2D6*4, the poor metabolizer allele can predict fibrosis progression rate. METHODS: One hundred fifty six caucasian patients with chronic HCV and were recruited. All the patients had a liver biopsy assessed by the META VIR scoring system. No patient had received interferon treatment before biopsy sample was obtained. They were divided into “fast fibrosers” and “slow fibrosers” according to Poynard’s fibrosis progression curves, based on age of exposure and duration of infection. We assessed the effect of the following factors on fibrosis progression rate: estimated duration of infection; age; age at infection; hepatitis C virus C (HCV) genotype; HCV viremia; CYP2D6 polymorphism; and histological activity grade. DNA was extracted from peripheral blood and CYP2D6*4 was tested by polymerase chain reaction (PCR) method, using fluorescent hybridization probes in a LightCycler instrument. RESULTS Thirty four patients were classified as ‘fast fibrosers’ and 109 patients as ‘slow fibrosers’. The mean rate of fibrosis progression per year was 0.094 fibrosis unit (95% CI 0.0796-0.108). Using stepwise logistic regression we found that CYP2D6 polymorphism and liver biopsy activity were independent factors associated with fast rate of fibrosis progression. There was no association between fibrosis progression rate and age of infection or HCV genotype. The OR for CYP2D6 polymorphism was 2.02 (95% CI 1.02-3.95). Means that carrying one CYP2D6*4 allele doubles the risk for fast progression to fibrosis, and homozygous state increases the risk by four folds. CONCLUSIONS: This study indicates that CYP2D6 genotyping is a useful tool to predict liver fibrosis progression rate in HCV patients. Prospective studies are needed to further validate the data that bear significant therapeutic implication.

880 IMPACT OF HEPATITIS B CORE ANTIBODY POSITIVITY ON CHRONIC HEPATITIS C PATIENTS

Takamasa Ohki, Ryosuke Tateishi, Shuichiro Shinia, Takahisa Sato, Ryoya Masuzaki, Tadashi Goto, Hideo Yoshida, Shuntaro Obi, Fumihiko Kanai, Haruhiko Kobashi, Masao Oomata; 1gastroenterology and hepatology, Tokyo Medical University, Tokyo, Japan; 2Department of Internal Medicine, Showa University School of Medicine, Tokyo, Japan

AIM: To investigate whether HBc-Ab positivity is a risk factor of hepatocarcinogenesis in chronic hepatitis C patients. METHODS: We retrospectively analyzed the incidence of hepatocellular carcinoma (HCC) among patients with HCV infection followed up at our institution. Between 1994 and 2004, a total of 1431 patients who were positive for HCV, negative for HBs-Ag, and without HCC visited our out patient clinic and were followed up. We enrolled 995 of them whose status of HBc-Ab at visit could be determined. They were divided into two groups according to HBc-Ab; 574 patients were positive for HBc-Ab and 421 patients were negative for HBc-Ab. Characteristics of those two groups were compared by Student T-test and chi-square test. The cumulative incidence of HCC was assessed by Kaplan-Meier method and the difference between the groups was assessed by the log-rank test. The effect of positivity of HBc-Ab on hepatocarcinogenesis was assessed by multivariate Cox proportional hazard regression adjusted for other risk factors such as age, sex, alcohol intake, comorbidity with diabetes mellitus, presence of obesity and liver function. RESULTS: There were 514 male and 481 female patients with the median age of 60.1 year (range, 52.4 - 66.9). There were significantly more men (51.7% vs. 48.3%, P < 0.001) and elderly patients (mean age, 61.0 vs. 57.0, P < 0.001) in those with HBc-Ab than those without. HCC developed in 302 patients during mean follow-up period of 6.3 years, showing cumulative incidence rates at 3, 5 and 10 years of 15.8%, 29.9%, and 49.5% in those with HBc-Ab and 11.8%, 20.8% and 39.4% in those without, respectively (P = 0.022 by the log-rank test). Adjusted by other significant factors including age, gender, alcohol intake, diabetes mellitus, obesity, albumin, aspartate aminotransferase, platelet counts and prothrombin activity, HBc-Ab positivity was not a significant risk factor (hazard ratio, 0.996; 95%CI, 0.766 - 1.218; P = 0.772). The apparent difference of HCC incidence between HBc-Ab positive and negative groups was confined by differences in gender and age. CONCLUSIONS: HBc-Ab positivity was not a significant independent risk factor of hepatocarcinogenesis among chronic hepatitis C patients.

Disclosures: The following people have nothing to disclose: Takamasa Ohki, Ryosuke Tateishi, Shuichiro Shinia, Takahisa Sato, Ryoya Masuzaki, Tadashi Goto, Hideo Yoshida, Shuntaro Obi, Fumihiko Kanai, Haruhiko Kobashi, Masao Oomata

881 CLARIFICATION OF INTERSPOUSAL HCV INFECTION IN ACUTE AND CHRONIC HEPATITIS C PATIENTS BY PHYLLOGENETIC ANALYSES OF HCV E1 AND NS5B REGION

Ikuo Nakamura, Kaori Ochiai, Yasuhiro Tanaka, Fumonori Moriyasu, Masashi Mizokami, Michio Imawari; 1Department of Gastroenterology and Hepatology, Tokyo Medical University, Tokyo, Japan; 2Division of Gastroenterology, Omiya Medical Center, Jichi Medical University, Saitama, Japan; 3Department of Clinical Molecular Informative Medicine, Nagoya City University, Nagoya, Japan; 4Second Department of Internal Medicine, Showa University School of Medicine, Tokyo, Japan

AIM: The aim of this study was to clarify the source of HCV infection in acute and chronic hepatitis C patients using phylogenetic analyses of nucleotide sequences of HCV E1 and NS5B region. Patients and Methods: Four acute hepatitis C patients and one chronic hepatitis C patient, whose spouses were HCV-positive, were hospitalized. Three of four acute hepatitis C patients were male and the other was female. One chronic hepatitis patient was female. The ages of acute hepatitis C patient ranged from 33 to 73 years old. And the age of chronic hepatitis patient, whose serum had been revealed to be HCV-positive
14 years before hospitalization, was 62 years old. No patient was intravenous drug user. No blood transfusion was performed in any patient. The diagnosis of acute hepatitis C was based on medical records, laboratory tests including HCV markers, and ultrasound and sonography. Additional tests on HCV viral load and HCV genotype were carried out. Then phylogenetic analysis of nucleotide sequences of partial HCV E1 region (427 nucleotides) of the acute hepatitis C patients and their spouses were performed. In addition, phylogenetic analysis of nucleotide sequences of partial HCV E1 region and partial NS5B region (336 nucleotides) of chronic hepatitis patient and her spouse were performed. Informed consent was obtained from all patients. Results: The peak values of serum ALT in 4 acute hepatitis patients ranged from 1054 U/l to 4500 U/l and those of serum total bilirubin ranged from 3.6 mg/dl to 23.8 mg/dl. HCV antibody in the serum changed from negative to positive in the course of hospitalization and HCV RNA could be detected in every patient. Therefore, they were diagnosed as acute hepatitis caused by HCV infection. Three of four couples of acute hepatitis C had HCV RNA of the same genotype. The genotypes were 1b in two couples and 1a in one couple. Homogeneity of nucleotide sequences of HCV partial E1 region ranged from 99% to 100%. The results of phylogenetic analyses suggested that interspousal HCV infection occurred in three couples. The couple of chronic hepatitis C patients had HCV RNA of the same genotype. Homogeneity of nucleotide sequences of HCV partial NS5B region and E1 region was 97% and 92% respectively. The rate of nucleotide substitution of HCV during marriage was speculated to be 0.5–1.1x10⁻³ /site/year. These results of phylogenetic analysis implied interspousal HCV infection in this couple. Conclusion: Interspousal infection may be an important source of acute and chronic HCV infection. The usefulness of phylogenetic analysis of nucleotide sequences of HCV partial E1 and NS5B region for clarifying interspousal HCV infection was validated.

**883 INDIRECT SERUM MARKERS OF FIBROSIS PREDICT MORTALITY IN WOMEN WITH HIV AND HCV INFECTIONS**

Kiran Bambha¹, Eric C. Seaberg², Christopher B. Pierè³, Audrey L. French³, Howard D. Strickler¹, Andrea A. Howard⁴, Phyllis C. Ten⁵, Gerald B. Sharp⁶, Michael Augenbraun⁷, Andrea Kovacs⁶, Marion G. Peters¹; ¹Univ. of California San Francisco, San Francisco, CA; ²Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; ³CORE Center/Stroger Hospital, Chicago, IL; ⁴Albert Einstein College of Medicine, Bronx, NY; ⁵Division of AIDS, National Institute of Allergy and Infectious Diseases, NIH, Bethesda, MD; ⁶State University of New York, Downstate Medical Center, Brooklyn, NY; ⁷University of Southern California, Keck School of Medicine, Los Angeles, CA

Co-infection with HCV is a major cause of morbidity and mortality in persons with HIV, with liver disease the leading cause of non-AIDS related death. Predictors of mortality are poorly defined and men predominate in most studies. We evaluated whether two indirect markers of hepatic fibrosis, the APRI and FIB-4 scores, predict mortality in the Women’s Interagency HIV Study (WIHS). Methods: WIHS is a prospective, multicenter, cohort study of women with or at risk for HIV. HCV status was assessed at enrollment; lab and clinical data were measured semi-annually. Associations between fibrosis scores and all-cause mortality were assessed using time-dependent Cox regression analyses. Results: 3168 women (160 HCV+HIV-, 831 HCV+HIV+, 1523 HIV+HCV, and 654 HIV-HCV) were followed up to 12 yrs (median 6 yrs); median age 35 yrs. Compared to HCV-, HCV+ women had higher median APRI (0.5 vs 0.2) and FIB-4 (1.2 vs 0.6) at baseline, (p-value <0.0001 for both). At baseline, 88% of HIV+HCV+ and 63% of HIV+HCV- women had minimal fibrosis, based on fibrosis scores, while 1% of HIV+HCV- and 6% of HIV+HCV+ women had severe fibrosis. 539 women with HIV died. The table shows baseline and last available APRI among the deceased. In multivariable models, APRI predicted all-cause mortality in WIHS. Moderate (0.5–1.5) or severe (>1.5) elevations at baseline conferred hazard ratios (HR) of 1.5 [95%CI,1.2–1.8] and 2.7, [95%CI,2.0–3.7], respectively, after controlling for HIV, HR 4.0 [CI,2.7–5.7]; HCV, HR 1.8 [CI,1.4–2.1]; HBV, HR 1.7 [CI,1.1–2.7]; HAART, HR 0.8 [CI,0.7–1.0]; heavy alcohol, HR 1.0 [CI,0.8–1.4]; age (10 year increments), HR 1.4 [CI,1.3–1.6]; body weight, HR 0.8 [CI,0.6–0.9]. FIB-4 results were similar. Conclusion: HCV+ women had higher baseline APRI and FIB-4 scores compared to HCV- women. Among HIV+/HCV+ women, those who died had evidence of more fibrosis, based on fibrosis scores, compared to HIV+/HCV-, at baseline and at last follow-up. Women with moderate or severe fibrosis had increased mortality risk (1.5 and 2.7-fold, respectively), compared to women with low fibrosis scores, after controlling for HCV, HIV, HAART, alcohol and weight. APRI and FIB-4 may have clinical prognostic utility among women with HIV and HCV.

---

**882 AUTO-ANTIBODIES IN CHRONIC HEPATITIS C INFECION: HOW FREQUENT ARE THEY AND WHAT DO THEY MEAN IN A COHORT OF 963 PATIENTS?**

Michael J. Williams, Adam Lawson, Keith R. Neal, Stephen Ryder, William L. Irving; Wolfson Digestive Diseases Centre, University of Nottingham, Nottingham, United Kingdom

Background: Chronic hepatitis C infection is associated with an increased prevalence of non-organ specific autoantibodies. Previous small studies have given widely varying estimates of prevalence and conflicting results with regard to the clinical implications for disease activity and response to treatment. Aim: To define the prevalence of anti-nuclear (ANA) and anti-smooth muscle (ASM) antibodies within a large cohort of treatment-naive chronic hepatitis C patients, and assess for differences in patient demographics, biochemical and histological markers of disease activity, and subsequent response to anti-viral treatment. Results: We studied 963 patients. 172 (17.9%) had at least one autoantibody, of which 118 (12.3%) were ASM and 68 (7.1%) were ANA. Autoantibody-positive patients were older (43 vs 39 years, p 0.001) but there were no significant differences in gender, BMI, alcohol intake, ethnicity or viral genotype. The presence of autoantibodies was associated with an increase in interface hepatitis score (1.1 vs 0.8, p 0.005) but no difference in other necroinflammatory measures, liver function tests or immunoglobulins. Fibrosis stage was not increased in patients with autoantibodies (2.0 vs 1.9, p 0.8), nor was the rate of fibrosis progression on later biopsies (50% progression vs 34%, p 0.1). There was no difference in response to anti-viral treatment (sustained virological response 52% in both groups, p 1.0). Conclusions: Autoantibodies are frequent in chronic hepatitis C infection, occurring in an older population and in association with increased interface hepatitis. However, they do not carry increased risk of fibrosis or failure of therapy.

POPLATION BASED HEPATITIES A, B AND C SERO-
SURVEY AND GENOTYPING IN BRAZIL IN CAPITALS
Leila B. Pereira1, Regina Moreira2, Cynthia Braga2, Ulisses Montarroyos1, Celina Martelli3, Mariília Turchi3, Luiza Lima3, Luiz C. Arraes3, Marcelo A. Costa3, Ricardo Ximenes1; 1University of Pernambuco, Recife, Brazil; 2Immunology, Aggeu Magalhães Center Research, Recife, Brazil; 3Adolfo Lutz Institute, São Paulo, Brazil; 4Federal University of Goias, Goiânia, Brazil; 5Federal University of Pernambuco, Recife, Brazil; 6Base Hospital of Brasília, Brasília, Brazil

Objectives: To estimate the seroprevalence of hepatities A (HAV), B (HBV) and C (HCV) and genotypes for HBV and HCV in three macroregions of Brazil (Northeast-NE, Central-West-CW and Federal-District-DF regions). Methods: A population-based survey was carried out in these regions (2004/2005), as part of a national survey, which is being conducted in all Brazilian regions. The sample was representative of the ensemble of state capitals in each region and for each age group considered. The sample was stratified by capital with a uniform sampling fraction. In each capital census tracts and blocks were drawn with probability proportional to size; then a systematic sample of households was drawn and their residents selected. The study was approved by regional and national ethical committees. Serology for HAV, HBV and HCV (ELISA) and genotyping for HBV and HCV were performed. Results: A total of 10,525 individuals were investigated. Seroprevalence of AntiHAV IgG in NE region: 41.50% (95%CI 35.80-47.36) in the age group 5-9 and 56.60% (95%CI 51.15-61.92) in the age group 10-19; in CW: 32.3 % (95%CI 27.1-37.8) in the age group 5-9 and 55.9% (95%CI 50.2-60.9) in the age group 10-19; and in DF: 33.8% (95%CI 27.1-37.8) and 65.1% (95%CI 59.1-70.7%) for age 5-9 and 10-19 age groups, respectively. Seroprevalence of AntiHBC in NE region ranged from 2.12% (95%CI 1.51-2.88) in the age group 10 to 19 to 11.62 (95%CI 10.20-13.16) in the age group 20-69; in CW region: 1.3% (95%CI 0.8-1.9) in the aged group 10 to 19 and 12.7% (95%CI 11.2-14.2) in the age group 20-69, and in DF: 1.1% (95%CI 0.6-2.1) in group aged 10-19 and 8.3% (95%CI 6.6-10.1) in the age group 20-69. Seroprevalence of AntiHBe in NE region ranged between 2.12% (95%CI 1.51-2.88) in the age group 10 to 19 to 11.62 (95%CI 10.20-13.16) in the age group 20-69; in CW region: 1.3% (95%CI 0.8-1.9) in the aged group 10 to 19 and 12.7% (95%CI 11.2-14.2) in the age group 20-69, and in DF: 1.1% (95%CI 0.6-2.1) in group aged 10-19 and 8.3% (95%CI 6.6-10.1) in the age group 20-69. Seroprevalence of HBSAg in NE: 0.11% (95%CI 0.01-0.39) in the age group 10-19 and 0.48 (95%CI 0.22-0.91) in the age group 20-69; in CW: ranged from 0.2% to 0.7% and in DF ranged from 0.2% to 0.4% according to age groups. HBV-DNA genotypes identified D, A and F in all regions. Anti-HCV in NE: 0.4 (95%CI 0.55-1.50) in the age group 10-19 and 1.5% (95%CI 1.30-2.61) in the age group 20 to 69; in CW: 1.1% (95%CI 0.6-1.6) in the aged group 10-19 and 1.9% (95%CI 1.42-2.7) in the age group 20-69 and in DF 1.2% (95%CI 0.5-2.0) in the age group 10-19 and 1.7% (95%CI 1.0-2.7) in age group 20-69. HCV-RNA genotype 1, 1b, and 3a were identified in all three regions. Conclusion: This population based survey detected high prevalence of HAV infection among children with evidence of early viral exposure. The HBV endemicity was low probably due to HBV vaccination offered by the national routine immunization program. High prevalence of anti-HCV was detected in all regions and different genotypes were found at Brazilian population.

Disclosures: The following people have nothing to disclose: Leila B. Pereira, Regina Moreira, Cynthia Braga, Ulisses Montarroyos, Celina Martelli, Mariília Turchi, Luiza Lima, Luiz C. Arraes, Marcelo A. Costa, Ricardo Ximenes.
sustained-response (64.8% vs. 52.3%, p=0.003). Stratification for HCV genotypes showed that this effect was restricted to HCV genotype-1 (66.3% vs. 51.0%, p=0.001). Prevalence of LDLR 3’UTR 2728-GG declined from non-response to relapsed-response to sustained-response (66.3% vs. 55.7% vs. 48.7%, p=0.001). Multivariate analysis confirmed the LDLR 3’UTR 2728-A/G SNP as an independent predictive factor for treatment response. There was no obvious association between LDLR SNPs and histological severity of liver fibrosis and inflammation in chronically HCV-infected patients. CONCLUSION: LDLR polymorphisms appear to be associated with spontaneous and treatment-induced recovery from HCV genotype-1 infection. Common SNPs affecting the host lipoprotein metabolism might contribute to genetic susceptibility to chronic HCV infection and response to therapy.

886 CORRELATES OF INCIDENT HCV INFECTION AND SERONEGATIVE-IMMUNE STATUS IN HIGH RISK, IDU PRISONERS
Paul S. Haber1, Barbara Cameron6, Lisa Elliott6, Suzy Teutsch5, Rose French2, Kate Dolan5, Bill Rawlinson5, Michael Levy3, John M. Kaldor4, Andrew R. Lloyd5; 1Drug Health Services, Royal Prince Alfred Hospital, Sydney, NSW, Australia; 2Viral Immunology Group, Burnet Institute, Melbourne, VIC, Australia; 3National Centre in HIV Epidemiology and Clinical Research, Sydney, NSW, Australia; 4Centre for Health Research in Criminal Justice, Sydney, NSW, Australia; 5National Drug and Alcohol Research Centre, University of NSW, Sydney, NSW, Australia; 6Centre for Infection and Inflammation Research, University of NSW, Sydney, NSW, Australia

Introduction: High rates of hepatitis C (HCV) infection are reported amongst prison inmates, primarily linked to injecting drug use (IDU). HCV-specific cellular immunity is found in a small subset of high risk, seronegative subjects and may protect against chronic infection. Both factors are likely to influence incident infection rates and outcomes. The aim of this study is to determine HCV incidence in seronegative IDU prison inmates, the prevalence of HCV-specific immunity, and associated risk behaviours. Subjects and methods: Adult inmates have been recruited into a prospective cohort – the Hepatitis C Incidence and Transmission Study-II (HITS-II) study provided they are: greater than 17 years of age; have a lifetime history of IDU; and imprisonment and documented negative HCV antibody status within 12 months. Subjects complete a detailed interview to record demographics and risk behaviours. Blood is collected to screen for: HCV antibodies by ELISA (Innogenetics); HCV viraemia (Bayer); interferon-gamma production by enzyme-linked immunospot (ELISpot) and multiplex in vitro cytokine production following stimulation with HCV peptides. Thresholds for positive responses were based on data in low risk, seronegative subjects (n=15). The frequencies of demographic and behavioural risk factors were compared (SPSS for Windows v.13.0) Results: 242 inmates have been enrolled, and 184 tested for HCV antibodies and viraemia. Five had antibody indeterminate status and were therefore excluded from the analyses. Of the 179 subjects, 39 (22%) had seroconverted. Female gender (p=0.047), an increased number of incarcerations (p=0.013), tattooing (p=0.021), and methadone treatment (p<0.0001) were associated with seroconversion. Of the 179 subjects, 102 have been tested for HCV-specific immunity, with 22/78 seronegatives (28%) and 18/24 (75%) seroconverters having positive responses in the interferon gamma ELISpot. Seronegative-immune status was positively associated with specific patterns of IDU, and negatively with a recent break from IDU (all p<0.01). The specificity of the ELISpot responses differed in that anti-Core, NS2 and NS4a responses were not found in seronegative-immune subjects. The multiplex assay revealed that seronegative-immune subjects also had generally low levels of interleukin-10 and high levels of tumour necrosis factor-alpha production in response to NS4-5 stimulation. Conclusions: Both incident infection and seronegative-immune status are common in high risk IDU prisoners. Further follow-up of the subjects in the HITS cohort will evaluate the details of the predictive risk behaviours and protective efficacy of the immune responses.

887 ANALYSIS OF HCV IN SOUTH EAST ASIA
Eleanor Barnes1, Oliver Pybus2, Paul Newton3, Rasachak Bouachan4, Syhavong Bounkong4, Rattanaphone Phetsouvanh4, Rachel Taggert4, Isabelle Sheriden1, Isla Humphreys1, Paul Klenerman1,2; 1Peter Medawar building, Nuffield department of medicine, Oxford, United Kingdom; 2Department of Zoology, Oxford, United Kingdom; 3Wellcome trust-Mahosot Hospital-Oxford university tropical medicine research collaboration, Oxford, United Kingdom; 4Wellcome trust-Mahosot Hospital-Oxford university tropical medicine research collaboration, Vientiane, Laos

Aim: We performed a detailed evolutionary analysis of HCV genotype-6 across S.E. Asia. Methods: Plasma was obtained from 31 patients admitted to Mahosot hospital, Vientiane, Laos with jaundice and/or hepatitis and who were HCV sero-positive. HCV viraemia was determined by RTPCR of the 5’UTR. Amplification of Core (464 bp) and NS5B (377bp) was performed in viremic patients by nested PCR. These sequences were concatenated and aligned with all genotype-6 sequences available from the HCV database that spanned both regions (n=105). The country of origin of all sequences were determined. Maximum likelihood phylogenies were estimated using RAUP under the HKY+G model with gamma-distributed among-site rate heterogeneity. Molecular clock and coalescent analyses were performed using BEAST. Results: 21/31 Laos HCV seropositive patients were viremic. Core regions were successfully amplified in 16 patients and these were all found to be HCV genotype-6. In 14/16 patients NS5B was amplified. Phylogenetic analysis of core/NS5B sequences in conjunction with 105 database genotype-6 sequences showed that: (a) genotype-6 was restricted to S.E. Asia or immigrants from S.E Asia. (b) Strikingly high genotype-6 diversity was observed within several countries. (c) There was close genetic proximity to strains from different countries (d) HCV genotype-6 has been evolving in S.E Asia for an estimated 1,200 years. Conclusions: HCV subtypes of genotype-6 are diversely spread throughout S.E. Asia, suggesting a history of virus movement and spread over many centuries.

THE PRACTICE OF HEPATITIS VACCINATION IN PATIENTS WITH HEPATITIS C AND THE VALIDITY OF PROCEDURE AND DRUG CODES FOR HEPATITIS A AND B VACCINATIONS IN VA ADMINISTRATIVE DATABASES

Christine Yeh1,2, Jennifer Kramer2, Hong Yu2, Hashem B. El-Serag1,2; 1Gastroenterology, Baylor College of Medicine, Houston, TX; 2Houston Center for Quality of Care and Utilization Studies, Michael E. DeBakey Veterans Affairs Medical Center, Houston, TX

Background: Hepatitis A and B vaccination is recommended in patients with chronic liver disease. We conducted a cross-sectional study to examine this practice in HCV-infected patients at a large VA hospital and to validate the CPT codes and drug codes for hepatitis A and B vaccinations in VA administrative databases. Methods: We reviewed charts of 243 HCV-infected patients seen at the Michael E. DeBakey VA Medical Center in Houston with (n=84) and without cirrhosis (n=159) who were randomly sampled from national VA administrative databases. We calculated rates of hepatitis A and B vaccination and serologic evaluation. We also calculated positive (PPV) and negative (NPV) predictive values for CPT and drug codes, as well as percent agreement (and kappa scores) between medical records and administrative data. Results: Approximately 7% of HCV-infected patients without cirrhosis and approximately 20% of patients with HCV and cirrhosis received hepatitis A or B vaccinations with a vaccine series completion rate between 65% and 72%. Of patients who did not receive both hepatitis A and B vaccinations, 11 and 20 patients had negative hepatitis A and B serology, respectively. Therefore, 23% and 43% had neither vaccination nor serology for hepatitis A and B, respectively. In both groups, the proportions were 36% for patients with cirrhosis. The presence of CPT or VA drug codes for hepatitis B vaccine yielded a PPV and NPV of 98.0% and 94.0%, respectively with 94.2% agreement (kappa = 0.67). The presence of codes for hepatitis A vaccine yielded a PPV and NPV of 93.2% and 94.0%, respectively with 93.9% agreement (kappa = 0.64). PPV and NPV for hepatitis A and B vaccinations were also high in the subset of patients with HCV and cirrhosis. Conclusions: Hepatitis vaccination rates in HCV-infected patients with and without cirrhosis are low, and over 25% of patients do not receive a full vaccination series. Presence of codes in VA administrative data for hepatitis A and B vaccinations in HCV-infected patients are highly predictive of the presence of vaccinations in medical records, and therefore can be reliably used for research purposes. Future studies to identify patient, provider, and facility determinants of hepatitis vaccination need to be performed.

COMMUNITY TRENDS IN DIAGNOSIS AND TREATMENT OF HEPATITIS C

Barbara P. Yawn, Liliana Rocca, Peter Wollan; Research, Olmsted Medical Center, Rochester, MN

Introduction: National data shows decreasing rates of hepatitis C but little is known about community based rates of recognition and treatment. Methods: The Olmsted County, MN hepatitis C registry collects data on all people diagnosed with hepatitis C residing within the county. The registry is populated with demographic data, dates of diagnosis, risk factors, contraindications to treatment and treatment information. We present data on trends for rates of diagnosis, rates of treatment and treatment contra-indications from our registry. Results: The registry includes data on 558 people. We found no changes in the age (average 36 years) and gender distribution (41%) of newly diagnosed cases from 1991 to the present. The incidence rate increased in the 1990’s (highest 1996 to 1999 at 39/100000) but is down to 13/100000 women and 19/100000 men (p for trend over time in both genders <0.0001) in the most recent years. There has been no change in genotype distribution over the period. Rates of treatment of newly identified cases have risen especially since 2000 (p for trend 0.001). Conclusion: New cases of hepatitis C continue to decline in the community population but many of those with hepatitis C are still not receiving therapy. Improved access to insurance and multi-disciplinary support for treating of non-hepatic co-morbidities, especially mental health problems might increase the rate of treatment in diagnosed cases.
Does Gender Matter? A Prospective Evaluation of Risk Factors for HCV Infection and Treatment Candidacy in Women

Sue Currie1,2, Hui Shen1, Norbert Brau2, Bhupinderjit S. Anand3, Ayse Aytaman4, Kyong-Mi Chang5, Ramsey Chi-Man Cheung5, Timothy R. Morgan6, Marcos Pedrosa1, Warren N. Schmidt7, Alexander Monto2,1, Rosemary McQuaid2, Teresa L. Wright2, Edmund J. Bini3; 1Medicine, GI Division, University of California, San Francisco, San Francisco, CA; 2Division of Gastroenterology, San Francisco Veterans Affairs Medical Center, San Francisco, CA; 3GI Division, New York VA Harbor Health Care System, New York, NY; 4GI Division, Houston VAMC, Houston, TX; 5GI Division, Philadelphia VAMC, Philadelphia, PA; 6GI Division, Phoenix VA Medical Center, Phoenix, AZ; 7GI Division, Palo Alto VA Medical Center, Palo Alto, CA; 10GI Division, Long Beach VAMC, Long Beach, CA; 11GI Division, Boston VAMC, Boston, MA; 12GI / ID Division, Iowa City VAMC, Iowa City, IA

Background: Historically, women have comprised a small percentage of the veteran population. However, they are now the fastest growing group of veterans. Because veterans have a higher overall prevalence of HCV than non-veterans, a better understanding of gender issues and HCV treatment candidacy may be especially important. Aim: To compare risk factors for HCV infection and treatment candidacy between women and men veterans. Methods: Data were prospectively collected in HCV RNA positive veterans from 24 Veterans Affairs Medical Centers. Risk factors for HCV were assessed by questionnaire and treatment candidacy was determined by standardized criteria. Patients were excluded from treatment if at least one of thirteen standardized criteria were met. Results: Of 4,269 patients, 118 (2.8%) were women. Univariate analyses showed that women were younger, more educated, and less likely to have a history of injection drug use, incarceration, heavy alcohol use or snorting cocaine, but were more likely to have had surgery, a needle stick injury or a blood transfusion. Despite these differences, baseline laboratory results and treatment candidacy (43% vs 40%, p = ns) were similar in men and women. Reasons for exclusion from therapy were similar in men vs women, such as ongoing substance use (20% vs 13%, p = 0.05), mental health issues (18% vs 19%, p = ns) and advanced liver disease (14% vs 13%, p = ns), but as table one shows, men were more likely to have more than contraindications to therapy (p<0.05). Men were also almost twice as likely as women to have 3 or more reasons for exclusion from therapy (OR=1.69, 95% CI=1.07 - 4.26). Conclusions: Women veterans with HCV have fewer high risk behaviors than men, yet their overall treatment candidacy rates are similar. These seemingly contradictory results may be due to patients’ exclusion from therapy based on only on a single contraindication and that women were much more likely than men to have only one reason for exclusion. These results suggest the need for gender-specific HCV risk factor screening and counseling, as well as an opportunity to improve treatment candidacy through substance use and mental health interventions, especially in women veterans who have fewer contraindications to HCV treatment.

Table 1. Exclusion criteria met for HCV treatment based on gender (maximum of 13 yes responses) N = 2,450

Prevalence and Predictors of Obesity Among Individuals Testing Positive for Hepatitis C Antibody in a Multicultural, Urban, Tertiary Care Referral Clinic

Wendong Chen1, Terrence Wong1, George Tomlinson1, Murray D. Krahn1, Jenny Heathcote1; 1Medicine, University of Toronto, Toronto, ON, Canada; 2Pharmacy, University of Toronto, Toronto, ON, Canada

Background: Obesity is considered an important factor contributing to hepatic steatosis and poor response to anti-viral therapy in patients with chronic hepatitis C virus (HCV) infection. Objective: To determine the prevalence of obesity and explore the possible factors associated with obesity in a HCV antibody positive, multicultural tertiary referral clinic population. Methods: Patient records describing visits to a downtown tertiary care liver clinic in Toronto, Canada between 1990 and 2006 were reviewed. We extracted data describing demography, lifestyle, and mode of HCV transmission, as well as weight and height. The one sample proportion test was used to compare the prevalence of obesity in the clinic population testing positive for HCV antibody and the Canadian general population. Regression analyses and propensity score analysis (based on the propensity to test positive for HCV antibody) were applied to explore possible factors associated with obesity in this population. Results: The 1,118 out of 3,505 HCV antibody positive patients met our inclusion criteria. The included patients had a significantly higher prevalence of obesity (28.8% vs. 14.9%, P<0.001) than the Canadian general population. After stratification by age and gender, the clinic population remained with a significantly higher prevalence of obesity than the Canadian general population in every age/gender category. In the univariate analyses age was positively associated with BMI (coefficients 0.073; P<0.001) and obesity (OR 1.020; 95% CI 1.003 to 1.038); Asian origin was negatively associated with BMI (coefficients -0.187; P<0.001); serum testing for positive HCV RNA was significantly associated with obesity (OR 1.731; 95% CI 1.075 to 2.788). In the multivariate regression analyses, age (OR 1.019; 95% CI 1.002 to 1.037) and serum positive HCV RNA (OR 1.798; 95% CI 1.109 to 2.917) were independent predictors for obesity. A total of 112 pairs of subjects qualified for matching by propensity score. The matched propensity score analysis demonstrated that the subjects with a positive serum HCV RNA test had significantly more obesity (32.1% vs. 18.8%; p<0.021) than those with a negative HCV RNA test. Conclusion: Age and serum HCV RNA [indicating chronic HCV infection] contribute to the high prevalence of obesity observed in a clinic population exposed to HCV.

COMPARTMENTALIZATION OF HEPATITIS C VIRUS QUASISPECIES FOLLOWING LIVER TRANSPLANTATION
Frédéric Schramm1,2, Eric Soulier1, Cathy Royer1, Samira Fafi-Kremer1,2, Nicolas Brignon1, Bernard Ellero3, Marie-Lorraine Woehl-Jaegle4, Carole Meyer5, Daniel Jaeck6, Philippe Wolf6, Thomas F. Baumert1,5, Françoise Stoll-Keller2,3, Evelyne Schwoerer2,3, Marie-Lorraine Woehl-Jaegle, Carole Meyer, Daniel Jaeck, Philippe Wolf, Thomas F. Baumert, Françoise Stoll-Keller, Evelyne Schwoerer

Introduction. Hepatitis C virus (HCV)-related cirrhosis is the main indication for liver transplantation (LT). HCV infects the liver graft in almost all HCV-infected patients following LT. HCV compartmentalization is defined as nonrandom distribution of viral variants among the different sites of replication, and potentially reflects the presence of different HCV reservoirs including non-hepatic cells during HCV infection. Aiming to address the impact of compartmentalization for outcome of HCV infection following LT, we analyzed the chronological evolution of HCV compartmentalization between plasma, a likely representation of hepatotropic variants, and PBMCs, presumably representing lymphotropic strains. Patients and methods. Two patients undergoing LT for HCV-related cirrhosis were included in the study presented here; plasma and PBMC samples were taken before LT, 7 days, 1 month and 12 months after LT. Clinical data were collected along with biochemical, virological and histological parameters. Plasma and PBMC quasispecies were studied by cloning and sequencing in the HVR1 region of the E2 glycoprotein. The compartmentalization was analyzed using a phylogenetical approach focusing on specific amino-acid signatures. Results. The compartmentalization persisted during LT: both patients exhibited the presence of specific viral variants in each compartment. For the first patient, bootstrapped phylogenetic trees suggested a compartmental distribution of viral variants before transplantation, still maintained at day 7, month 1 and month 12 following LT (clusters of cellular variants with bootstrap values >60% at each time); interestingly, no positive selection pressure was observed in the PBMC fraction as shown by the Nei and Gojobori method. Two amino-acid signatures were observed for this patient: a lysine mutation to a serine in position 397 of HVR1 and an aspartic acid mutation to an asparagin in position 404, present in plasma at month 1, were absent in PBMCs. Compartmentalization following LT has been shown for the second patient, and absent selective pressure in the PBMC fraction was also observed. Conclusions. Immuno-suppressive status of liver-transplanted patients sustains HCV compartmentalization with potential selection of hepatotropic but not lymphotropic variants following LT. Further studies are underway to analyze the impact of compartmentalization for mechanisms of HCV reinfection.

HEPATOLOGY, Vol. 46, No. 4, Suppl. 1, 2007 AASLD ABSTRACTS 633A

STEATOHEPATITIS: RISK FACTORS AND IMPACT ON DISEASE SEVERITY IN HIV-HCV COINFECTION
Richard K. Sterling1,2, Melissa J. Contos1, Richard T. Stravitz1, Velimir A. Luketic1, Michael Fuchs1, Mitchell L. Shiffman1, Arun J. Sanyal1; 1Section of Hepatology, Virginia Commonwealth University, Richmond, VA; 2Infectious Diseases, VCUHS, Richmond, VA

Hepatic steatosis (HS) has been reported in those with HIV-HCV coinfection and associated with use of antiretroviral therapy (ART) and insulin resistance (IR). However, the presence of features of steatohepatitis (SH) including cytoplasmic ballooning (CB), its risk factors, and impact on disease severity in such patients are unknown. AIM: To prospectively define the prevalence and severity of the features of SH, its risk factors, and impact on the severity of liver disease in HIV-HCV coinfection. METHODS: Consecutive subjects with HIV-HCV coinfection underwent liver biopsy. SH was defined by the presence of HS and CB with or without Mallory hyaline or pericellular fibrosis (PF). Its individual parameters were graded according to the NASH CRN criteria (Kleiner et al, Hepatol 2005). Inflammation and fibrosis were also graded by the Ishak score; Ishak 3-6 fibrosis represented advanced fibrosis (AF). IR was measured by HOMA-IR and metabolic syndrome (MS) was defined by ATP III criteria. RESULTS: A total of 222 subjects (74% male, mean age 45, 78% African American) were studied. The mean BMI was 26 and 18% were obese (BMI > 30). Median[IQR] AST, ALT, and ALP were 62[43-102], 68[43-101], and 112[85-104], respectively. All patients were HCV RNA positive and 90% were genotype 1. Mean CD4 count was 535, 10% had a CD4 < 200, and HIV was < 400 copies in 45%. The prevalence of risk factors for HS were as follows: diabetes (31%), hypertension (15%), dyslipidemia (8%), MS (9%), and alcohol abuse (21%). ART therapy included a nucleoside reverse transcriptase inhibitor (NRTI) in 93%, non-nucleoside reverse transcriptase inhibitor (NNRTI) in 30% and protease inhibitor (PI) in 47%. HS was present in 23% and SH was present in 17%. The steatosis was absent in 77%, mild (5-33%) in 19%, and moderate-severe (>33%) in 4% of affected subjects. CB and PF were present in 30% and 13% respectively. The mean(SD) Ishak score was 6.9(4.6) and 33% had AF. Both HS and CB were associated with BMI, MS, HOMA and presence of either was strongly associated with AF [p<.0001]. MS and absence of PI use were independent predictors of HS by multiple logistic regression; alcohol use and HOMA-IR was associated with CB; NRTI use were also associated with SH, and use of d4T with AF. CONCLUSIONS: SH is commonly present in HIV-HCV coinfection. Alcohol consumption, IR and specific components of ART contribute to steatosis and SH. Both steatosis and SH increase the risk of having advanced fibrosis. These data raise the possibility that specific types of ART (NRTI, PI, and specifically d4T) may contribute to the progression of fibrosis in HIV-HCV coinfection.

BACKGROUND
Recent European reports suggest that hepatitis C virus (HCV) in specific circumstances may be sexually transmitted among HIV-infected (HIV+) men who have sex with men (MSM). A prospective study is conducted during 2006 and 2007 in France to describe clinical and epidemiological characteristics of HCV-infected MSM and to evaluate the incidence of HCV among this population. Preliminary results on descriptive analysis are presented here. METHODS A random and proportional probability sample of 84 medical wards was drawn according to the number of HIV and AIDS cases in MSM reported since 2003 to the National HIV surveillance system. Acute HCV was defined by a positive anti-HCV antibody (Ab) or HCV polymerase chain reaction (PCR) within one year of a documented negative anti-HCV test. Information was collected on socio-demographics, clinical and biological status of acute HCV, HBV and HIV infections and on HCV risk factors. Two types of questionnaires were completed: one by physicians on clinical data and HCV risk factors and one (self-administered) by patients on sexual behavior, HCV risk factors and exposures. RESULTS Between January 2006 and May 2007, 43 out of the 49 patients meeting the case definition of acute HCV were included after consent, mainly (72%) in Paris. Median age at HCV diagnosis was 38 years [min: 26; max: 58]. Median duration of HCV infection was 6.5 years [min: 0; max: 22]. HCV was suspected because of elevated ALT in 72% of the patients (unknown: 23%). HCV infection was asymptomatic for 66% (unknown: 16%). HCV viral load was undetectable for 16 of the 22 treated patients. 66% of the patients with available HCV genotyping (21/32) were infected with genotype 4 whereas this genotype represents only 10% of the prevalent cases in France. Self-administered questionnaires were available for 27 patients: in the 6-month period prior to HCV, the median number of sexual partners was 20 [min: 0; max: 170]; unprotected anal sex was reported in 81%, having had sexually transmitted infections (STI) in 74% and bleeding during anal sex in 41%. Recreational drug use before sex (such as ecstasy, cocaine,...) was specified by 63% of the patients. CONCLUSIONS In France, HIV+ MSM with frequent unprotected anal sex together with STI and mucosal trauma may be at risk of sexual HCV transmission. Therefore, it is necessary to reinforce prevention strategies targeted to this population.

FACTORS ASSOCIATED WITH SEVERE LIVER DISEASE IN NEWLY REFERRED HEPATITIS C VIRUS-INFECTED FRENCH DRUG USERS: A MULTICENTER STUDY OF 4373 PATIENTS, 2001-2004

Christine Larsen1, Jean-Pierre Bronowicki2, Patrice Couzigou2, Elisabeth Delarocque-Astagneau1, Odile Goria2, Dominique Guyader2, Patrick Hillon2, Patrick Marcellin2, Corinne Pioche1, Françoise Roudot-Thoraval1, Christine Sylvain1, Jean-Pierre Zarski1

AIMS To analyze factors associated with severe liver disease in drug users infected with hepatitis C virus (HCV) at first referral to a hepatology reference center in France between 2001 and 2004. METHODS A national surveillance system was set up in 2000 to describe changes in epidemiological and clinical characteristics of HCV-infected patients at first referral in 26 hepatology reference centers. Data on risk factors, suspected year of infection, past or current alcohol consumption, HCV RNA status, ALT level, HBV and HIV status were routinely collected. The severity of the liver disease is assessed either by a "clinical" evaluation based on biochemical tests and morphological examination (mainly ultrasonography) or by a histological evaluation (Metavir scores at liver biopsy). Participants included in this analysis are those recorded in the system from 2001 to 2004 and reporting past or current injecting or nasal drug use. Severe liver disease (SLD) was defined as the presence of cirrhosis or primary liver cancer. A log-Poisson model was used to estimate prevalence ratios. RESULTS Among the 4 373 drug users, median duration of HCV infection was 18 years, 7% were HCV-infected (HIV+) and 38% reported past excessive alcohol consumption. Of these, 3 153 were HCV RNA+ with available clinical evaluation of SLD at first referral. Predominant reported HCV genotypes were genotype 3a (24%), genotype 1a (23%) and genotype 1b (14%). SLD at "clinical" evaluation was diagnosed in 7% and was independently associated with genotype 3 [prevalence ratio (PR) = 1.5; 95% confidence interval (CI): 1.1-2.0], HIV+ status [PR = 2.3; 95% CI: 1.1-4.6], past excessive alcohol consumption [PR = 2.5; 95% CI: 1.7-3.6], duration of HCV infection ≥ 18 years [PR = 3.7; 95% CI: 2.2-6.1] and age > 40 years [PR = 4.1; 95% CI: 2.2-7.7]. CONCLUSIONS Our findings based on surveillance data suggest that HCV genotype 3 may be associated with severe liver disease in drug users. They also underscore the role played by excessive alcohol consumption and HIV infection in the severity of HCV infection in this population. These results highlight the need for targeted management of HCV-infected drug users, especially on alcohol consumption and HIV co-infection. Moreover, the role of genotype 3 in severe liver disease needs to be further explored.

BACKGROUND/AIMS: Host genetic single nucleotide polymorphisms (SNPs) are likely to influence the outcome of HCV infection. Infectious HCV particles have been shown to bind to host lipoproteins and low-density lipoprotein receptors (LDLR) have been termed candidate receptors for the hepatocellular internalization of these “lipo-viro particles” (LVP). Recent studies suggested that common SNPs in the gene encoding apolipoprotein E (apoE) - a major structural LDL component and natural ligand of LDLR and well-characterized risk factor for elevated plasma cholesterol levels - might be associated with spontaneous resolution of HCV infection, severity of histological liver damage and response to therapy in chronic HCV infection. The aim of the present study was to further investigate the role of apoE polymorphisms in a large group of well-characterized patients with chronic hepatitis C.

METHODS: We determined the prevalence of apoE genotypes and apoE alleles in 701 chronically HCV-infected patients, 523 healthy controls and 283 individuals with non-HCV associated chronic liver disease by PCR and RFLP analysis. We went on to assess whether apoE SNPs might be associated with the severity of histological inflammation and fibrosis of 555 liver biopsies from chronic HCV carriers. RESULTS: The comparison of apoE allele proportions in chronically HCV-infected patients revealed significant differences in comparison to healthy controls (p=0.002). This was primarily due to a substantial under-representation of the apoE4 allele (10.5% vs. 13.8% in healthy controls; p=0.011) and apoE4 allele positive genotypes (20% vs. 27% in healthy controls; p=0.002) in the group of patients with chronic HCV infection. The frequency of apoE4 alleles was increased in the group of patients with histological mild liver disease but very similar for severe hepatic fibrosis and inflammation. Patients with non-HCV associated chronic liver disease presented with an apoE allele and genotype distribution very similar to healthy controls and differed also significantly from HCV patients CONCLUSION: The significant under-representation of the apoE4 allele in chronically HCV-infected patients suggests that apoE4 allele carriers might be protected from chronic HCV infection. Common apoE SNPs affecting the host lipoprotein metabolism might therefore contribute to the genetic susceptibility to chronic HCV infection.

Disclosures: The following people have nothing to disclose: Tobias Mueller, Reinhard Gessner, Christoph Sarrazin, Eckart Koettgen, Juliane Halang, Eckart Schott, Alexandra Bergk, Viola Weich, Beate Schlosser, Bertram Wiedenmann, Thomas Berg
Background/Aim: The role of serum HBV-DNA levels in the natural history and management of chronic HBV infection is currently under investigation. We evaluated the fluctuating course of serum HBV-DNA levels during the natural history of chronic HBV infection in the general population of Northern-Eastern Greece, in association with liver disease progression. Patients/Methods: 257 adults (34±12.3yrs old) with chronic HBV infection, recruited and prospectively followed-up for a period up to 12 yrs (1992/94-2006). Viral markers/liver biochemistry/physical examination performed every 6m. Liver biopsy/abdominal ultrasound were performed at entry and every 2.4yrs. Serum HBV-DNA levels measured by Amplicor HBV Monitor. Results: 14/257 (5.5%) patients were HBeAg(+) with mean HBV-DNA levels 2.5±10(7)copies/ml (6.2±10(6)-7.1±10(7)). At entry, 195/257 (76%) were HBeAg/anti-HBe(+), with a history of normal ALT for at least 12 months: a) 97/195 (50%) individuals had undetectable serum HBV-DNA levels at entry although 31/97 (32%) had detectable in at least one occasion, always below 10(4)copies/ml, had no liver disease at entry and at follow-up period by imaging evaluation, b) 94/195 (48%) had HBV-DNA levels <10(4)copies/ml, normal liver histology (97%) at entry and at follow-up period and, c) 4/195 (2%) had HBV-DNA >10(4)copies/ml, nearly normal liver histology of whom 2 exhibited abnormal ALT levels after 3yrs. At entry, 48/257 (19%) patients were HBeAg(1/anti-HBe(+), with a history of elevated ALT levels for >6m; a) 12/48 (25%) had an erratic ALT pattern, mean HBV-DNA levels 3.5±10(5)copies/ml (2.1±10(3)-1.5±10(8)) of whom 5/12 (42%) had HBV-DNA levels <10(4)copies/ml for at least one occasion and, b) 36/48 (75%) had persistent elevated ALT>1.5xULN, mean HBV-DNA levels 1.2±10(6)copies/ml (6.7±10(3)-8.7±10(8)) of whom 8/36 (22%) had HBV-DNA >10(4)copies/ml for at least one occasion. In HBeAg(-) patients with active disease, 22/48 (46%) had moderate/severe histology at entry and 5/48 (10%) developed liver disease progression during the follow-up period. The multivariate-adjusted OR (95% CI) of fibrosis was 604.865 (67.233-999.999) for serum HBV-DNA levels >10(4) vs <10(4)copies/ml; 0.002 (0.001-0.015) for serum ALT level at study entry >40IU vs <40IU; 0.057 (0.006-0.519) for age >40 vs <40 years old. Conclusions: a) 27% of patients with chronic HBeAg(+) hepatitis could be misclassified as inactive carriers if testing was performed on one occasion and not serially, b) serum HBV DNA levels >10(4)copies/ml were significantly associated with liver disease activity and c) close monitoring of serum HBV-DNA is a useful clinical tool in the management of chronic HBeAg(+) patients.

The following people have nothing to disclose: George Zacharakis, John Koskinas, Stamatis Kotsiou, Fevronia Tzara, Nikolaos Vafeiadis, Menelaos Papoutselis, Eustratios Maltezos, Dimitrios Kountouras, Sivridis Eleftherios, Athanasios Archimandritis, Kostantinos Papoutselis.
Background and Aim: Seroclearance of hepatitis B surface antigen (HBsAg) is a rare event in chronic hepatitis B patients. We conducted a large scale longitudinal study investigating the virological, histological and clinical aspects, including the risk of development of hepatocellular carcinoma (HCC) in patients with HBsAg seroclearance. Patients and Methods: Two hundred and ninety-eight patients (211 male and 87 female; median age on presentation: 43.1 years) with HBsAg seroclearance were recruited and followed up every 3 – 6 months for clinical assessment. Intrahepatic HBV DNA and covalently closed circular DNA (cccDNA) were measured by real-time PCR. Serum HBV DNA was measured by the Artus HBV RG Test (Qiagen, Germany). Liver stiffness was assessed by FibroScan (Echosens, France). Results: The median age of HBsAg seroclearance was 49.6 years. The median follow-up duration was 108.9 months and the median follow-up duration after HBsAg seroclearance was 36.4 months. Liver biopsies were performed on 29 patients (median time of biopsy: 48.6 months after HBsAg seroclearance). All had detectable intrahepatic HBV DNA (median 1.68 copies/cell), and cccDNA were detectable in 23 patients (79.3%, median: 0.03 copies/cell). Of the 29 patients with liver biopsy, 9 and 16 patients had sera available within 1 year and between 5 – 10 years after HBsAg seroclearance, respectively, for HBV DNA analysis. All 9 patients had undetectable HBV DNA (<1.1 IU/mL) within 1 year of HBsAg seroclearance, and 4/16 patients had detectable HBV DNA levels between 5 – 10 years of HBsAg seroclearance (median: 2.37 IU/mL). Of the 26 patients with adequate liver tissues for histological examination, 4 had mild fibrosis (F1) and 5 had minimal necroinflammation. FibroScan was performed on 76 and 78 patients who had HBsAg seroclearance at age <50 and ≥50 years respectively. Significant fibrosis (liver stiffness > 8.1 kPa) was observed only in 7.9% (6/76) patients with HBsAg seroclearance at age <50 compared to 29.5% (23/78) patients with HBsAg seroclearance at age ≥50 (p = 0.001). Seven patients developed HCC (median age: 69.3). Kaplan-Meier analysis showed that the chance of HCC development in patients with HBsAg seroclearance at age <50 was significantly less than those with HBsAg seroclearance at age ≥50 (p = 0.004). Conclusion: Although serum HBV DNA was detectable in only a small proportion of patients with HBsAg seroclearance, intrahepatic HBV DNA was still present in all patients. Nevertheless, patients who cleared HBsAg at age <50 had significantly less fibrosis and lower chance of HCC development than those with HBsAg seroclearance at ≥50 years.

902 REDUCED HBV REPLICATION IN HBEAG-NEGATIVE PATIENTS IS DUE TO LOWER COVALENTLY CLOSED CIRCULAR DNA CONTENT AND IMPAIRED VIRION PRODUCTIVITY

Tassilo Volz1, Marc Lutgethmann1, Alexander Quaas2, John W. Murray2, Maura Dandri1, Joerg Petersen1; 1Gastroenterology, Hepatology, Infectious Diseases, University Hospital Hamburg-Eppendorf, I. Medizinische Klinik, Hamburg, Germany; 2Pathology, University Hospital Hamburg-Eppendorf, Hamburg, Germany; 3School of Mathematics and Statistics, University of New South Wales, Sydney, NSW, Australia

Background&Aims: Knowledge of factors regulating transcriptional activity of hepatitis B virus (HBV) covalently closed circular DNA (cccDNA) may help understanding mechanisms of viral decay and how these processes are thwarted in chronically HBV-infected patients. Methods: Liver biopsies from 119 treatment naïve chronically infected patients [42 HBeAg-positive and 77 HBeAg-negative] were determined for transcriptional and replicative activity of HBV. Results: Significantly lower median serum HBV-DNA (-4log) and intrahepatic HBV-DNA (-2log) and cccDNA (1log) amounts were measured in HBeAg-negative vs. HBeAg-positive patients. Despite a good correlation found between intrahepatic amounts of pregeny virions and serum HBV-DNA titres in all patients, cccDNA levels did not correlate with serum titres in HBeAg-negative individuals. Analysis of HBV-RNA transcripts demonstrated that impaired virion productivity in HBeAg-negative individuals was due to lower steady-state levels of pregenomic RNA produced per cccDNA molecule. Interestingly, preS/S RNAs levels and serum HBsAg concentrations did not differ between HBeAg-positive and HBeAg-negative patients when normalized for cccDNA contents, demonstrating that subviral particle production was not impaired in HBeAg-negative patients and correlated with cccDNA levels. Though the majority of HBeAg-negative individuals harboured cccDNA with common precore and/or basal core promoter (PC/BCP) mutations, occurrence of these variants did not responsible for reduced viral replication. Instead, replacement of wild type cccDNA with populations of BCP mutations re-established high virion productivity. Conclusions: Lower viremia in HBeAg-negative individuals is not only due to lower cccDNA content but also to impaired virion productivity, which can arise without emergence of HBeAg variants and without affecting HBsAg production.

903 HIGH VIRAL LOAD AND HEPATITIS B VIRUS (HBV) SUBGENOTYPE CE HAVE INCREASED RISK OF HEPATOCELLULAR CARCINOMA (HCC) – A 7-YEAR PROSPECTIVE FOLLOW-UP STUDY

Henry Ly Chan1, Chi-Hang Tse1, Frankie Ma2, Jane Koh2, Vincent W. Wong3, Grace LH Wong1, Joseph J. Sung3, Tony SK Mok2; 1Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong, China; 2Clinical Oncology, The Chinese University of Hong Kong, Hong Kong, China

Background: The determination of risk factors for HCC is important to design cancer surveillance strategy. Genotype C HBV is associated with a higher risk of HCC than genotype B HBV, but the effect of HBV subgenotypes on HCC is uncertain. We aimed to investigate the impact HBV DNA levels and HBV genotypes/subgenotypes on the risk of HCC. Methods: A prospective cohort of chronic HBV infected patients recruited in a surveillance program for hepatocellular carcinoma (HCC) since 1997 was studied. Ultrasound and alpha-fetoprotein were regularly performed for HCC surveillance. HBV DNA at recruitment was measured by Taqman real-time polymerase chain reaction assay. HBV subgenotyping was determined by direct sequencing of the S gene. Results: Among 1006 patients (68% male) aged 48 ± 7 years, 86 (9%) patients developed HCC at a median follow-up of 7.7 years. 377 (38%) patients had liver cirrhosis. 146 (15%) patients had low serum albumin. 851 (85%) patients had ALT levels below 1.5 x upper limit of normal and the mean log HBV DNA was 4.72 ± 1.84 copies/ml. 152 (15%) patients had received anti-viral treatment during the follow-up period. The hazard ratio of each log step increase in HBV DNA was 1.38 (95% CI 1.23, 1.55; p<0.0001). With referent to the low HBV DNA stratum (log HBV DNA ≤ 4.5 copies/ml), the hazard ratio for HCC of the intermediate HBV DNA stratum (log HBV DNA > 4.5 – 6.5 copies/ml) was 1.62 (95% CI 1.05, 2.48; p=0.027) and that of the high HBV DNA stratum (log HBV DNA > 6.5 copies/ml) was 2.73 (95% CI 1.76, 4.25; p<0.001). Among 769 patients with genotyping results, 330 patients had genotype B HBV (all subgenotype Ba) and 439 patients had genotype C HBV (94 subgenotype Ce and 345 subgenotype Cs). With referent to genotype B HBV, HBV subgenotype Ce has the highest risk of HCC (hazard ratio 2.75; 95% CI 1.66, 4.56; p<0.001) and HBV subgenotype Cs has intermediate risk (hazard ratio 1.70; 95% CI 1.09, 2.64; p=0.02). On multivariate analysis, HBV DNA (hazard ratio 1.79; 95% CI 1.27, 2.52; p<0.001) and HBV subgenotypes (hazard ratio 1.53; 95% CI 1.17, 2.01; p=0.002) were independent risk factors of HCC. Liver cirrhosis, male gender, older age and low serum albumin were also risk factors of HCC whereas serum bilirubin, ALT level, ascites and use of anti-viral treatment were not. Using genotype B HBV and low HBV DNA stratum as referent, the hazard ratio of HCC for HBV subgenotype Cs was 2.85 (95% CI 1.68, 4.84; p<0.001) and that for HBV subgenotype Ce was 4.00 (95% CI 2.08, 7.69; p<0.001). Conclusions: High HBV DNA level and HBV genotype C, particularly subgenotype Ce, are independent risk factors of HCC in chronic hepatitis B.

904 ANALYSIS OF HBV MUTATIONS IN PATIENTS WITH EPIDEMIC FULMINANT HEPATITIS

Jun Inoue, Yoshiyuki Ueno, Futoshi Nagasaki, Hirofumi Nittsuma, Tooru Shimosegawa; Division of Gastroenterology, Tohoku University Graduate School of Medicine, Sendai, Japan

Background and aims: It is thought that both host and viral factors contribute to the development of fulminant hepatitis B. Especially, mutations in the core promoter region (A1762T/G1764A) and/or the precore region (G1896A) have been reported to be associated with fulminant hepatitis. We experienced five patients who died of fulminant hepatitis B from the same infectious source. The HBV isolates obtained from them were 99.8-100% identical to each other, and the genotype was revealed to belong to B2, which is known to cause fulminant hepatitis less frequently. This strain had mutations including A1762T/G1764A and G1896A. Additionally, it had a mutation of G1862T in the precore region. We focused on the high pathogenicity of this strain, and analyzed mutations that are associated with fulminant hepatitis. Methods: The full-length genome of HBV that was divided into two overlapping
HEPATOLOGY, Vol. 46, No. 4, Suppl. 1, 2007 AASLD ABSTRACTS 639A

regions was amplified with polymerase chain reaction (PCR). A plasmid carrying 1.3-fold the HBV genome obtained from a fulminant hepatitis patient (pBFH2) was constructed with the PCR products. Using site-directed mutagenesis, the mutations at nt 1762/1764, 1896 and 1862 in pBFH2 were converted to the wild type nucleotides with comprehensive combinations. HepG2 cells were transfected with these plasmids, and HBV-related particles that were released into the culture medium 3 days after transfection were assayed with real-time PCR (HBV DNA) and enzyme-linked immunosorbent assay (HBsAg, HBeAg). Intracellular HBV DNA in the harvested HepG2 cells was measured with southern blot analysis and real-time PCR.

Results: In the analysis of HBV DNA in the culture medium, the largest single factor contributing to the replication efficiency was A1762T/G1764A. The presence of G1862T alone reduced the extracellular HBV DNA, and the production was recovered with coexisting A1762T/G1764A. When intracellular single-stranded (ss) HBV DNA was assayed by real-time PCR, it was revealed that G1862T accumulated the ss HBV DNA in cells, and coexisting A1762T/G1764A increased the accumulation further. Conclusions: Although G1862T was reported to reduce the replication of HBV, the fact that the mutation was found in this fulminant strain prompted us to investigate in more detail information about this mutation. In this study, it was suggested that the presence of G1862T impaired the release of HBV virion and the replicative intermediates were accumulated in hepatocytes. When A1762T/G1764A, which is known to enhance the viral replication, was present with G1862T, the replicative intermediate in cells was further increased, which might be associated with fulminant hepatitis.

HBV SUPPRESSES TLR-MEDIATED INNATE IMMUNE RESPONSES IN PARENCHYMAL AND NON-PARENCHYMAL LIVER CELLS

Jun Wu1, Mengji Lu2, Zhongji Meng1, Martin Trippler1, Ruth Broering1, Agnes Szczechonek1, Ulf Dittmer2, Michael Roggen2, Guido Gerken1, Joerg F. Schlaak1, 1Dept. of Gastroenterology and Virology, University Hospital of Essen, Essen, Germany; 2Dept. of Virology, University Hospital of Essen, Essen, Germany

Background and Aims: It has been suggested that the genes reflecting the innate immune response are not detectable in the initial phase of HBV infection. Recent studies indicate that HBV may have developed strategies to suppress the initial antiviral response of the host including TLR pathways. We have previously shown that non-parenchymal liver cells (NPC; Kupffer cells (KC), liver sinusoidal endothelial cells (LSEC)) can be activated by TLR 3 and -4 to produce IFN-β and other mediators which can potently suppress HBV replication. Therefore, the aim of our study was to investigate whether HBV has the ability to suppress TLR-induced antiviral responses in parenchymal and non-parenchymal liver cells. Methods: We have isolated murine KC by counterflow elutriation as well as murine LSEC by anti-LSEC antibodies which correlated with suppressed ISG induction by poly I:C and LPS on the transcriptional level. TLR 1-9 stimulation had no direct antiviral effect on differentiated HBV-Met cells in contrast to primary hepatocytes and undifferentiated cells. Conclusions: Our data indicate that HBV can suppress the antiviral activity of NPC induced by TLR 3 and -4 stimulation. Integrated HBV can downregulate the innate immune response of hepatocytes towards TLR stimulation. This is of particular relevance for the regulation of the local innate immune response against HBV in the liver and may explain why HBV appears to behave as "stealth virus" initially after infection.

906
CHANGES IN SERUM HBV DNA LEVEL USING A TRAJECTORY MODEL PREDICT THE RISK OF HCC IN CHRONIC HEPATITIS B PATIENTS: THE R.E.V.E.A.L.-HBV STUDY

Chuen-Fei Chen1,2, Hwai-Yang Yang1,2, Uchenna Iloeje3, Jun Su4, Chin-Lan Jen1,2, San-Lin You1,2, Chien-Jen Chen1,2, 1Genomics Research Center, Academia Sinica, Taipei, Taiwan; 2Graduate Institute of Epidemiology, National Taiwan University, Taipei, Taiwan; 3Global Epidemiology and Outcomes Research, Bristol-Myers Squibb Co, Wallingford, CT

Introduction: Elevated serum HBV DNA level is a strong risk predictor of developing hepatocellular carcinoma (HCC) in chronic hepatitis B (CHB) patients. Our aims were to evaluate the relationship between HBV DNA viral load changes over time and HCC risk, and the baseline factors associated with HBV DNA level changes over time. Methods: A sub-group of the R.E.V.E.A.L.-HBV cohort of HBsAg-seropositive and anti-HCV-seronegative patients, without liver cirrhosis at entry was included in this analysis. There were 1,289 participants with HBV DNA ≥10^4 copies/mL at entry with ≥2 HBV DNA measurements included, and 2,020 participants with HBV DNA <10^4 copies/mL at entry as the reference group. Low, medium, high and very high serum HBV DNA levels were defined as <300, 300—<10^5, 10^5—<10^7, and ≥10^7 copies/mL, respectively. Low, medium, and high serum ALT levels were defined as <15, 15—44, and ≥45 U/L, respectively. A semi-parametric group-based modeling was used to determine major trajectory classes of HBV DNA and ALT. Factors associated with HBV DNA trajectory were examined using polytomous logistic regression. Cox’s proportional hazards modeling was used to analyze associations between HBV DNA trajectory classes and HCC risk. Results: There were 89 new HCC cases among 3,309 participants during 40,024 person-years of follow-up. Among those with HBV DNA ≥10^4 copies/mL, four HBV DNA trajectory classes were identified: class I, medium-to-low (n=148); class II, medium-to-medium (n=380); class III, high-to-high (n=542); and class IV, persistently very high (n=219). Four ALT trajectory classes were identified: class A, low-to-medium (n=1,056); class B, medium-to-medium (n=1,507); class C,
high-to-medium (n=187); and class D, medium-to-high (n=174).

Gender, HBsAg status, and ALT level at entry were significantly associated with the HBV DNA trajectory. Compared with HBV DNA <10^4 copies/mL at study entry as the reference group, the multivariate-adjusted hazard ratio HRadj (95%CI) of developing HCC by HBV DNA trajectory class was 0.7 (0.1—5.1) for class I; 2.6 (1.1—6.0) for class II; 8.5 (4.6—15.8) for class III; and 10.0 (4.7—20.7) for class IV after adjustment for gender, age, cigarette smoking, alcohol consumption, and ALT trajectory. The HRadj (95%CI) of developing HCC by ALT trajectory class was 1.4 (0.8—2.7) for class B, 3.2 (1.5—6.9) for class C, and 2.3 (1.0—5.2) for class D compared with class A as the reference group. Conclusions: Serum HBV DNA level over time is a strong predictor of HCC independent of gender, age, cigarette smoking, alcohol consumption, and ALT trajectory.

907
HBV VIRAL LOAD LESS THAN 10^4 COPIES/mL IS ASSOCIATED WITH SIGNIFICANT RISK OF HEPATOCELLULAR CARCINOMA IN CHRONIC HEPATITIS B PATIENTS: AN UPDATE FROM THE R.E.V.E.A.L.-HBV STUDY

Uchenna Iloeje1, Hwai-I Yang2,3, Jun Su1, Chuen-Fei Chen2,3, Chin-Lan Jen2,3, San-Lin You2,3, Chien-Jen Chen2,3; 1Global Epidemiology and Outcomes Research, Bristol-Myers Squibb Co, Wallingford, CT; 2Genomics Research Center, Academia Sinica, Taipei, Taiwan; 3Graduate Institute of Epidemiology, National Taiwan University, Taipei, Taiwan

Introduction: Major international treatment guidelines classify CHB patients with low-level viremia (<10^4 copies/mL) as having inactive disease with little or no risk of disease progression. Risk of disease progression in these subjects has not been properly evaluated. Methods: All HBsAg-negative subjects without HCV infection (anti-HCV negative) and the subset of the R.E.V.E.A.L.-HBV study cohort without HCV infection or liver cirrhosis at baseline were included in this analysis. Ascertainment of HCC was by data linkage with computerized profiles of the National Cancer Registry and Death Certification System in Taiwan, and all HCC cases were confirmed using established criteria. The risk of HCC progression by baseline and follow-up viral load was determined (in comparison to HBsAg-negative persons). The risk of HCC associated with even the lowest detectable level of HBV DNA was 3-fold greater and highly significant. During follow-up, an HBV DNA level maintained between 300—9,999 copies/mL was associated with a significantly higher risk of HCC when compared to those achieving a level <300 copies/mL.

HRadj (95%CI) 2.7 (1.1—6.6). Conclusion: Results show that CHB patients with an HBV viral load of less than 10^4 copies/mL are at a significantly higher risk of developing HCC than HBsAg-seronegative persons. The risk of HCC associated with HBsAg-seronegative persons, the HRadj (95%CI) of developing HCC by ALT trajectory class was 1.4 (0.8—2.7) for class B, 3.2 (1.5—6.9) for class C, and 2.3 (1.0—5.2) for class D compared with class A as the reference group. Conclusions: Serum HBV DNA level over time is a strong predictor of HCC independent of gender, age, cigarette smoking, alcohol consumption, and ALT trajectory.

HEPATITIS B VIRUS VACCINE ESCAPE MUTANTS HAVE IMPAIRED VIRION SECRETION EFFICIENCY IN CELL CULTURE

Karen Kwei, Xiaoli Tang, Tamako Konkin, Jisu Li, Jack R. Wands, Shuping Tong; Liver Research Center, Rhode Island Hospital and The Warren Alpert Medical School of Brown University, Providence, RI

Background/Aims: Vaccine failure and graft reinfection despite immunoglobulin are attributed to escape mutants with amino acid substitutions in the alpha determinant of viral envelope proteins. Recent studies revealed virion secretion defect of the prototype G145R mutant. In this study we systemically analyzed virion secretion capacity of 20 potential immune escape mutants. Methods: Huh7 cells were transiently transfected with a 1.5mer replication construct that cannot express envelope proteins and a 0.7mer expression construct of envelope proteins. Virus particles were immunoprecipitated from culture supernatant by an anti-preS2 antibody before Southern blot analysis. Results: All the mutants expressed similar levels of envelope proteins based on Western blot analysis of cell lysate. However, secreted HBsAg as measured by the Abbott kit was reduced moderately or completely for mutants affecting several cysteines or residues near G145. Those mutants showed total loss or marked reduction in virion secretion. In addition, several mutants with no impairment in HBsAg detection also displayed moderate or severe reduction in virion secretion. Co-expression of wild-type envelope proteins at 1:1 but not 1:5 (wt : mutant) ratio markedly improved virion secretion. Introduction of an M133T second-site mutation, which creates a novel N-linked glycosylation site, also restored virion secretion. Conclusions: Structural changes around the alpha determinant impair virion secretion. The detection of immune escape mutants in patient blood may result from rescue by the co-infecting wild-type virus. Immunogenic escape mutants will not replace wild-type virus unless under conditions of anti-HBs immune pressure, or if they acquire a compensatory mutation.

infection.
cDNA histones are hypo-acetylated and methylated in occult patients with inactive HBV and occult HBV carriers (6) HBVccc-HBV synthesis, HBVcccDNA levels are similar in HDV intracellular cccDNA levels (5) Despite the persistence of replication (4) Serum HBsAg amount does not correlate with patients indicating different grade of HDV interference on HBV HBV DNA levels may be largely different among HDV infected parable between HDV positive and negative individuals (3) according to their HDV status whereas cccDNA levels are com-

cation, serum and total intrahepatic HBV DNA levels differ individual (2) In anti-HBe positive patients with active HBV repli-
cation (hfgl2) in response to HBV proteins. Method: HBc, HBs or HBx transcription factor(s) and the upstream signal transduction pathway involved in transcription of the human fgl2 gene (hfgl2) in response to HBV proteins. Method: Hbc, HBs or HBx expression plasmids were cotransfected with a hfgl2 promoter luciferase report construct into CHO cells and HepG2 cells respectively. Peripheral blood mononuclear cells (PBMC) were isolated from 10 patients with severe acute on chronic (AOC) hepatitis B, 10 patients with minimal chronic hepatitis B, 8 HBsAg carriers, and 6 health volunteers as controls. A polyclonal antibody against c-Ets-2 was used to detect the expres-
dion of c-Ets-2 in response to HBc protein, while JNK inhibitor SP600125 abolished the upregulated expression of c-Ets-2 in response to HBc protein by flow cytometry, Western blotting and confocal microscopy. Phosphorylation of ERK, JNK and p38 MAPK in PBMC was detected by Western blotting. Results: Luciferase assay showed both Hbc and HBx protein, but not HBs protein enhanced hfgl2 transcription in both CHO cells and HepG2 cells. A strong regulatory region from -712 to -568 was demonstrated to play an important role in hfgl2 gene transcription in response to both HBc and HBx proteins.

### 910 HEPATITIS B VIRUS PROTEINS INDUCE ACTIVATION OF HFGL2 TRANSCRIPTION THROUGH C-ETS-2 TRANSCRIPTION FACTOR AND MAPK SIGNAL PATHWAY

Meifang Han, Yaoyong Zhou, Dong Xi, Weiming Yan, Xiaoping Luo, Qin Ning; Department of Infectious Disease, Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China

Objective: Fibrinogen–like protein 2 (fgl2)/ fibroleukin is piv-
otal in the pathogenesis of both experimental and human ful-
minant viral hepatitis. This work was to characterize the transcription factor(s) and the upstream signal transduction pathway involved in transcription of the human fgl2 gene (hfgl2) in response to HBV proteins. Method: Hbc, HBs or HBx expression plasmids were cotransfected with a hfgl2 promoter luciferase report construct into CHO cells and HepG2 cells respectively. Peripheral blood mononuclear cells (PBMC) were isolated from 10 patients with severe acute on chronic (AOC) hepatitis B, 10 patients with minimal chronic hepatitis B, 8 HBsAg carriers, and 6 health volunteers as controls. A polyclonal antibody against c-Ets-2 was used to detect the expres-
dion of c-Ets-2 in response to HBc protein, while JNK inhibitor SP600125 abolished the upregulated expression of c-Ets-2 in response to HBc protein by flow cytometry, Western blotting and confocal microscopy. Phosphorylation of ERK, JNK and p38 MAPK in PBMC was detected by Western blotting. Results: Luciferase assay showed both Hbc and HBx protein, but not HBs protein enhanced hfgl2 transcription in both CHO cells and HepG2 cells. A strong regulatory region from -712 to -568 was demonstrated to play an important role in hfgl2 gene transcription in response to HBc or HBx proteins by a series of promoter deletion assay. By site-directed mutagenesis, EMSA and ChIP, binding of transcription factor c-Ets-2 and its cognate cis-element in the region -712/-
568 was demonstrated to play an important role in hfgl2 gene transcription in response to both Hbc and HBx proteins. shRNA interference of the c-Ets-2 expression was able to abolish hfgl2 gene transcription by 64.8% and 60.0% in response to HBc and HBx proteins respectively. Peripheral blood mononuclear cells (PBMC) were isolated from 10 patients with severe acute on chronic (AOC) hepatitis B, 10 patients with minimal chronic hepatitis B, 8 HBsAg carriers, and 6 health volunteers as controls. A polyclonal antibody against c-Ets-2 was used to detect the expres-
dion of c-Ets-2 in response to HBc protein, while JNK inhibitor SP600125 abolished the upregulated expression of c-Ets-2 in response to HBc protein by flow cytometry, Western blotting and confocal microscopy. Phosphorylation of ERK, JNK and p38 MAPK in PBMC was detected by Western blotting. Results: Luciferase assay showed both Hbc and HBx protein, but not HBs protein enhanced hfgl2 transcription in both CHO cells and HepG2 cells. A strong regulatory region from -712 to -568 was demonstrated to play an important role in hfgl2 gene transcription in response to HBc or HBx proteins by a series of promoter deletion assay. By site-directed mutagenesis, EMSA and ChIP, binding of transcription factor c-Ets-2 and its cognate cis-element in the region -712/-
568 was demonstrated to play an important role in hfgl2 gene transcription in response to both Hbc and HBx proteins. shRNA interference of the c-Ets-2 expression was able to abolish hfgl2 gene transcription by 64.8% and 60.0% in response to HBc and HBx respectively. In human, c-Ets-2 protein was highly expressed in PBMC isolated from patients with severe AOC hepatitis B when compared with health controls. Increased phosphorylation activation of ERK, JNK and p38 MAPK were found in PBMC isolated from patients with severe AOC hepatitis B when compared with health controls. Treatment with ERK inhibitor PD098059 abolished the upregulated expression of c-Ets-2 in response to Hbc protein, while JNK inhibitor SP600125 abolished the upregulated expression of c-Ets-2 in response to HBx protein. Conclusion: Hbc and HBx initiated the transcription of hfgl2 gene through c-Ets-2 transcription factor, which was dependent on the activation of ERK and JNK signal path-
way in corresponding to either Hbc or HBx proteins. This work
911 EFFICIENT CROSSTALK BETWEEN HBV-SPECIFIC T HELPER AND CYTOTOXIC T CELLS CHARACTERIZES SUCCESSFUL CONTROL OF HEPATITIS B VIRUS INFECTION

Ivana Carey, Maria Mytilinaiou, Sanjay Bansal, Antonietta Gianattasio, Francesca Meda, Maria Serena Longhi, Giorgina Mieli-Vergani, Diego Vergani; Institute of Liver Studies, King's College London School of Medicine at King's College Hospital, London, United Kingdom

Strong T helper 1 (Th1) HBV-specific immune response leads to cytotoxic T lymphocyte (CTL) activation and control of viral replication. In patients with chronic hepatitis B infection, inefficient viral control may derive from impaired memory/effector CTL maturation caused by inadequate crosstalk between HBV-specific Th1 cells and CTL. Programmed cell death (PD-1) receptor, linked to functional suppression of HBV-specific T cells, may be involved in this process. Aims: To evaluate T helper and CTL HBV-specific responses in four stages of HBV infection and establish their impact on memory/effector cell maturation. Patients: 34 HLA-A2+ve children (16 males, median age 12.8 y) were divided into 4 groups according to HBcAg/HBsAg status and ALT activity (Table 1); 5 HCV infected children (3 males, median age 13.2 y) and 5 healthy individuals (1 male, median age 31.5 y) served as controls. Methods: HBV-specific Th immune responses were determined by interferon (IFN)-γ, IL2 and IL-10 Elispot after stimulation of peripheral blood mononuclear cells (PBMC) with HBV antigens (HBcAg, HBsAg and HBsAg). CD8+ reactivity after incubation with the HLA-A2 restricted immunodominant HBV-core (a,b) pentamer was determined by INF-γ, granzyme B and IL-2 Elispot and staining with HLA-A2 HBV-core (a,b) pentamer. Phenotype of HBV-specific cells was determined by flow-cytometry with anti-CD27, CD28 , CD45RA, CD62L and PD-1 antibodies. HBV DNA was quantified by real-time PCR (log10 copies/ml). Results: HBV-specific production of Th1 cytokines was higher in group D than groups A, B and C. (IFN-γ HBV core: 479±145 vs. 12.6±3±4.4, 62.6±21.5 and 64.3±23.1 specific spot forming cells per 1 million PBMC (spSFC/10^6 PBMC), p=0.03). Levels of proinflammatory cytokines produced by Th cells andCTL after antigen-specific stimulation correlated with the number of HBV-core (a,b) pentamer+ve cells (r=0.569, p=0.001) and mature memory/effector CTL (r=0.413, p=0.02). The number of PD-1+ve HBV-specific CTL was lower in group D than in groups A, B and C (76±4.8 vs 91.3±2.3, 81.6±7 and 81.8±5.4%, p=0.02). HBV DNA viral load correlated inversely with HBV-specific Th1 (r=-0.36, p=0.046) and CTL responses (r=-0.59, p=0.001) and number of pentamer+ve cells (r=-0.37, p=0.03). Conclusion: Efficient crosstalk between HBV-specific T helper and cytotoxic T cells leads to maturation of memory/effector T cells and successful control of viral replication.

912 EVOLUTION OF VIRAL QUASISPECIES IN THE POLYMERASE GENE OF HEPATITIS B VIRUS DURING ANTIVIRAL TREATMENT: FROM NAIVE TO VIRAL BREAKTHROUGH

Sang Hoon Ahn1,2, Hye Young Chang1,2, Hyo Jung Shim1,2, Do Young Kim1,2, Yong Han Paik1,2, Kwan Sik Lee1,2, Byung Soo Moon1, Chae Yoon Chon1,2, Young Myung Moon4, Kwang Hyub Han1,2; Internal medicine, Yonsei University College of Medicine, Seoul, South Korea; 2Liver cirrhosis clinical research center, Yonsei University College of Medicine, Seoul, South Korea; 3Brain Korea 21 project for medical science, Yonsei University College of Medicine, Seoul, South Korea; 4Internal medicine, Kwandong University College of Medicine, Koyang, South Korea

Background/Aim: Drug resistance is emerging as the single most significant factor in treatment failure. The presence of different viral genomes in a patient (viral quasispecies), including preexisting mutations in the polymerase gene of hepatitis B virus (HBV), might be a mechanism of virus survival under selective antiviral drug pressure. We thus investigated viral quasispecies evolution and preexisting drug resistance mutations. Patients and Methods: Five chronic hepatitis B patients with lamivudine (LAM) failure were enrolled in this study. Patient sera were obtained before the treatment and at the time of viral breakthrough during LAM treatment. The polymerase chain reaction (PCR) product of the HBV polymerase gene (rt1-rt280) was cloned into pOE7T Easy Vector. After transformation, 100 clones were picked up at each time point. Cloned HBV DNA was confirmed using XbaI and PstI digestion and sequenced. The reference gene of HBV genotype C was NCBI GenBank No.AF286594, which was considered the wild type. Results: At baseline, the wild-type was present at 0–11% in five patients. Several substitutions in the HBV DNA polymerase region were observed, including reported antiviral resistant sites. Patients had 31–81 mutations of various types. Before treatment (naive), rtL80I (1%), V84F (5%), rtT128I (1%), rtV173L (2%), rtV173A (2%), rtI181V (1%), rtI181L (8%), S202G (2%), rtV173L (2%), rtL180M (1%), rtA181T (1%), rtA181I (1%), rtS202G (2%), rtL180M (1%), rtL180P (1%), V84F (5%), rtT128I (1%), rtV173L (2%), rtV173A (2%), rtI181V (1%), rtI181L (8%), S202G (2%), rtV173L (2%), rtL180M (1%), rtA181T (1%), rtA181I (1%), rtS202G (2%), rtL180M (1%), rtL180P (1%), V84F (5%), rtT128I (1%), rtV173L (2%), rtV173A (2%), rtI181V (1%), rtI181L (8%), S202G (2%), rtV173L (2%), rtL180M (1%), rtA181T (1%), rtA181I (1%), rtS202G (2%), rtL180M (1%), rtL180P (1%), V84F (5%), rtT128I (1%), rtV173L (2%), rtV173A (2%), rtI181V (1%), rtI181L (8%), S202G (2%), rtV173L (2%), rtL180M (1%), rtA181T (1%), rtA181I (1%), rtS202G (2%), rtL180M (1%), rtL180P (1%), V84F (5%), rtT128I (1%), rtV173L (2%), rtV173A (2%), rtI181V (1%), rtI181L (8%), S202G (2%), rtV173L (2%), rtL180M (1%), rtA181T (1%), rtA181I (1%), rtS202G (2%), rtL180M (1%), rtL180P (1%), V84F (5%), rtT128I (1%), rtV173L (2%), rtV173A (2%), rtI181V (1%), rtI181L (8%), S202G (2%), rtV173L (2%) were identified, while rtT54S, rtH55R, rtS106C, rtY124N, rtD134G, rtP143Q, rtS223A, rtL229V, and rtP237H mutations became prevalent. Conclusion: We demonstrated the evolution of mutations in the polymerase gene of HBV during antiviral treatment. Our study may help clarify the drug resistance pathway and emphasize the early detection of drug-resistant mutants before or during...
913 FACTORS ASSOCIATED WITH HBsAg SEROCLEARANCE IN ASYMPTOMATIC CARRIERS OF ENDEMIC AREAS DURING A LONG FOLLOW-UP PERIOD OF UP TO 17 YEARS

Stamatia Kotsiou1, George Zacharakis1,2, John Koskinas2, Fevernia Tzara3, Nikolaos Vafeiadis4, John Messaritakis5, Athanasios Archimandritis6, Eustratios Maltezos7, Kostantinos Papoutsellis8; 1People's Health Care Organization, Thessaloniki, Greece; 2Unit of Preventive Medicine, Social Security Institute, Alexandroupolis, Greece; 3Academic Department of Medicine, Democritus University of Thrace Medical School, Alexandroupolis, Greece

Background: The seroclearance of hepatitis B s antigen (HBsAg) is a rare event and usually confers favorable outcome if there is no preexisting cirrhosis or viral superinfection, though adverse complications still can occur. However, the factors associated with HBsAg seroclearance are still under investigation. Aim: The aim of this long-term follow-up study was to reexamine the rates of HBsAg seroclearance and possible factors associated with HBsAg seroclearance. Patients/Methods: There were 1139 HBsAg-positive asymptomatic adult carriers, 31.9±23.3 years old, men (59%) and women enrolled in Eastern-Northern Greece between 1990 and 1999 in this analysis prospectively followed-up for a period up to 17 years (1990-2007). Viral markers/liver biochemistry/physical examination performed at entry and every 6-24 months. Abdominal ultrasound was done at entry and every 3/4yrs. Serum HBV-DNA levels measured by Amplicor HBV Monitor kit. The HBsAg status in last follow-up samples was also tested. Logistic regression analysis was used to derive multivariate-adjusted odds ratio (OR) and 95% confidence interval (CI) for factors associated with HBsAg seroclearance. Results: Serum HBsAg cleared in 137 patients (12%) at the mean age of 41±15.3 years after the entry. The cumulative probability of HBsAg seroclearance after 17 years was only 5.3% (varied from 1.9% in low endemic areas to 21% in high endemic areas) for carriers with age at entry <20 years but around 27% for those with age at entry >20 years (varied form 11% in low to 45% in high endemic areas). Hepatitis relapse in 182 patients (16%) 0.5 to 16 years after the entry as depicted by ALT levels elevated >1.5 UNL and detectable serum HBV-DNA levels. During the follow-up period, age at entry and sustained remission of hepatitis were significantly associated with HBsAg seroclearance (p<0.05). The multivariate-adjusted OR (95% CI) of HBsAg seroclearance was 1.21 (1.32-2.43) for serum ALT level at study entry >40 IU versus <40 IU; 6.26 (1.87-23.47) for age <20 years versus >20 years; and 2.18 (7.25-23.91) for serum HBV DNA level <10(3) copies/mL versus >10(3) copies/mL. Conclusions: The cumulative rate of HBsAg seroclearance was 30% in asymptomatic carriers after 17 years of follow-up. Longer follow-up period and sustained remission were associated with a significantly increased HBsAg seroclearance rate.

Disclosures: The following people have nothing to disclose: Stamatia Kotsiou, George Zacharakis, John Koskinas, Fevernia Tzara, Nikolaos Vafeiadis, John Messaritakis, Athanasios Archimandritis, Eustratios Maltezos, Kostantinos Papoutsellis.

914 HEPATITIS B VIRUS QUASISPECIES EVOLUTION IN HBEAG SEROCONVERTERS

Yan Cheng1, May Ling Tan1, Seng Gee Lim1,2; 1Virology group, Institute for Medical Biology, A-star, Singapore, Singapore; 2Dept of Gastroenterology and Hepatology, National University Hospital, Singapore, Singapore

Background: We have recently demonstrated that hepatitis B virus (HBV) quasispecies diversity is higher in patients in HBsAg serocarriers (Gastroenterology, in press), while non-serocarriers have very low viral diversity. However, it is unclear how HBV viral genetic diversity transitions from a low diversity state to a high diversity state. Aim: To evaluate the long term evolution pattern of HBV quasispecies in spontaneous seroconverters that transition from low to high viral diversity state. Methods: Eight chronic hepatitis B HBeAg seroconverters, with long term stored serum and clinical follow-up of 6-15 years before seroconversion were studied. Two chronic hepatitis B patients without HBeAg seroconversion with matching length of follow-up and stored serum were included as controls. Serum samples from 7-12 time-points were used for nested PCR, cloning and sequencing of the precore/core gene (20 clones/sample). In total, 1685 sequences were analysed. Only genotype B patients were involved in this study. Sequences were aligned using ClustalX, then SPLITMA phylogenetic trees were constructed using Pebble 1.0 following which maximum likelihood estimates of pairwise distances under a GTR+I+G model was assessed. Viral diversity and substitution rates were then estimated. Results: The genetic diversity in HBeAg seroconverters was very low at baseline and similar to controls but gradually increased from 2.7±1.0exps-3 substitutions/site to 1.1±1.0exps-2 substitutions/site prior to seroconversion (Spearman's correlation analysis, R=0.67 and p<0.0001) followed by a striking increase post-seroconversion. The evolutionary rates in these patients showed a more complex pattern over time. Conclusions: There is a gradual transition of HBV quasispecies from a low diversity to high diversity status just prior to HBeAg seroconversion. High viral diversity appears to be a pre-requisite for HBeAg seroconversion.

915 TLR9 EXPRESSION OF PLASMACYTOID DENDRITIC CELLS IN PATIENTS WITH CHRONIC HEPATITIS B INFECTION

Nina Jia, Qing Xie, Baoyan An, Hui Wang, Xiaqi Zhou, Qingsuo, Hong Yu, Wei Cai; Department of Infectious Diseases, Ruijin Hospital, Shanghai Jiaotong University School of Medicine, Shanghai, China

Background and Aims: Chronic HBV infection is the result of a complex interaction between a replicating noncytopathic virus and a down-regulated antiviral immune response. Immature plasmacytid dendritic cell (pDC) is the cell type responsible for the majority of the IFN-I production, which is the most important part of the native immunity against virus and mature plasmacytid dendritic cell is the antigen-representing cell, which may prime naive CD4+ T cells and develop Th1 response. TLR9 functions as a pattern recognition receptors (PRRs) by interacting with CpG motif of virus. High level of cytokines such as interferon (IFN)-α, IFN-β are expressed by CpG stimulation. Previously, we have shown that TLR9 low expression and functional impairment of pDCs in patients with chronic hepatitis B. This antiviral treatment to prevent antiviral therapy failure. Key Words: Hepatitis B virus, Mutations, Antivirals, Resistance, Quasispecies

Disclosures: The following people have nothing to disclose: Stamatia Kotsiou, George Zacharakis, John Koskinas, Fevernia Tzara, Nikolaos Vafeiadis, John Messaritakis, Athanasios Archimandritis, Eustratios Maltezos, Kostantinos Papoutsellis.
study aims to evaluate the frequency and function of circulating pDCs in patients at various stages of HBV infection, and to explore the role of TLR9 and pDCs function in the disease progression after HBV infection. Methods: Peripheral blood was collected from 69 hepatitis B (HB) virus-infected persons, including 44 cases of asymptomatic HBV infection, 30 cases of chronic HB, 25 cases of liver cirrhosis, and 21 healthy blood donors used as controls. Flow cytometry was used to analyse the frequency of circulating pDCs and the mean fluorescence intensity (MFI) of TLR9. Fresh peripheral blood mononuclear cells (PBMCs) were stimulated in vitro using CpG 2216. The supernatants were measured for IFN-α production using ELISA method. Results: Compared with healthy controls, the MFI of TLR9 from patients was significantly reduced (p < 0.0001). In addition, the MFI of TLR9 in patients with asymptomatic HBV infection and liver cirrhosis was significantly decreased compared with that of chronic HB (p < 0.05). The peripheral pDCs frequency in patients with chronic HB and liver cirrhosis were significantly more lower compared to the control group (p < 0.05). Moreover, pDCs frequency inversely correlate with ALT levels (r = -0.348, p < 0.05). The ability of PBMCs to secrete IFN-α also decreased significantly in patients with chronic HBV infection. Conclusions: Our results suggest that patients with chronic HBV infection have a significantly lower TLR9 expression of circulating pDC, as well as decreased number and impaired function of circulating pDC, which may be partially related to HBV disease progression in these patients.

916 HEPATITIS B VIRUS X PROTEIN (HBX) TRIGGERS HEPATIC STELLATE CELLS (HSCS) ACTIVATION THROUGH TRANSFORMING GROWTH FACTOR BETA (TGF-β) SIGNALLING PATHWAY

Samuel Martín-Vilchez1, Yolanda Rodríguez-Munoz2, Paloma Sanz-Cameno1, Manuel Lopez-Cabrera2, Ricardo Moreno-Otero2, Enrique Lara-Pezzi2, 1Liver Unit, Hospital Universitario La Princesa, Madrid, Spain; 2Molecular Biology Unit, Hospital Universitario La Princesa, Madrid, Spain

Activated hepatic stellate cells are the principle cell type responsible of liver fibrosis due to their great capacity to synthesize different extracellular matrix fibrillar proteins like collagen type I, and profibrotic growth factors like connective tissue growth factor (CTGF), and TGF-β. Hepatitis B virus is the main cause of hepatocarcinoma being HBx closely implicated in its development. However, HBx contribution to liver fibrosis has not been investigated. Our aim was to study if HSCs activation could be mediated by HBx and through which signalling pathways. METHODS Primary human HSCs were incubated with conditioned media from the following hepatic cell lines: CMX that bears two head to tail copies of the HBV genome. CHL and HepG2 were the control parental cell lines. To study HSCs which bears two head to tail copies of the HBV genome. CHL and HepG2 were the control parental cell lines. To study HSCs activation markers expression were reduced. Neutralization assays showed that HBx influence is mediated by TGF-β signalling pathway. In conclusion, these results strongly suggest that HBx could be a promoting agent of liver fibrosis being capable of inducing the secretion of soluble mediators that result in the paracrine activation of HSCs at least in a TGF-β manner.

Disclosures: The following people have nothing to disclose: Samuel Martín-Vilchez, Yolanda Rodríguez-Munoz, Paloma Sanz-Cameno, Manuel Lopez-Cabrera, Ricardo Moreno-Otero, Enrique Lara-Pezzi.

917 INFLUENCE OF SERUM HBV DNA LEVEL ON A RECURRENCE OF HEPATOCELLULAR CARCINOMA AFTER CURATIVE TREATMENT WITH RADIO-FREQUENCY ABLATION

Tadashi Goto, Ryosuke Tateishi, Hideo Yoshida, Takahisa Sato, Takamasa Ohki, Ryota Masuzaki, Fumihiro Kanai, Shuichiro Shina, Haruhiko Kobashi, Takao Kawabe, Masao Oma; Department of Gastroenterology, Faculty of Medicine, University of Tokyo, Tokyo, Japan

Background: Elevated serum HBV DNA level is a strong risk predictor of hepatocellular carcinoma (HCC) independent of HBsAg, serum alanine aminotransferase level, and liver cirrhosis (JAMA 2006). However, there are few studies investigating influence of serum HBV DNA level on recurrence of HCC. Aim: The purpose of this study was to evaluate whether serum HBV DNA level was associated with the recurrence rate after curative treatment of HBV related-HCC (HBsAg positive and HCV-Ab negative) with radio-frequency ablation (RFA) retrospectively. Methods: Consecutive patients with HBV related-HCC who were curatively treated with RFA at their first hospital admission from February 1999 to September 2006 were analysed. Concentration of HBV DNA is measured by transcription-mediated amplification (TMA) or polymerase chain reaction (PCR). Age, gender, albumin, alanine aminotransferase, platelet count, AFP, L3(%), DCP, tumor size, and the tumor number were also obtained for analysis. Risk factors for recurrence after RFA were evaluated using univariate and multivariate analyses. Results: A total of 66 patients (47 males, 19 females, mean age 66.4 ± 8.5 years) with HBV related-HCC were curatively treated with RFA during the study period. These patients were followed up for a mean of 3.2 years. recurrence of HCC occurred in 38 patients. 1-, 3- and 5-year recurrence rates were 30.0%, 60.4%, and 74.3%, respectively. By univariate analysis, platelet count (<15 x 10^4/mm³), the tumor number (multiple) and HBV DNA (≥ 4.0 logcopies/ml) were associated with the recurrence of HCC. A stepwise, multivariate Cox regression analysis revealed that platelet count (risk ratio, 3.74; 95% CI, 1.56-8.97, p = 0.003) and concentration of HBV DNA (risk ratio, 2.87; 95% CI, 1.16-7.09, p = 0.023) were independent risk factors for recurrence of HCC.

HEPATITIS B VIRUS (HBV) X PROTEIN (HBX) PROMOTES HUMAN HEPATIC STELLATE CELLS ACTIVATION AND PROLIFERATION MODULATED BY MATRIX METALLOPROTEINASE 2 (MMP-2)

Yolanda Rodriguez-Munoz, Samuel Martín-Vilchez, Paloma Sanz Cameno, Ricardo Moreno-Otero, Manuel Lopez-Cabrera, Enrique Lara-Pezzi; 1Hepatology Unit, Hospital Universitario “La Princesa”, Madrid, Spain; 2Molecular Biology Unit, Hospital Universitario “La Princesa”, Madrid, Spain

Human Hepatic stellate cells (HHSCs) activation is crucial for liver fibrosis development. This event is characterized by α-smooth muscle actin (α-SMA) synthesis, an increased production of profibrotic factors like collagen type 1 (COLI), MMP-2, connective tissue growth factor (CTGF) and a successive enhanced proliferation that define the later perpetuation phase.

HBx is a multifunctional regulator that modulates gene transcription and several signalling pathways. Also it has been shown to be essential for hepatocellular carcinoma (HCC) development; however its role in fibrosis is still unknown.

OBJECTIVE: The aim of this study is to analyze the effects of HBx protein over HHSCs activation and perpetuation steps.

METHODS: Primary HHSCs were incubated with conditioned media from hepatic cell lines: CMX which expresses HBx in a dexamethasone (DX)-inducible manner; 2.2.15, which bears two copies of the HBV genome. Parental cell lines CHL and HepG2 were used as controls. Human HHSCs were incubated during 24 hours with different conditioned media. Fibrosis markers expression α-SMA, COLI, CTGF and MMP-2, was analyzed by immunofluorescence, Western Blot (WB) and zymography. HHSC proliferation was spectrophotometric analyzed using a cell growth determination kit. RESULTS: HHSCs activation was demonstrated by the “de novo” expression of α-SMA as showed in immunofluorescence. WB and zymography from HHSCs exposed to conditioned media from HBx expressing cells, displayed an increased expression COLI, CTGF and MMP-2 as compared to human HHSCs incubated with control media. In proliferation assays, conditioned media from CMX and 2.2.15 cells had a positive effect on HHSCs growth, compared to those exposed to CHL or HepG2 media. Furthermore, HHSCs incubated with presence of conditioned medium from dexamethasone-stimulated CMX cells showed a higher proliferation rate than those conditioned with unstimulated CMX or CHL media. CONCLUSION: Our results reveal that HBx could trigger HHSCs activation as demonstrated by the enhanced expression of COLI, CTGF and α-SMA in HHSCs exposed to HBx viral protein. Additionally, an increased proliferation has been shown in HHSCs grown in the presence of conditioned medium from HBx-expressing cells. Furthermore, since a direct link between MMP-2 expression and HHSCs proliferation has been reported (Olaso E et al., 2001; Ikeda K et al., 1999), direct and paracrine induction of MMP-2 by HBx may contribute to this enhanced proliferation too. Taken together our results confirm the modulating role of HBx over HHSCs not only in the activation process but also the following perpetuation step modulated at least by the induction of MMP-2.

EXPRESSION LEVELS OF HNF4A LINK EFFICIENT HBV REPLICATION TO HEPATOCYTE DIFFERENTIATION STATE

Maria J. Quasdorff, Marianne Hoeseel, Margarete Odenthal, Uta Zedler, Felix Bohne, U. Drebber, Tuan H. Nguyen, Philipp Grippon, Dirk Stippel, Tobias Goeser, Ulrike Protzer; 1Gastroenterology and Hepatology, University of Cologne, Cologne, Germany; 2Molecular Infectiology at the CMMC, University of Cologne, Cologne, Germany; 3Institute of Pathology, University of Cologne, Cologne, Germany; 4Institute National de la Santé et de la Recherche Médicale (INSERM), U522, Hôpital de Pontchaillou, Rennes, France; 5Visceral Surgery, University of Cologne, Cologne, Germany; 6Department of Microbiology, Geneva School of Medicine, Geneva, Switzerland

The efficiency of HBV replication is discussed to depend on hepatocyte differentiation. Cellular factors that link HBV replication to hepatocyte differentiation, however, are not known so far. We hypothesized that expression levels of liver specific transcription factors determine hepatocyte differentiation as well as efficiency of HBV replication. Methods: We correlated expression levels of hepatocyte differentiation markers and transcription factors to efficiency of HBV replication following adenovirus-mediated transfer of 1.3 HBV genomes at equal levels into freshly isolated primary human hepatocytes (PHH), HepG2, HepaRG, HuH7 (hepatoma) and Pop10 (hepatocyte) cell lines. We quantified expression of albumin, ferritin, liver specific antigen (LSA), organic anion transporting polypeptide - C (OATP-C), bile salt exporting pump (BSEP), CYP1A2, 2′,3′-triphosphodiysterogenase (TDO), steroid regulatory element binding protein-2, apolipoprotein B100 and hepatocyte nuclear factors (HNF) HNF1α, HNF4α, HNF3α/β/γ, C/EBPα/β and LRH-1 by real-time RT-PCR and Western Blot. To monitor HBV replication, we quantified HBV pregenomic RNA (pgRNA), HBV core and large (L) envelope proteins, replicative intermediates and progeny virus. Results: The efficiency of HBV replication was 13.6-, 14.4- and 15.7-fold higher in PHH than in HepG2, HepaRG or HuH7 cells, respectively, and increased in HepaRG cells 3.3-fold upon differentiation. No HBV replication was detected in Pop10 cells. In all cells, expression levels of pgRNA determined replication efficiency and correlated closely with expression of LSA, TDO, OATP-C and BSEP as well as HNF1α, HNF3α and HNF4α. When maintaining HBV replicating cell lines HepG2.H1.3 and HepG2.2.15 under differentiating conditions, pgRNA increased 8.6- and 8.1-, HBV core 14- and 10-, Lproteins 8.8- and 7.1- and progeny HBV 715- and 100-fold, respectively. Again, this correlated with increased levels of HNF1α, HNF3α and HNF4α and mRNA for OATP-C and BSEP. Knock down of HNF4α and HNF1α using specific siRNAs decreased pgRNA by 77% and 57%, expression of HBV core by 80% and 45% and Lproteins by 30% and 75%, HBV replicative intermediates by 50% each and HBV progeny release by 88% and 74%, respectively. Decrease in HBV replication was confirmed at the single-cell level after knock down of HNF4α. Levels of HNF4α closely correlated with HBV core protein and pgRNA in all analyzed tumor-peritumor samples of patients with HBV related hepatocellular carcinoma. Conclusion: High expression levels of HNF4α, maintaining a high level of hepatocyte differentiation and polarization, are required for efficient HBV replication.

Disclosures:

Introduction: Previous publications from the R.E.V.E.A.L.-HBV study have demonstrated that HBV DNA at the time of cohort entry strongly predicts future risk of hepatocellular carcinoma (HCC). However, the impact of chronically elevated HBV DNA over time on the risk of HCC accounting for changes in serum ALT level has not been evaluated. The aim of this study was to assess HCC risk associated with multiple observations of serum HBV DNA and ALT levels over time. Methods: A subset of the R.E.V.E.A.L. study cohort with baseline HBV DNA ≥10^4 copies/mL, no evidence of liver cirrhosis at entry, anti-HCV negative and ≥2 frozen serum samples available for HBV DNA testing were analyzed. HCC was ascertained through data linkage with computerized profiles of the National Cancer Registry and Death Certification System in Taiwan. All HCC cases were confirmed using established criteria. Multivariable adjusted hazards ratios (HR_adj) were derived using time-dependent Cox proportional hazard models where both HBV DNA and serum ALT were time dependent variables using multiple samples over the follow-up period. Results: Interim analysis of results identified 71 new HCC cases from 1,289 people over 15,508 person-years of follow-up. Males made up 68.8% of the population. In the final model adjusting for gender, age, cigarette smoking and alcohol consumption, serum ALT as a time-dependent variable, and HBeAg status, the risk of developing HCC was strongly associated with increasing HBV DNA level (P for trend <0.001) in a dose-dependent relationship. The HR_adj (95% confidence interval) were 6.1 (0.8—48.2), 6.2 (0.8—48.4), 7.7 (1—60.8), and 13.1 (1.7—99.6), for patients with serum HBV DNA level of 300—9,999 copies/mL, 10,000—99,999 copies/mL; 100,000—999,999 copies/mL; and ≥10^6 copies/mL respectively, compared with those who spontaneously achieved an undetectable HBV DNA level (<300 copies/mL). Other important variables included increasing serum ALT level, HBeAg-positive serostatus, age, and alcohol consumption. Conclusion: The relationship between HBV DNA level and risk of HCC remained very strong in these analyses using follow-up HBV DNA levels. The risk increased as HBV DNA level increased.

SPECTRUM OF STEATOSIS IN CHRONIC HEPATITIS B (CHB) AND ITS RELATION TO BIOCHEMICAL, METABOLIC, VIROLOGICAL AND HISTOLOGICAL PARAMETERS
Deepak K. Singh1, Archana Rastogi2, Puja Sakhija1, Ranjana Gondal1, Akshat Jain1, Sayed Hissar2, Ashish Kumar2, Shiv K. Sarin2; 1Pathology, G B Pant hospital, Delhi, India; 2Gastroenterology, G B Pant Hospital, Delhi, India

Steatosis predicts progression of histologic injury, insulin resistance and reduced response to antiviral therapy in patients with hepatitis C. However, there is limited data in patients with chronic hepatitis B (CHB). This is relevant since response to current antiviral therapies for CHB is poor. Aim: To assess the spectrum of hepatic steatosis in CHB and to determine its relationship with biochemical, metabolic, virologic and histologic parameters. Patients and Methods: Liver biopsies of 350 patients with chronic HBV infection were blindly assessed by three experienced pathologists and categorized as: Group 1: no steatosis (≤5%) and group 2: hepatosteatosis (>5%). Demographic, biochemical, metabolic, virologic and histologic parameters were compared between two groups. HBV DNA was quantified by Hybrid capture assay and HBV genotyping was done by multiplex PCR. Results: Group 1 had 232 (66.3%) and group 2 had 118 (33.7%) patients. In group 2, 65 (55.1%) patients had mild and 53 (44.9%) had moderate to severe steatosis. More than 90% cases showed macrovesicular steatosis. Group 2 patients showed significantly higher age (35.5±10.5 yrs vs 28.1±13.9 yrs, p=0.000), male preponderance (M:F ratio-8.8:1 vs. 4.8:1, p=0.02), higher BMI (26.2±9.2 Kg/m2 vs. 20.7±3.9 Kg/m2, p=0.000), triglyceride (149.4±62.2 vs. 81.9±31.4, p=0.000) and insulin levels (13.1±9.1 vs 9.1±6.0, p=0.027). Waist circumference, blood sugar, cholesterol and leptin (2.3±1.9ng/mL vs 2.4±1.3ng/mL, p=0.95) were also higher in group 2 but not statistically significant. Mean HAI and fibrosis scores in group 2 were higher than group 1 (Group 1 vs 2, HAI, 4.5±2.9 vs 4.8±2.6, p=0.02; fibrosis 1.5±1.2 vs 1.7±1.2, p=0.17). More patients in group 1 had higher HBeAg positivity (Group 1 vs 2, 57.2% vs 47.3%, p=0.039). There was no significant difference in ALT (median, 1.14 vs 99, p=0.36) and HBV DNA levels (2.4E08±4.9E08 vs 1.9E08±4.6E08, p=0.48). In group 2, hepatic steatosis was more frequent in patients with HBV genotype D than in genotype A (58.1% vs. 42.0%, p=0.01). Conclusions: In our study steatosis was seen in one third cases with chronic HBV infection. These patients showed higher necroinflammatory activity and fibrosis. Association of steatosis with metabolic determinants and its presence in the liver suggests the role of host factors in the etiology of steatosis in chronic hepatitis B. There is no relation to viral factors like viral load and HBeAg status although there is a possibility of relation to genotype D. The efficacy of combined “antiviral and metabolic” approaches versus standard antiviral regimes in patients with steatosis and chronic hepatitis B infection needs to be evaluated.

PREVALENCE OF FIBROSIS AND CIRRHOSIS IN CHRONIC HEPATITIS B: IMPLICATIONS FOR TREATMENT AND MANAGEMENT

James Fung, Ching Lung Lai, David But, Danny Wong, Ting Kin Cheung, Man-Fung Yuen; Department of Medicine, University of Hong Kong, Hong Kong, China

Aim: To document the prevalence and factors associated with severe fibrosis and cirrhosis in a large population of Asian chronic hepatitis B (CHB) patients. Methods: Transient elastography was performed in unselected CHB patients using Fibroscan (Echosens, France). Liver stiffness score of >8.1 kPa was used as a cut-off for the presence of severe fibrosis or liver cirrhosis. Demographics and laboratory parameters were recorded. Results: A total of 951 patients were recruited, of which 605 (64%) were males, with median age of 43 years, and positive HBeAg in 226 (24%). Overall 319 (34%) had severe fibrosis, with higher prevalence seen in males compared with females (39% vs 24% respectively, p<0.01). Severe fibrosis was seen with increasing age from 20% in patients < 25 years to 81% in those >65 years. In patients who were ≤ 45 years of age, there was no significant difference in prevalence of severe fibrosis between HBeAg-positive and HBeAg-negative patients. After the age of 45 years, higher prevalence of severe fibrosis was seen in HBeAg(+) patients compared to HBeAg(-) patients (58% vs 43% respectively, p=0.03). There was also increasing prevalence of severe fibrosis with increasing ALT levels: in patients with ALT less than 0.5 x upper limit of normal (ULN) and 0.5-1 x ULN 11% vs 30% respectively, p<0.01) and 0.5-1 x ULN and 1-2 x ULN (30% vs 48% respectively, p<0.01). There was a borderline significance in those with 1-2 x ULN and 2-5 x ULN (48% and 59% respectively, p=0.06) and no significant differences between those with ALT 2-5 x ULN and >5 x ULN. Higher prevalence of fibrosis was seen in patients with HBV DNA ≥4 log copies/ml compared to those below this level (41% vs 27% respectively, p<0.01). Using multivariate analysis by regression to determine factors associated with severe fibrosis, gender, age and ALT were significant factors (both p<0.001), whereas HBV DNA was not significant (p=0.25). In total there were 486 patients who had completely normal liver biochemistry with normal ALT levels, bilirubin ≤20 umol/L and albumin ≥40g/L. Of these, 89 (18%) had severe fibrosis. For those patients over the age of 45 years and with normal liver enzymes (n=211), 34% had underlying severe fibrosis. Conclusion: The overall prevalence of severe fibrosis in CHB patients was 34% with higher rates seen in older age groups, males, and in patients with higher ALT levels. There was a higher prevalence seen in male patients compared to female patients from age 36 to 55 years. Higher prevalence of fibrosis was also seen in HBeAg-positive patients compared to HBeAg-negative patients after the age of 45 years.

ANALYSIS OF FULL HEPATITIS B VIRUS GENOME IN PATIENTS WITH AND WITHOUT HEPATOCELLULAR CARCINOMA

Kaiyu Zhang, Fumio Imazeki, Kenichi Fukai, Keiichi Fujiwara, Makoto Arai, Yutaka Yonemitsu, Osamu Yokosuka; Chiba University, Chiba, Japan

Hepatitis B virus (HBV) genotype C and the basic core promoter (BCP) mutations were reported to be associated with the development of hepatocellular carcinoma (HCC). In this study the full sequences of HBV genomes were analyzed in order to find the other predictors of HCC development. Forty-four patients with HBsAg positive and HBV genotype C were studied. Among them, 24 cases developed HCC (HCC group) and the other 20 cases did not (non-HCC group) during the follow-up period. In the former 24 cases, the serum samples at the beginning of follow-up (HCC B) and at the detection of HCC (HCC A) were examined. In the latter 20 cases who did not develop HCC, the serum samples were obtained at the beginning of follow-up (non-HCC B) and at the end of observation period (non-HCC A). The two groups were matched in age, gender and follow-up time. All HBV sequences from serum samples were directly sequenced and compared with HBV X01587. HBV X promoter activity was examined using luciferase reporter assay. The nucleotide substitution rate in the full genome was 21.26±5.0×10⁻³/nt and 23.50±3.7×10⁻³/nt at the beginning of follow-up in the non-HCC group and HCC group, respectively (p=NS), and was 22.35±6.73×10⁻³/nt and 24.89±5.4×10⁻³/nt at the end of follow-up in the non-HCC group and HCC group, respectively (p=NS). More nucleotide and amino acid substitution rates were detected in the HCC group, compared with the non-HCC group. The substitution from G to A at nt 1317 in the X promoter was detected in 4 cases (20%) and 5 cases (25%) of 20 non-HCC B and non-HCC A cases, respectively, and in 14 cases (58.3%) and 15 cases (62.5%) of 24 HCC B and HCC A cases, respectively (non-HCC B vs HCC B, p=0.02; non-HCC A vs HCC A, p=0.02). The substitution from T to C/A/G at nt 1341 was detected in 3/2/1 cases (25%) and 3/3/1 cases (41.7%) of 24 HCC B and HCC A cases, while in none of 20 non-HCC B and non-HCC A cases (non-HCC B vs HCC B, p=0.03; non-HCC A vs HCC A, p=0.11). Pre-S2 deleted mutants were detected in B cases of 24 HCC B and 7 cases of 24 HCC A cases, respectively, while in none of the non-HCC group (HCC B vs non-HCC B, p<0.01; HCC A vs non-HCC A, p=0.01). We also examined the activity of HBV X promoter with mutations at nt 1317 and 1341 in comparison with that without mutations. The mutants at nt 1317 did not have any effect on the activity of X promoter, however, the mutants at nt 1341 from T to C/A/G resulted in 1.5, 2.3, 3.9 times increased X promoter activation, respectively. Substitutions and deletion of nucleotides of the HBV genome, especially the pre-S2 deletion and G1317A, T1341C/A/G mutations may be useful markers for predicting the development of HCC.

HEPATITIS B VIRUS INHIBITS TLR9-MEDIATED INTERFERON ALPHA SECRETION IN PLASMACYTOID DENDRITIC CELLS

Isabelle E. Vincent1, Uzma Hasan2, Julie Lucifora3, Christian Trepo1, Isabelle Chemin1; 1INSERM U871, Lyon, France; 2International agency for research on cancer/WHO, Lyon, France

Background and Aims: Hepatitis B virus (HBV) infection causes acute and chronic immunomodulated liver injury. Viral factors responsible for immune evasion and establishment of a persistant HBV infection remain unclear but in vivo studies highlight deficient innate responses to HBV. Plasmacytid dendritic cells (pDC) play a crucial role in innate immunity through their ability to secrete large amounts of type I interferons in response to viral pathogens in absence of active replication. Although still controversial, many studies do suggest a functional impairment of pDCs in chronic HBV infections, in both human and wood-
chucks. To investigate a direct role of HBV in this functional impairment, interactions between purified pDC and HBV particles were studied in vitro. Methods: For this purpose, HBV virions were purified using sucrose gradient from HepG2215 cells supernatants and viral load quantified by real time PCR. Interferon-alpha (IFN-α) and IL-6 secretions were determined by Elisa. Total PBMCs and purified pDCs were obtained from healthy blood donors and stimulated with oligonucleotides containing unmethylated deoxyxycytidyl-deoxyguanosine dinucleotides motifs (CpG) in the presence of HBV. Results/Discussion: Stimulation of pDC with HBV at MOI 10 to 1000 did not lead to any detectable levels of IFN-α and IL-6. When total PBMC and purified pDC were stimulated with CpG, secretion of IFN-α was reduced up to 40% by HBV. Inhibition was observed at 24 and 48h post-CpG stimulation and already detectable after 9h. Such an early inhibition suggest that mechanisms other than active viral replication are responsible for pDC dysfunction, consistent with studies suggesting an endocytosis mechanisms for HBV entry within DCs as opposed to an infection process. Contrary to the INF-α inhibition, the capacity of total PBMC to secrete Il6 was unchanged in presence of HBV. Conclusion: Overall, these findings do suggest that HBV alone is not recognized by pDC as a foreign "signal" and therefore fails to trigger this key component of innate immunity. This extent to which this pDC dysfunction plays a role in the outcome and immunopathogenesis of HBV infection warrants further studies.

TRACING HEPATITIS B VIRUS DNA BACK TO THE 16TH CENTURY IN A KOREAN MUMMY
Athalia Klein1, Mark Spigelman2, Paul Grant3, Orit Pappo4, Myung-ju Kim5, Dong Hoon Shin6, Daniel Shouval1; 1Liver Unit, Hadassah Univ Hospital, Jerusalem, Israel; 2Kuwin Center, Hebrew University, Jerusalem, Israel; 3Virology, University College London NHS Trust, London, United Kingdom; 4Pathology, Hadassah Hospital, Jerusalem, Israel; 5Anatomy and Radiology, Dankook University College of Medicine, Chonan, South Korea; 6Anatomy, Seoul National University College of Medicine, Seoul, South Korea

Background and Aims: It is presumed that Hepatitis B virus (HBV) has infected humans for thousands of years, but precise evidence is lacking. Korea is a country with endemic hepatitis B. A rare find of a "naturally" mummified child from the 16th century AD, in Korea, with a relatively preserved liver, enabled testing for the presence of HBV-DNA sequences. Methods: Despite the age of the mummy (verified by C14 testing of cloths from intra abdominal tissue), a parenccymatous organ was identified in the right upper abdominal quadrant by laparoscopy. Tissue samples were subjected to conventional microscopy and DNA extraction. A search for ancient HBV-DNA was conducted in three independent laboratories in Korea, UK and Israel. Pre-core, core and DNA polymerase sequences were analyzed in Jerusalem; DNA contamination was destroyed in liver tissue by laparoscopy by incubation in a fresh bleach solution. HBV DNA was extracted twice, using in-house guanidium thiocyanate or a commercial columns kit. PCR amplification and analysis of the pre C/C region was performed using a HBV Monitor kit (Roche). An HBV Genotyping kit (INNogenetics) was used for analysis of the polymerase gene Results: A 104 bp fragment from the preC/C region was amplified in Jerusalem and the genotype was determined by analysis of a 234 bp fragment from the polymerase gene. The genotype was confirmed by amplifying and sequencing a 239bp fragment from the core gene by the Korean team. A 98bp fragment from the S gene was amplified in London. These results confirm the presence HBV-DNA sequences, genotype C in material removed from the mummy. removed from the mummy. The tissue tested was also subjected to microscopic analysis. Although, as expected, no hepatic or lymphoid cells could be identified on H&E staining, the overall organization resembled the appearance of liver tissue. The architecture, as demonstrated by Masson trichrome and reticulin stains, appeared normal overall, with minimal fibrotic expansion of the portal tracts and condensation of the sinusoidal walls, as expected after the lysis of hepatocytes. Conclusion: Extraction of DNA from the a liver remnant of a 500 year old Korean mummy revealed evidence for presence of intrahepatic HBV-DNA. No statement can be made regarding the stage of HBV infection in this child presumed to be an HBsAg carrier. Other evidence obtained suggest that the child died of tuberculosis based on identification of mycobacterium tuberculosis sequences in nodules removed from intra abdominal tissue.

EFFECT OF ANTIVIRAL THERAPY ON THE IMMUNOHISTOCHEMICAL EXPRESSION OF BCL-XL AND BAX PROTEIN IN PATIENTS WITH HBEAG-NEGATIVE CHRONIC HEPATITIS B
Evangelos Chologantas1, George V. Papatheodoridis1, Emanuel K. Manessis1, Kalipoi Petroki1, Stephanos J. Hadzijanniss1; 12nd Department of Internal Medicine, Hippokration General Hospital, Athens, Greece; 2Department of Medicine and Hepatology, Henry Dunant Hospital, Athens, Greece

BACKGROUND: Although increasing evidence suggest that apoptosis of hepatocytes plays an important role in the initiation of liver injury/carcinogenesis, the exact role of antiviral therapy in apoptosis has never been investigated. AIMS: To evaluate the immunohistochemical expression of anti-apoptotic bcl-xl and pro-apoptotic bax proteins in hepatocytes of patients with HBeAg-negative chronic hepatitis B (CHBe-) before and after treatment. MATERIAL AND METHODS: Thirty six paired liver biopsies from CHBe- patients: between the 1st and 2nd biopsy, 29 patients received 12-month courses of antiviral therapy (interferon-alpha: 17, ade-fovir: 12) and 7 untreated patients were used as controls. In each pair of biopsies, changes in expression of apoptotic proteins (D-bcl-xL and D-bax), total apoptotic trend (D-apoptosis: difference between D-bcl-xL and D-bax), necroinflammation (D-grade) and fibrosis (D-stage) (using the Ishak score) were evaluated. RESULTS: Bax-positive compared to Bax-negative biopsies had significantly worse necroinflammation (8.2 vs 6.7, p=0.05) and fibrosis score (3.9 vs 3, p=0.036). Bcl-xL-positive compared to bcl-xl-positive biopsies had significantly lower intra lobular inflammation (1.6 vs 2.2, p=0.03). Negative, compared to stable/positive D-bax from 1st to 2nd biopsy, was associated with significantly greater improvement in necroinflammation only in treated patients (mean D-grade : 4.6 vs -1.6, p=0.06) and improvement in fibrosis in the interferon treated patients (D-stage: -0.4 vs 0.55, p=0.05). Stable/decreased compared to increased D-apoptosis was associated with significantly worsen fibrosis, particularly in patients treated with adefovir (D-stage: 2.3 vs 0, p=0.004). In the 11 patients without significant changes from 1st to 2nd biopsy (D-stage ≤1 and D-grade ≤2), positive D-apoptosis was significant more frequent in treated than untreated control
The following people have nothing to disclose: Masaya Sugiyama, Yasuhito and liver damage in vivo, which might be associated with Precore mutation of Bj could induce high replication types demonstrated in chimeric mice may influence HBV infection. Conclusion: Virological differences among HBV genotypes, while HBsAg was expressed at the highest level in HBV/Ae. The protein production of Bj_PCm transiently were expressed in a trend similar to HBV DNA levels among were expressed in a trend similar to HBV DNA levels among. HBcrAg in serum was measured by real-time detection PCR among HBV genotypes in vivo. Methods: Sera of six HBV carriers [three each for Bj_wild-type (from acute HB patients) and Bj_PCm (fulminant HB patients)] were prepared. The sera or virions of HBV recovered from culture media, that were produced by transfection with plasmids (3 strains each for Ae, Ce, Bj_wild-type and Bj_PCm) carrying 1.24-fold the HBV genome in Huh7 cells, were inoculated into uPA/SCID mice with the liver replaced by human hepatocytes (chimeric mice). HBV DNA in mice serum was measured by real-time detection PCR weekly and then histopathologic changes of liver were examined with H.E, Masson trichrome, Orcein stainings, and immunostaining using anti alpha-smooth muscle actin (alpha-SMA) antibody. Results: The replication efficiency in chimeric mice was the highest in HBV/C and Bj_PCm, followed by Ae (P<0.05). HBV DNA levels of Bj_wild-type were extremely lower than the others by 4 log levels. To exclude the possibility that immature virus particles were produced in culture media, sera of 6 HBV carriers with Bj_wild-type or Bj_PCm were inoculated with chimeric mice. The HBV DNA levels in mice serum were similar to those by injection of culture media. HBcrAg in serum were expressed in a trend similar to HBV DNA levels among HBV genotypes, while HBsAg was expressed at the highest level in HBV/Ae. The protein production of Bj_PCm transiently increased and peaked in earlier phase. Based on histopathologic examinations, chimeric mice inoculated with HBV/C or Bj_PCm for 6 months showed that human hepatocytes had somewhat ground-glass appearance and hepatic fibrosis, while chimeric mice inoculated with HBV/Ae or Bj_wild-type were not induced. Conclusion: Virological differences among HBV genotypes demonstrated in chimeric mice may influence HBV infections with distinct genotypes in clinical and epidemiological settings. Precore mutation of Bj could induce high replication and liver damage in vivo, which might be associated with development of fulminant hepatitis.

927 DIFFERENCES OF EARLY DYNAMICS AND LIVER DAMAGE AMONG HEPATITIS B VIRUS GENOTYPES IN UPA/SCID MICE WITH HUMAN HEPATOCYTES

Masaya Sugiyama1, Yasuhito Tanaka1, Isao Maruyama2, Takashi Shimada2, Masashi Mizokami1; 1Nagoya city university, Nagoya, Japan; 2PhoeniBio Co., Ltd., Higashi-Hiroshima, Japan

Background: Hepatitis B virus (HBV) genotypes/subgenotypes indicate different clinical features, i.e. genotype C is associated with hepatocellular carcinoma and Bj with precore mutation (PCm) is associated with fulminant hepatitis. We previously showed the difference of each genotype in vitro and partially in vivo. Aim: Our purpose of this study is to investigate the differences of viral replication, protein production and liver damage among HBV genotypes in vivo. Methods: Sera of six HBV carriers (three each for Bj_wild-type [from acute HB patients] and Bj_PCm [fulminant HB patients]) were prepared. The sera or virions of HBV recovered from culture media, that were produced by transfection with plasmids (3 strains each for Ae, Ce, Bj_wild-type and Bj_PCm) carrying 1.24-fold the HBV genome in Huh7 cells, were inoculated into uPA/SCID mice with the liver replaced by human hepatocytes (chimeric mice). HBV DNA in mice serum was measured by real-time detection PCR weekly and then histopathologic changes of liver were examined with H.E, Masson trichrome, Orcein stainings, and immunostaining using anti alpha-smooth muscle actin (alpha-SMA) antibody. Results: The replication efficiency in chimeric mice was the highest in HBV/C and Bj_PCm, followed by Ae (P<0.05). HBV DNA levels of Bj_wild-type were extremely lower than the others by 4 log levels. To exclude the possibility that immature virus particles were produced in culture media, sera of 6 HBV carriers with Bj_wild-type or Bj_PCm were inoculated with chimeric mice. The HBV DNA levels in mice serum were similar to those by injection of culture media. HBcrAg in serum were expressed in a trend similar to HBV DNA levels among HBV genotypes, while HBsAg was expressed at the highest level in HBV/Ae. The protein production of Bj_PCm transiently increased and peaked in earlier phase. Based on histopathologic examinations, chimeric mice inoculated with HBV/C or Bj_PCm for 6 months showed that human hepatocytes had somewhat ground-glass appearance and hepatic fibrosis, while chimeric mice inoculated with HBV/Ae or Bj_wild-type were not induced. Conclusion: Virological differences among HBV genotypes demonstrated in chimeric mice may influence HBV infections with distinct genotypes in clinical and epidemiological settings. Precore mutation of Bj could induce high replication and liver damage in vivo, which might be associated with development of fulminant hepatitis.

928 GENDER DIFFERENCE IN THE NATURAL COURSE OF HBEAG-POSITIVE CHRONIC HEPATITIS B

Elaine Y. Lin1, Yi-Cheng Chen1, Shiu-Feng Huang2, Chau-Ting Yeh1, Yun-Fan Liaw1; 1Liver Research Unit, Chang Gung Memorial Hospital & Chang Gung University, Taipei, Taiwan; 2Division of Molecular and Genomic Medicine, National Health Research Institutes, Miaoli, Taiwan

PURPOSE: Cross-sectional age-specific seroprevalence studies from Taiwan have provided evidence to suggest that male patients have earlier spontaneous hepatitis B e antigen (HBcAg) seroconversion but, paradoxically, bear a worse prognosis in disease progression when compared to their female counterparts. On the other hand, recent studies have shown that patients infected with genotype B hepatitis B virus (HBV) have earlier HBcAg seroconversion and better prognosis than genotype C infected patients. This longitudinal study was conducted to clarify this gender-related paradox while taking account the HBV genotype factor. METHODS: HBcAg seropositive patients from 1977 to 1998 were recruited if they met the following criteria: (1) Histologic and biochemical confirmation of chronic hepatitis B; (2) Follow-up every 3-6 months and ≥ 2 years; (3) No concomitant hepatitis C or D virus infection; (4) No drug treatment during follow-up. The clinical course and biochemical/serological changes were compared between male and female patients using t test, X² and Kaplan-Meir survival analysis. RESULTS: There were 454 males and 110 females who met our entry criteria. The age, baseline serum alanine aminotransferase (ALT) level and HBV genotype distribution were comparable between male and female patients. During a mean follow-up period of 12 years, there was no significant difference in the timing and the cumulative incidence of spontaneous HBcAg seroconversion between male and female patients (97.6 vs 100%; P=0.915). To minimize the influence of other confounding factors, the 110 female patients were compared with a 1:1 group of male patients well matched for age (± 2 years), baseline ALT (± 20 U/L) and duration of follow-up (± 1 year). The HBV genotype distribution in the female and the matched male patients was comparable (P=0.864). There was no significant difference in the incidence of hepatitis flare with ALT over 5 times the upper limit of normal (66.4 vs 72.5%; P=0.326) and in the 12-year cumulative incidence of HBcAg seroconversion (85.5 vs 74.4%; P=0.129). However, 47.7% of the male patients showed persistent ALT elevation, with or without ALT flare, in contrast to 14.5% of the female patients (P<0.0001). CONCLUSION: This longitudinal study showed that there was no difference in the occurrence of hepatitis flare and spontaneous HBcAg seroconversion between males and females with active chronic hepatitis B. Male patients were found to have a higher propensity for persistent ALT elevation, which may be responsible for a more progressive course.

BOW BODY MASS INDEX (BMI) PREDICTS DISCORDANCE BETWEEN TRANSIENT ELASTOGRAPHY (TE) AND LIVER BIOPSY (LB) ASSESSMENT OF LIVER FIBROSIS

Mirella Fraquelli1, Cristina Rigamonti2, Giovanni Casazza3, Maria Francesca Donato2, Dario Conte1, Maria Grazia Rumi2, Pietro Lampertico2, Guido Ronchi2, Massimo Colombo2; 1II Division of Gastroenterology, Fondazione IRCCS Ospedale Policlinico, Milan, Italy; 2I Division of Gastroenterology, Fondazione IRCCS Ospedale Policlinico, Milan, Italy; 3Dept of Statistic and Biometry, University of Milan, Milan, Italy

Background and aim. In patients with chronic liver disease (CLD) liver fibrosis stage can be accurately predicted by TE. Variables associated with discordant results between TE and LB need to be defined. Methods. All consecutive patients with CLD who underwent percutaneous LB for diagnostic/therapeutic purposes were concurrently examined by TE (FibroScan®). Echo-sens, Paris, France). Grading (A) and staging (F) were assessed by METAVIR score. Steatosis was arbitrarily graded from 0 to 3 (0<5%, 1=5-24%; 2=25-50%; 3=50% of fatty hepatocytes). Only TE examinations with at least 10 validated measurements and a success rate of at least 60% were considered adequate. Statistical analysis. Determinants of TE stiffness value (log transformed) were investigated by the multiple linear regression model and variables possibly influencing discordance between TE and LB by a logistic regression model. The variables included in the models were: gender; age; body mass index (BMI, kg/m2) (<19 vs 19-25 vs 26-30 vs >30 kg/m2); etiology; AST, ALT and GGT levels (<1.5 vs 2-3 vs >3 ULN), APRI score (<0.5 vs 0.5-1 vs >1), steatosis (0-1 vs 2; 2 vs 3); A (0-1 vs 1-4) and F; LB specimen length (≤20 vs >20 mm). Discordance was the lack of correspondence between the METAVIR F and TE diagnostic cut off (7.9, 10.3 and 11.9 kPa for F=2, F=3 and F=4, respectively) identified in a previous cohort. Results: 303 males and 257 females (50±12 years) were studied. TE examination failed in 30 (5%) mainly due to high BMI. In four cases (0.7%) LB was inadequate as shorter than 15 mm or contained <11 portal spaces. By multivariate analysis, fibrosis stage (p=0.0001), BMI (p=0.0004), etiology (p=0.02), GGT (p=0.0001), APRI score (p=0.0001) and A (p=0.0001) were significantly related to TE values. TE and LB were discordant in 116 cases (22%) for the diagnosis of F=2 and in 85 (16%) for the diagnosis of F=3. The probability of discordance was positively associated with BMI (BMI<19 vs 19-25, OR=3.2, 95%CI 1.3-7.8 for F=2; OR=4.9, 95%CI 2.0-11.8 for F=3). Conclusion: In the face of many factors other than fibrosis influencing TE results, low BMI was the only predictor of discordance between TE results and LB.

RAPID IMPROVEMENT OF INNATE IMMUNE RESPONSES AND MONOCYTE TOLL-LIKE RECEPTOR-2 (TLR2) EXPRESSION DURING LAMIVUDINE AND PEGYLATED INTERFERON THERAPY FOR CHRONIC HEPATITIS B (CHB)

Kumar Visvanathan1, Narelle Skinner1, Alex J. Thompson3,2, Paul V. Desmond2, William Abbott4, Ed Gane4, Stephen Locarnini2; 1Medicine, Monash University, Clayton, VIC, Australia; 2VIDRL, Melbourne, VIC, Australia; 3Gastroenterology, St. Vincent’s Hospital, Fitzroy, VIC, Australia; 4NZ Liver Transplant Unit, Auckland, New Zealand

Background/Aims: Toll-like receptors (TLR’s) are critical receptors that promote innate immune responses to pathogen-associated molecular patterns. Activation of TLR’s leads to production of pro-inflammatory cytokines. We have previously demonstrated that patients with HBeAg positive CHB have suppressed TLR2 expression on peripheral monocytes and hepatocytes associated with decreased pro-inflammatory cytokine expression. Methods and Patients: The TLR2 and TLR4 expression on peripheral blood monocytes was measured from 21 patients with untreated HBeAg-positive and HBeAg-negative CHB and 10 uninfected control patients. These 21 patients were treated with lamivudine 100mg daily. Individual patient blood was stimulated with specific TLR ligands and the resultant supernatant was assayed for TNF-α and IL-6 by ELISA. In addition serum HBeAg was measured by enzyme immunoassay. Similar data was also obtained for 20 HBeAg positive patients treated with pegylated interferon Results: Expression of TLR2 on peripheral monocytes was significantly reduced in patients with HBeAg-positive CHB in comparison to HBeAg-negative CHB and to controls whilst it was significantly increased in HBeAg-negative CHB compared to controls (P=0.001). TLR2 levels increased within four weeks of effective therapy in HBeAg-positive patients (P<0.05) whilst remaining stable in HBeAg negative patients. The level of TLR4 expression did not differ significantly between the groups. The functional relevance of these findings was established by the demonstration in HBeAg positive patients of initial reduced TNF-α and IL-6 and phospho-p38 kinase production after stimulation of monocytes with specific TLR ligands. This immunosuppression improved rapidly during treatment (P<0.05). In HBeAg negative patients innate immune responses were initially increased but normalized with therapy. In the HBeAg positive patients treated with pegylated interferon TLR2 expression was further suppressed at 4 weeks (P<0.05) before improving over subsequent months. Cytokine production secondary to stimulation with Pam-3-Cys and LPS were markedly increased at week 4, dropping dramatically thereafter (P<0.05). Correlations of these results with HBV viral load and eAg levels (eAg positive patients) will also be presented. Conclusions: This is the first study to investigate how peripheral innate immune responses and TLR expression changes with different therapies. It demonstrates a potentially important interaction between HBeAg, HBV and the innate immune response and suggests that TLR2 expression and activation could represent a sensitive new biomarker in the treatment of HBeAg-positive CHB.

931 DIFFERENTIAL EXPRESSION OF HEPATIC APURINIC/APYRIMIDINIC ENDONUCLEASE 1, A DNA REPAIR ENZYME, IN CHRONIC HEPATITIS B VIRUS AND HEPATITIS C VIRUS INFECTION

Shinichi Sumiyoshi, Yoshimasa Kobayashi, Kenichi Souda, Kinya Kawamura, Kazuhito Kawata, Yurimi Takahashi, Satetsu Makino, Hidenao Noritake, Hirotsahi Nakamura; Internal Medicine, Hama-matsu University School of Medicine, Hamamatsu, Japan

Background: Hepatocellular carcinoma (HCC) is frequently encountered in chronic hepatitis B virus (HBV) or hepatitis C virus (HCV) infection, while HCC rarely develops in autoimmune hepatitis (AIH) and primary biliary cirrhosis (PBC). However, the mechanisms responsible for HBV- or HCV-mediated hepatocarcinogenesis have not been fully clarified, yet. Cellular DNA damage can lead to mutation induction and subsequent carcinogenesis if DNA repair processes are not completely effective. Apurinic/apyrimidinic endonuclease 1 (APE-1; also designated Ref-1) is one of the major DNA repair enzymes, and its altered expression is associated with tumorigenesis. Therefore, APE-1/Ref-1 may be involved in HBV- or HCV-mediated hepatocarcinogenesis. The aim of the present study was to examine hepatic expression of APE-1/Ref-1 in patients with chronic HBV or HCV infection, compared with those with AIH or PBC. Methods: Liver biopsies were obtained from 14 patients with chronic hepatitis B, 10 patients with chronic hepatitis C, 5 patients with AIH and 5 patients with PBC. APE-1/Ref-1 expression was assayed by Western blot or real time-PCR, and its distribution was determined by immunohistochemistry. Results: APE-1/Ref-1 protein levels were reduced by 64% in HBV-infected livers compared with AIH and PBC livers, while HCV livers had no significant difference in APE-1/Ref-1 protein levels compared with those of autoimmune chronic liver diseases. APE-1/Ref-1 mRNA levels were reduced by 58% in HBV livers compared with HCV livers. APE-1/Ref-1 had a predominant nuclear localization in the majority of hepatocytes with a panacinar distribution in all of the liver specimens. The hepatocytic nuclear APE-1/Ref-1 expression was also reduced in the HBV group. Conclusions: Patients with chronic HBV infection, not chronic HCV infection, showed reduced expression of hepatic APE-1/Ref-1 compared with those with autoimmune chronic liver diseases. Hepatic APE-1/Ref-1 expression may undergo differential regulation in chronic HBV and HCV infection. Downregulation of hepatic APE-1/Ref-1 expression may contribute to the development of HCC in chronic HBV infection.

932 GENETIC POLYMORPHISMS AT THE APOLPOLYPEPTIDE E LOCUS AFFECT THE OUTCOME OF CHRONIC HEPATITIS B

Davide Bitetto1, Rosalba Minisini2, Carlo Fabris1, Michela Burlone3, Stefano Fangazio3, Edmondo Falletti1, Carlo Smirne, Pierluigi Tonitucci4, Giovanna Fattovich4, Mario Pirisi5; 1Medical Liver Transplant Unit, Azienda Ospedaliero-Universitaria, Udine, Italy; 2DLMCeS, University of Eastern Piedmont, Novara, Italy; 3Dpt of Surgical and Gastroenterological Sciences, Verona, Italy

Introduction. Genetic variations at the apolipoprotein E (ApoE) locus are known to affect plasma lipoprotein concentrations; therefore, by modulating transport into the blood circulation and entry into the hepatocytes of hepatitis B virus (HBV), they may influence the course of HBV infection. The present study aimed to verify this hypothesis. Methods. One-hundred five HBV positive, HCV negative patients (74 males, 31 females, median age 51 years, range 22-84) were studied. Among them, a cohort of 62 patients (42 males, 20 females, median age 51 years, range 2-81) had undergone periodical clinical monitoring for a median time of approximately 20 years since first identified as HBsAg carriers. ApoE genotypes were determined by a previously described polymerase chain reaction/restriction length fragment polymorphism method. Results. Twenty-seven patients out of 105 (26%) fulfilled criteria for being inactive HBV carriers, whereas 61 had chronic hepatitis B (58%; 15 with cirrhosis) and 17 had undergone liver transplantation for hepatic failure and/or hepatocellular carcinoma (16%). The allelic frequencies of the ApoE gene were the following: ApoE2 = 15%; ApoE3 = 78%; ApoE4 = 7%. There was a strong linear trend for E3 homozygotes to be progressively overrepresented among patients with liver disease of advancing severity: E3/E3 were 13/27 (48%) among inactive HBV carriers, 36/61 (59%) among patients with chronic hepatitis B, and 16/17 (94%) among patients transplanted for hepatitis B-related sequelae (p<0.005). In the longitudinal cohort, 12/62 patients (19%) became HBsAg negative after a median follow-up time of 14.6 years (range, 1.5-32.3). Being an E3/* carrier was associated with significantly lower probability of losing HBsAg (95/56, 16% vs. 3/6, 50%, p<0.05), as well as significantly longer time to HBsAg loss (p<0.03 by Mantel-Cox test). Conclusions. The probability of undergoing disease progression is higher, and that of remaining inactive carriers or of losing HBsAg is lower among possessors of the ApoE3 allelic variant. Down-regulation and/or reduced binding involving the LDL-receptor might explain the more benign course of hepatitis B among ApoE2-E4 carriers.

933 PREDICTIVE MODEL FOR FIBROSIS AND CIRRHOSIS IN CHRONIC HEPATITIS B USING LIVER STIFFNESS MEASUREMENT

James Fung, Ching Lung Lai, Daniel Fong, John Yuen, Danny Wong, Man-Fung Yuen; University of Hong Kong, Hong Kong, China

Aim: To correlate liver stiffness measurements with demographic and laboratory parameters, and assess the predictive value of these parameters as non-invasive markers of fibrosis and cirrhosis in chronic hepatitis B (CHB). Methods: Transient elastography was performed in 265 CHB patients using Fibroscan (Echosens, France). Liver stiffness scores of >8.1 and >10.3 kPa were used as cut-off values for significant fibrosis and cirrhosis, respectively. To derive a new index using commonly measured laboratory markers, the study sample was randomly split into a training set and a validation set. Results: Of the 265 patients, 170(64%) were male. Ninety-six patients (36%) were HBsAg-positive, and 90 patients (34%) had severe fibrosis or cirrhosis. The median liver stiffness score was 6.3 kPa (range, 3.0 to 56.3). Liver stiffness correlated positively with ALT, bilirubin and AFP, and negatively with albumin levels. Using 13 parameters (age, sex, platelet, AST, ALT, GGT, AFP, albumin, globulin, bilirubin, ALT, HBV DNA, and HBeAg), the sequence of variables in order of their associations with liver stiffness (co-effi-
HBV DNA at the end of therapy [mean ± SEM 4.31 ± 1.25 vs. 8.31 ± 0.87 log10 copies/ml respectively, p=0.04] in patients with SVR was lower when compared with those without SVR. Similarly, those with SVR had a higher, though insignificant IL-17 at the end of therapy [mean ± SEM 2.13±0.08 vs. 1.73±0.48 % respectively, p=0.47] and end of follow-up [mean ± SEM 2.57±0.28 vs. 2.35±0.74 % respectively, p=0.79] when compared with patients without SVR. Conclusion: Pegylated interferon alfa-2a induced viral load reduction results in an increase in IL-17. SVR may be associated with a higher IL-17. The role of IL-17 in CHB infection and immunopathogenesis requires further investigation.

934 INHIBITION OF VIRAL REPLICATION WITH PEGYLATED INTERFERON ALFA-2A INCREASES IL-17 IN CHRONIC HEPATITIS B

Hai-ying Zhang, Jian Li, Chee-Kin Hui, Kwok-fan Cheung, Yui-Hung Yueng, Kan Leung, Lei Lu, George K. Lau; the university of hong kong, Hong Kong, China

Background and Aim: Interleukin (IL)-17 is produced mainly by activated CD4+ T cells, currently known as Th17. Chronic hepatitis B (CHB) infection is associated with weak and narrowly focused immune response with low CD4+ and CD8+ activity. This is the first report of IL-17 in CHB infection. We assessed IL-17 expression in the CD4+ T cells (Th17) of 50 consecutive CHB patients treated with pegylated interferon alfa-2a for 48 weeks.

Methods: Peripheral blood mononuclear cells (PBMC) were stained with CD45, CD4, IL-17 and analyzed by three-color flow cytometry. PBMC of 8 hepatitis B e antigen (HBeAg) positive patients; 4 with sustained virological response (SVR) and 4 without SVR; were collected every 4 weeks during treatment until end of therapy (week 48) and every 12 weeks until the end of follow-up (week 72). Serum HBV DNA was quantified by quantitative PCR with a linear range of 100 to 109 copies/ml. SVR was defined as HBeAg seroconversion with serum HBV DNA < 104 copies/ml at the end of follow-up. HBeAg seroconversion was defined as HBeAg negativity with hepatitis B e antibody on 2 consecutive occasions 3 months apart. IL-17 was defined as CD4+IL-17+ cells/CD45+ cells.

Results: In parallel with decline in serum HBV DNA, we found an increase in IL-17 at the end of follow-up when compared with baseline [mean±standard error of mean (SEM) 2.46±0.37 vs. 1.44±0.23 % respectively, p=0.03]. There was a trend that IL-17 at the end of therapy was also higher than at baseline [mean±SEM 1.93±0.23 % respectively, p=0.05]. The serum HBV DNA at the end of therapy [mean±SEM 3.10±0.59 vs. 5.41±0.49 log10 copies/ml respectively, p=0.04] and end of follow-up [mean±SEM 4.31±1.25 vs. 8.31±0.87 log10 copies/ml respectively, p=0.04] in patients with SVR was lower when compared with those without SVR. Similarly, those with SVR had a higher, though insignificant IL-17 at the end of therapy [mean±SEM 2.13±0.08 vs. 1.73±0.48 % respectively, p=0.47] and end of follow-up [mean±SEM 2.57±0.28 vs. 2.35±0.74 % respectively, p=0.79] when compared with patients without SVR. Conclusion: Pegylated interferon alfa-2a induced viral load reduction results in an increase in IL-17. SVR may be associated with a higher IL-17. The role of IL-17 in CHB infection and immunopathogenesis requires further investigation.

DNA in serum (P<0.005). Conclusion: (1) HBV cccDNA and pgRNA were undetectable in the serum of CHB patients; (2) HBV viral loads in PBMC were associated with the serum HBV DNA; (3) Lamivudine therapy had less effect on the HBV viral loads in PBMC compared with the serum viral loads. The inefficiency of antiviral therapy on PBMC viral loads may relate with the HBV persistence.

936
PREDICTORS OF SIGNIFICANT HISTOLOGICAL FINDINGS IN CHRONIC HEPATITIS B PATIENTS WITH PERSISTENTLY NORMAL ALT LEVELS
Honglian Gui, Qing Xie, Hui Wang, Zhimei Lin, Wei Cai, Xiaqiou Zhou, Hong Yu, Qing Guo; Department of Infectious Disease, Ruijin Hospital, Shanghai Jiaotong University school of medicine, Shanghai, China

Background/aim: Current guidelines recommend antiviral therapy for chronic hepatitis B (CHB) patients with elevated ALT and high viral load. Little histological data exists for patients with persistently normal ALT levels (PNAL) and/or significant fibrosis Ishak's staged at 3 or greater) in such patients. Methods: The study of all patients with CHB who underwent percutaneous liver biopsy and who had detectable viral load (Taqman Real Time PCR, lower limit of detection is 10^3 copies/ml) was performed. 139 patients who had PNAL and/or significant fibrosis were identified. The aim of the study is to find the predictors of significant histological findings (significant necroinflammation with a score of HAI 4 or greater and/or significant fibrosis Ishak's staged at 3 or greater) in such patients. Methods: The study of all patients with CHB who underwent percutaneous liver biopsy and who had detectable viral load (Taqman Real Time PCR, lower limit of detection is 10^3 copies/ml) was performed. 139 patients who had PNAL (defined as normal ALT measured on at least 3 occasions in the intervals of more than two months over a period of 12 or more months apart prior to biopsy) were identified (group A). These patients were compared with 135 patients with abnormal ALT during the same period and who had no prior antiviral treatment. The comparisons included age, ALT, viral load, HBeAg status, and histological finding. Results: The ALT values of all 139 patients with PNAL had been normal from one year to thirty years, and the median was six years. Even though 66 (47.5%) patients with PNAL had normal liver histology, 33 (23.7%) patients were found to have significant histological findings, even 13 (9.4%) had established cirrhosis. When compared to patients within 0–0.75 × ULN ALT, patients within 0.75–1 × ULN ALT had higher rate of significant histological findings (43.5% vs. 19.8%, p=0.029). In the subgroup of patients with PNAL, significant histological findings increased sharply after the age of 40 yrs as seen in other cohorts (p=0.005). However, the subgroup of patients with PNAL and significant histological findings was not identified by viral load or HBeAg status. Conclusions: 23.7% of CHB patients with PNAL regardless of HBeAg status or viral load levels had significant histological findings including inflammation and fibrosis. Liver biopsy should be considered in CHB patients with PNAL and detectable viral load, even IFL, especially in those older than age 40 yrs and higher ALT within 0.75–1 × ULN.

937 TREATMENT-INDUCED HBeAg SEROCONVERSION IS A POOR THERAPEUTIC ENDPOINT
Seng Gee Lim1,2, Aung Myat Oo2, Shanthi Wasser3; 1Gastroenterology and hepatology, National University Hospital, Singapore, Singapore; 2Immunovirology, BMSI, A*STAR, Singapore, Singapore; 3Medicine, Yong Loo Lin School of Medicine, NUS, Singapore, Singapore

INTRODUCTION HBeAg seroconversion is considered a key therapeutic endpoint of Chronic Hepatitis B treatment, but its effectiveness as an endpoint is compromised by HBeAg negative reactivation and its durability, consequently we sought to examine these events in patients with well documented spontaneous or treatment induced HBeAg seroconversion. METHODS All patients with documented HBeAg seroconversion were followed prospectively at 3-monthly intervals. Persistent reactivation was defined as return of HBeAg with or without loss of anti-HBe, after loss of HBeAg and development of anti-HBe. The outcome events of reactivation and seroreversion were compared in spontaneous and treatment induced seroconversion using Kaplan-Meier survival analysis and Cox Regression. Data is presented as median (range). RESULTS There were 298 patients with documented seroconversion, of which 116 patients were treatment-induced and 182 were spontaneous. The patients were mainly male (71.81%), with age of 34.81 (68.7) years, with follow up duration of 39.29 (188.03) months post-seroconversion. Persistent reactivation occurred in 71 patients (Cumulative proportion=39.27%), with older age (P=0.001), male gender (P=0.002), higher ALT at seroconversion (P=0.006) being more likely to develop reactivation. No significant difference rate of reactivation was observed among different treatment groups (IFN, lamivudine & adefovir) (P=0.598). Treatment-induced seroconversion was less robust and remission of ALT was of shorter duration than spontaneous seroconverters (median 14.13 months versus 22.44 months, P=0.037). They were also more likely to develop HBeAg negative reactivation at 48 months (37.76% versus 24.96%, P=0.0482). Treatment responders are more likely to develop reactivation after adjusting for age, gender and ALT with Cox regression (Adjusted cumulative proportion: 48.5% versus 34.0% at 96 months, P=0.045). HBeAg reversion occurred in 39 patients (19.64%). Again, treatment induced seroconverters are more likely to get HBeAg reversion than spontaneous seroconverters: 24.09% versus 11.29% at 48 months (P=0.0094). After adjusting for age, gender, and ALT at seroconversion by Cox regression, the difference is consistent (P=0.010). CONCLUSION The effectiveness of treatment induced seroconversion is significantly worse than that of spontaneous seroconverters with significantly higher and faster HBeAg negative reactivation rate with less durable seroconversion over time. Treatment induced seroconversion may not be a good therapeutic endpoint in the treatment of chronic hepatitis B.

FOUR-YEAR ENTECAVIR TREATMENT IN NUCLEOSIDE-NAIVE HBeAg(+) PATIENTS: RESULTS FROM STUDIES ETV-022 AND -901

Steven Han¹, Ting-Tsun Chang², You-Chen Chao³, Seung-Kew Yoon⁴, Robert G. Gish⁵, Hugo Cheinquer⁶, Flair Jose Carrillo⁷, Hui Zhang⁸, Helena Brett-Smith⁹, Robert Hindes⁸; ¹Division of Digestive Disease, UCLA School Of Medicine, Los Angeles, CA; ²National Cheng Kung University Medical College, Tainan, Taiwan; ³Tri-Service General Hospital, Taipei, Taiwan; ⁴Kangnam St. Mary’s Hospital, Soeul, South Korea; ⁵California Pacific Medical Center, San Francisco, CA; ⁶Universidade Federal Do Rio Grande Do Sul, Porto Alegre, Brazil; ⁷Department of Gastroenterology, University of São Paulo School of Medicine, Sao Paulo, Brazil; ⁸Bristol-Myers Squibb Pharmaceutical Research Institute, Wallingford, CT

Background: Entecavir (ETV) 0.5 mg demonstrated superior virologic suppression compared to lamivudine (LVD) 100 mg in study ETV-022¹. One hundred and eighty-three entecavir-treated patients from ETV-022 enrolled in rlover study ETV-901. We present efficacy and safety results in a cohort of patients from ETV studies -022 and -901 who received a total of 4 years of therapy with ETV.

Methods: The nucleoside-naive HBeAg(+) 4-year cohort consists of ETV patients who completed ETV-022 and enrolled into ETV-901 with a treatment gap ≤35 days. In ETV-901, patients were treated with 1 mg of ETV. The proportions of patients with HBV DNA <300 copies/mL by PCR assay, ALT normalization, HBeAg loss and HBeAg seroconversion were evaluated among patients with available samples at week-192. Results: The nucleoside-naive HBeAg(+) 4-year ETV treatment cohort consists of 146 patients. Efficacy parameters through 4 years of ETV therapy are presented below. The safety profile of ETV was consistent with previously reported experience. Conclusions: At Week 192, 91% of patients who received ETV treatment during 4 years achieved undetectable HBV DNA and 86% had ALT normalization, with patients continuing to experience HBeAg loss and HBeAg seroconversion during Years 3 and 4. The safety profile was consistent with previously reported experience. ¹ Chang TT, et al, N Engl J Med 2006;354:1001-1010.

**Numbers/proportions represent additional patients achieving HBeAg loss or HBeAg seroconversion during treatment in ETV-901; serology tests were performed by local laboratories**

THE MULTI-DRUG RESISTANT HBV RTA181T HAS A SECRETION DEFECT AND SIGNIFICANTLY REDUCES THE KINETICS OF VIRAL REBOUND

Stephen Locarnini, Nadia Warner; Victorian Infectious Diseases Reference Lab, North Melbourne, VIC, Australia

Background/Aims: Lamivudine (LMV) [rtM204V/I] or adefovir (ADV) [rtN236T] resistance results in rebound of serum HBV DNA of at least 1.0 log10 IU/ml increase over 3-6 months (Locarnini et al. 2004. AVR:9:679). The rtA181T mutant is also associated with both LMV and ADV resistance but occurs as a mixed population with wild-type (wt) HBV. The rtA181T also encodes a stop codon in the overlapping surface gene at aa172 (sW172*) resulting in truncation and loss of the last 54 amino acids of the C-terminal hydrophobic region. The aims of this study were to examine the in vitro effects of this mutation on HBV replication, and its effect on HBV DNA levels in patients following its selection Methods: To measure HBV replication, HuH7 cells were transfected with infectious clones encoding wt HBV, rtA181T or a mixture of both. HBV replication products were detected by Western blotting (WB), Southern blotting (SB), Immunohistochemistry (IHC) and electron microscopy (EM). The clinical occurrence and accompanying viral load data from patients with rtA181T was determined using SeqHepB (Yuen et al. 2007. AVR:75:64). Results: The rtA181T change resulted in a severe secretion defect preventing egress of surface proteins and virions from the cell as demonstrated by SB, WB and IHC. WB also revealed that the surface proteins from the rtA181T transfected cells were truncated and displayed differential glycosylation and stability. When rtA181T was transfected and expressed with wt to mimic a mixed infection as found in vivo, secretion of subviral particles was restored, but virion secretion was still greatly impaired. There was also increased intracellular accumulation by IHC, although not as extensive as with rtA181T alone. EM of cell supernatant detected viral-like structures secreted from doubly-infected cells that comprised mainly of spherical particles, with few virions or filaments compared to wt. Thus, rtA181T is dependant on wt HBV for secretion but acts as a dominant negative mutant on HBV virion secretion resulting in its retention within the cell. Examination of sequential HBV DNA levels from the blood of patients where only the rtA181T change was detected by direct PCR-sequencing, revealed that viral load rebound did not occur at all or increased in incremental amounts of less than 1.0 log10 IU/ml over 12-18 months. Conclusion: The HBV rtA181T mutation causes a secretory defect and exerts a dominant negative effect on wt HBV virion secretion. The rtA181T masks viral rebound, which in the clinical situation can result in mis-diagnosis of drug resistance if only viral load is used (> 1.0 log10 IU/ml increase over 3-6 months) as criterion for breakthrough failure.

940 CREATURE KINEASE (CK) ELEVATIONS AND MUSCLE TOXICITIES ASSOCIATED WITH CHRONIC TELBIVUDINE (LdT) USE IN PROSPECTIVE CLINICAL TRIALS

Charlene A. Brown1, Fraser Smith2, Katherine A. Laessig2; 1Division of Antiviral Products, Office of Antimicrobial Products, Center for Drug Evaluation & Research, US Food & Drug Administration, Silver Spring, MD; 2Division of Biometrics IV, Office of Biostatistics, Center for Drug Evaluation & Research, US Food & Drug Administration, Silver Spring, MD; 3Division of Antifungal & Ophthalmology Products, Office of Antimicrobial Products, Center for Drug Evaluation & Research, US Food & Drug Administration, Silver Spring, MD

Background: Nucleoside-associated myopathy has been well described in treatment of the Human Immunodeficiency Virus; however, CK elevations and myopathy have been a more unusual adverse event with the use of nucleosides for treatment of Hepatitis B Virus (HBV). We reviewed the LdT approval database for CK elevations and adverse event patterns consistent with muscle toxicity. Methods: Data were reviewed from trials that prospectively measured CK levels and recorded clinical adverse events, and in which LdT was used in at least one arm in New Drug Approval 22-011. We examined the time to onset and frequency of CK elevations from the pivotal Phase 3 trial (52 week data) using Kaplan-Meier plots and Fisher’s Exact Analysis (LdT vs. lamivudine (LAM)). We also reviewed detailed event narratives of clinical adverse events (AE) for CK elevations or events suggestive of myopathy, the Food and Drug Administration Adverse Event Reporting System for reports of muscle toxicity since LdT market approval (10/25/06) and preclinical evaluations for mitochondrial toxicity submitted with the Application. Results: The pivotal Phase 3 trial safety database included 680 (LdT) and 687 (LAM) subjects with HBeAg-positive and HBeAg-negative chronic HBV. More LdT subjects developed new-onset CK elevations compared to LAM subjects (Grade 1-4: 72% LdT, 42% LAM) after several months on study drug. After reviewing narratives for serious adverse events and study drug discontinuations/interruptions, there were a total of 16 LdT and 1 LAM subject with CK elevations or muscle symptoms; 6 of whom had a convincing picture of myopathy with muscle weakness, 2 of whom had biopsy confirmation, and 1 of whom was on a concomitant drug associated with myopathy. All presented after more than 300 days on study drug. History, degree and timing of CK elevations, and demographic characteristics were variable. No reports of LdT-associated CK elevations, myopathy or muscle weakness have been reported to our Adverse Event Reporting System since approval. No evidence of mitochondrial toxicity was found in review of preclinical studies. Conclusions: We found an emerging pattern of a cumulative toxicity resulting in myopathy with chronic LdT that may or may not be associated with mitochondrial toxicity. The imperfect relationship between the timing and severity of CK elevations and myopathy, coupled with the variable demography and symptom presentation in these clinical trial settings suggest that further characterization of this toxicity, its mechanism and its predisposing factors is warranted. These toxicities may occur more frequently in the general population with longer-term use of LdT.

941 MUTATIONS IN IMMUNODOMINANT EPITOPES OF HEPATITIS B VIRUS (HBV) CORE REGION: ENHANCEMENT OF VIRAL EVOLUTION BY THE EFFECT OF INTERFERON THERAPY

Francisco Rodriguez-Frias1,3, Rosendo Jardi1,3, Maria Buti2,3, Melanie Schaper1,2, David Taberner1, Rafael Esteban1,3; 1Biochemistry, Vall d’Hebron University Hospital, Barcelona, Spain; 2Hepatology, Vall d’Hebron University Hospital, Barcelona, Spain; 3CIBEREHD, Barcelona, Spain

Background and aims In HBV infection, the host immune system attacks core peptides as the main target. Amino acid (aa) substitutions in immunodominant epitopes of the HbcAg sequence may allow HBV to escape immune surveillance, thereby maintaining infection. The aim of this study was to analyze aa substitution rates in HbcAg immunodominant epitopes in a group of chronic hepatitis B (CHB) patients, throughout IFNa therapy and during a period without this therapy. Patients and methods A cohort of 44 CHB patients (19 HBeAg+) (BASELINE group) was studied retrospectively, all cases with a baseline serum sample. Sixteen (1 HBeAg+) of these patients who did not respond to 24 weeks of IFNa therapy (IFN group) were longitudinally studied. Eleven of the 16 patients (1 HBeAg+) and 10 other CHB cases (5 HBeAg+) (untreated group) were longitudinally studied in the absence of antiviral treatment. In the IFN and untreated groups, serum samples were analyzed during therapy and every six months over the non-treatment period. The complete sequence of HBV core region (precore and HbcAg) was determined by direct sequencing. The viral genotyope was established by comparison of obtained sequences with consensus sequences deduced from the alignment of 185 complete sequences of the eight HBV genotypes obtained from GenBank. Yearly rates of aa changes in the immunodominant HbcAg epitopes (B cell Hbc/Hbe1-aa 74 to 84, and Th cell-aa 50 and 69) were calculated in the IFN and untreated groups. In the BASELINE group this changes were recorded in relation to the consensus sequences. Results: Rates of aa changes in the immunodominant HbcAg epitopes are shown in table. Conclusions The higher rates of aa substitutions suggest enhancement of the evolutive pressure due to IFN therapy, which may allow HBV to escape from immunosurveillance, resulting in persistent infection. This does not seem to be related to viral genotype or precore variants. In baseline samples the highest variability in Th cell epitope (aa 50-69) could be related with the absence of the immunotolerogen effect of HBeAg. This study was supported by a grant from the Spanish Ministry of Health (FISS PI061512).

A HIGH PREVALENCE OF SIGNIFICANT LIVER DISEASE IN ASYMPTOMATIC HEPATITIS B PATIENTS WITH HIGH VIRAL LOAD; CANDIDATES FOR ANTIVIRAL THERAPY

Jun Yong Park1,2, Young Nyun Park3,4, Do Young Kim1,3, Yong Han Paik1,4, Kwan Sik Lee1,3, Byung Soo Moon1, Kwang-Hyub Han1,3, Chae Yoon Chon1,3, Young Myoung Moon5, Sang Ho Ahn1,3, 1Department of Internal Medicine, Yonsei University College of Medicine, Seoul, South Korea; 2Department of Pathology, Yonsei University College of Medicine, Seoul, South Korea; 3Liver Cirrhosis Clinical Research Center, Yonsei University College of Medicine, Seoul, South Korea; 4Brain Korea 21 Project for Medical Science, Seoul, South Korea; 5Department of Internal Medicine, Kwandong University College of Medicine, Seoul, South Korea

Background/Aim: Current treatment guidelines recommend that antiviral therapy should be considered in chronic hepatitis B (CHB) patients with high viral load if a biopsy shows significant liver disease despite ALT levels two times or less than the upper limit of normal (ULN). We evaluated the histological findings in CHB patients with high viral load and persistently normal or slightly elevated serum ALT levels. Methods: Between January 2003 and June 2006, all consecutive treatment-naive patients with CHB who underwent ultrasonography-guided percutaneous liver biopsy, expressed HBsAg for at least 6 months, and had detectable serum HBV DNA on a direct hybridization assay, and normal or slightly elevated serum ALT levels (≤2×ULN) for 12 months were included in this study. One hundred and five patients were enrolled. Serum ALT levels were tested in at least three consecutive samples within a 12-month period, and all values were less than two times normal. Histological assessment was based on the METAVIR classification (significant histology was defined as ≥ grade A2 or ≥ stage F2). Results: All 105 patients had HBV DNA titers above 105 copies/mL. The mean (± SD) ALT level at biopsy was 42 ± 19 (range, 8-75) and the mean age was 37 ± 14 years (range, 18-68). 36 patients had persistently normal ALT levels. Significant fibrosis was observed in 63 patients (60.0%) and significant histology was found in 69 patients (65.7%). On multivariate analysis, the serum ALT levels and age at study entry were independent meaningful factors associated with significant histology. Compared to the lowest ALT levels (<0.5×ULN), 0.5-1×ULN, 1.5-2×ULN and 1.5-2×ULN had odds ratios (95% CI) for significant histology of 1.1 (0.2-5.1), 3.9 (0.7-21.6) and 8.0 (1.1-60.5), respectively. Compared to patients younger than 20 years, the odds ratios for patients in their 20s, 30s, 40s, and over 50 years old were 7.1 (1.4-36.9), 14.2 (2.1-94.2), 24.4 (4.2-141.3), and 38.8 (4.0-309.8), respectively. Conclusion: A large proportion of CHB patients with high viral load and ALT two times or less than the ULN had significant liver disease on liver biopsy. Our findings warrant a more accurate evaluation in a practical setting and, if confirmed, would have a great impact on future treatment approaches for patients awaiting potential antiviral therapy.

ONCOLOGISTS AND HEPATITIS B: RESULTS OF A QUESTIONNAIRE SURVEY TO DETERMINE THEIR CURRENT LEVEL OF AWARENESS AND CLINICAL PRACTICE OF ANTIVIRAL PROPHYLAXIS TO PREVENT REACTIVATION

Arash Farhadi1, James H. Lewis1, Omar S. Khokhar1, Lisa H. McGrail2; 1Gastroenterology, Georgetown University Medical Center, Washington, DC; 2Medical Oncology, Sibley Memorial Hospital, Washington, DC

The risk of chronic hepatitis B virus (CHBV) reactivation under the influence of chemotherapy or other immunosuppression is being increasingly recognized. However, many oncologists either have not observed this complication, and/or are not aware of current recommendations for Hep B prophylaxis.

METHODS: In an effort to determine the degree of awareness of the potential reactivation risk and to understand the current practice of screening and prevention among oncologists, we prepared a questionnaire that was administered to 131 Hematology-Oncology physicians in the Washington, DC area during March and April 2007. Questions related to their awareness of the risk of hepatitis B reactivation, screening patients for HBV, awareness of preventative treatment for HBV and how they would administer prophylaxis and follow their patients.

RESULTS: Responses to 10 questions are as follows: 1) Are you aware that reactivation of HBV can occur: Yes 78%; No 22%. 2) Are you aware that prophylactic antiviral therapy is available: Yes 56%; No 44%. 3) Have you ever seen reactivation of HBV in your practice: Yes 30%; No 70%. 4) Do you screen for HBV prior to chemotherapy: Yes 38% (86% use selective criteria vs 14% use universal screening); No 62%. 5) Which pts would you prophylax: chronic carrier 46%; active HBV 76%; resolved HBV infection 52%. 6) Which antiviral would you give: lamivudine 46%; adefovir 14%; not sure 48%. 7) How often would you monitor: q2wk 4%; q4wk 18%; q6wk 14%; q8wk 16%; q12wk 12%; not sure 36%. 8) How long would you continue prophylaxis after completing chemotherapy: 1 mo. 8%; 2 mo. 15%; 3 mo. 71%; 4 mo. 8%. 9) Would you monitor for reactivation even if you did not give prophylaxis: Yes 66%; No 6%; Not sure 28%. 10) Would you want a gastroenterologist or hepatologist to follow the pt with you: Yes 88%; No 12%.

DISCUSSION: While most oncologists are aware of the potential risk of HBV reactivation, only 30% have ever seen a reactivation and most are not screening pts for HBV prior to chemotherapy. Fewer than half of our respondents were aware that prophylactic antiviral agents are available, and even fewer were aware that prophylaxis has been shown to reduce HBV flares, and most were not sure what agent to select. A majority would, however, seek the recommendations of a gastroenterologist or hepatologist and most felt that prophylactic treatment should continue for at least 3 months after chemotherapy was completed.

CONCLUSIONS: Improving awareness of HBV reactivation and antiviral prophylaxis in the Oncology community seems warranted.

PRE-EMPTIVE LAMIVUDINE REDUCES THE RISK OF CHEMOTHERAPY-INDUCED HBV-RELATED MORBIDITY AND MORTALITY IN HBsAg-POSITIVE CANCER PATIENTS: META-ANALYSIS

Rohit Loomba1, Ayana Rowley2, Robert Wesley3, T. Jake Liang1, Jay H. Hoofnagle1, Frank Pucino2, Gyorgy Csako4; 1Liver Diseases Branch, NIDDK/NIH, Bethesda, MD; 2Pharmacy Department, CC, NIH, Bethesda, MD; 3Hospital Epidemiology, CC, NIH, Bethesda, MD; 4Laboratory Medicine, CC, NIH, Bethesda, MD

Background: Lamivudine (LAM) has been used for preventing HBV-reactivation in hepatitis B surface antigen (HBsAg)-positive cancer patients undergoing chemotherapy but its beneficial effects have not been assessed quantitatively. Purpose: To estimate the degree of beneficial effect of pre-emptive LAM in reducing chemotherapy-induced HBV-related morbidity and mortality in HBsAg-positive cancer patients. Methods: Databases searched (until February 2007) included Medline, Ovid, Toxnet, Scopus, and Web of Science. Studies with data suitable for risk estimation of cancer chemotherapy-induced HBV reactivation in HBsAg-positive patients receiving pre-emptive LAM vs. controls that met the pre-specified criteria on outcomes and sample size. 2 investigators independently performed the literature search and data extraction, and 2 different investigators independently reviewed whether the studies met pre-specified criteria. A two-tailed p-value <0.05 was considered statistically significant. Comprehensive Meta-Analysis Software was used for the analysis. Results: Twelve studies met predefined criteria (2 RCT, 6 prospective, and 4 retrospective cohort studies). Of 12 trials in the meta-analysis, 10 were conducted in East Asia, and one each in Turkey and Israel. All studies were in English except for one in Chinese. 214 patients received pre-emptive LAM, and 399 patients served as controls receiving either no (3 studies) or deferred LAM (9 studies). The log odds ratios demonstrating risk reduction with pre-emptive LAM vs. no pre-emptive LAM in HBsAg-positive individuals undergoing cancer chemotherapy was 0.06 (95% confidence interval [CI], 0.03-0.13) for HBV reactivation, 0.07 (95% CI, 0.04-0.14) for HBV-related hepatitis, 0.20 (95% CI, 0.06-0.64) for liver failure, and 0.21 (95% CI, 0.08-0.58) for mortality. Combining results from all the studies indicated that HBV reactivation was decreased from 35.6% to 2.8% (p<0.0001) with pre-emptive LAM therapy, while HBV-related hepatitis was decreased from 32.3% to 2.8% (p<0.0001), HBV-related liver failure from 5.7% to 0.5% (p = 0.0002) and HBV-related mortality from 7.0% to 0.5% (p < 0.0001). Based upon this analysis, 1 death can be prevented by treating 15 patients with pre-emptive LAM in this clinical setting. Limitations: Small studies; only two involved a randomized-controlled design. Discussion: This meta-analysis demonstrated that pre-emptive LAM reduces the risk of HBV-reactivation, HBV-related hepatitis, HBV-related acute liver failure, and HBV-related mortality by 16, 14, 5, and 5-fold, respectively. Conclusions: HBsAg-positive patients undergoing cancer-chemotherapy warrant pre-emptive therapy with LAM.

Background/Aim: Recent studies have shown that, in contrast to lamivudine, adefovir dipivoxil (ADV) therapy is associated with delayed and infrequent selection of drug resistant hepatitis B virus reverse transcriptase (RT) mutations. To date, apart from rtN236T and rtA181V ADV-resistant mutations, the impact of other mutations in the HBV RT region on the susceptibility to ADV is unknown. The aim of this study is to genotypically and phenotypically analyse emerging mutations in the HBV RT during ADV treatment. Patients/Methods: 68 patients (44±14 years) with chronic HBV (CHB)-infection treated with ADV (18±13 months) demonstrating persistent viraemia (5.5±1.0 log10 IU/ml) and 1.4±0.6 HBV IE/ml were included in this analysis. The RT-region was amplified by PCR after extraction of viral DNA from patient sera. Mutational analysis of the RT-region was done by sequencing followed by genotyping. Selected mutations were introduced into HBV replication competent constructs using site-directed mutagenesis and analyzed for sensitivity to ADV (IC50) in HepG2 cell culture experiments. Results: The ADV resistant mutations rtA181V and/or rtN236T were detected in 11 patients. Sequence exchanges at positions rtL122(F), rtN124(H), rtP130(Q), rtD131(N) in the RT-fingers domain were detected in 60% of the patients. However, these changes could be also detected in treatment naive patients and represent polymorphisms. Additionally, the exchange rtN248H in the E-domain was frequent (26/72; 36%). Statistical analysis revealed that rtN248H positively correlated with ALT (r=0.65, p=0.0001), rtP130Q (r=0.5, p=0.0001) and rtN124H (r=0.42, p=0.0001), and negatively correlated with rtL180M (r=-0.45, p=0.001). The phenotypic cell culture analysis of rtN248H showed a moderate reduction of sensitivity to ADV (IC50 <6µM ADV) compared to wild type HBV (IC50 <3µM ADV) and rtN236T (IC50 >10µM ADV). Notably, the recently published mutation rtL233V could not be detected in any of our ADV treated patients. Conclusion: Apart from the previously described rtN236T and rtA181V ADV resistant mutants, our analysis shows no evidence for further distinct ADV resistant mutations. However, antiviral treatment of CHB patients with ADV can select further exchanges in the HBV polymerase. Exchanges in the RT-fingers domain, e.g. rtL122F, rtN124H, rtP130Q, and rtD131N, may represent polymorphisms and have little or no impact on antiviral susceptibility. Phenotypic analysis of exchanges in the RT-E-domain, rtN248H, showed only a slight reduction in sensitivity to ADV. Suspected ADV resistant mutations, e.g., rtQ215S and rtL333V, were extremely rare or not detectable in our patients.

948 ANALYSIS OF DETERMINANTS FOR SUSTAINED VIROLOGIC RESPONSE TO LAMIVUDINE MONOTHERAPY IN PATIENTS WITH HBEAG POSITIVE CHRONIC HEPATITIS B: A MULTI-CENTER TRIAL

Hyun Woon Lee1,8, Heon Ju Lee2,8, Jae Won Choi2,8, Jae Seok Hwang3,8, Woo Jin Chung3, Joo Hyun Sohn4,8, Taeyob Kim5, Jae Young Jang5, Ki Jun Han6,8, Jun Yong Park1,8, Do Young Kim1,8, Sang Hoon Ahn1,8, Yong Han Paik1,8, Chun Kyo Lee7,8, Kwan Sik Lee1,8, Chae Yoon Chan1,8, Young Myoung Moon1, Kwang-Hyub Han1,8; 1Internal Medicine, Yonsei University College of Medicine, Seoul, South Korea; 2Yeungnam university college of medicine, Daeug, South Korea; 3Keimyung University School of Medicine, Daegu, South Korea; 4Hanyang University College of Medicine, Guri, South Korea; 5Soochunhyang University Hospital, Seoul, South Korea; 6Kwandong University College of Medicine, Goyang, South Korea; 7National Health Institute Corporation Ilsan Hospital, Goyang, South Korea; 8Liver Cirrhosis Clinical Research Center, Seoul, South Korea

Backgrounds/Aims: Several reports showed inconsistent results on the durability of virologic response after successful lamivudine monotherapy. Especially, the question remains whether virologic responses can be maintained over extended follow-up period. The aim of our study was to evaluate post-treatment relapse rates for 5 years after virologic responses and to elucidate the predictive factors for sustained virologic response in patients who experienced HBeAg loss to lamivudine monotherapy. Methods: 748 patients (Male: Female = 570:178) with HBeAg positive chronic hepatitis B were treated with lamivudine from 7 medical institutions in Korea between January 1999 and August 2004. The mean duration of lamivudine monotherapy was 34 months (range, 12-88). Among 178 patients, who discontinued lamivudine monotherapy after complete response (HBeAg loss, undetectable HBV DNA and ALT normalization), 138 patients (77.5%) maintained sustained virologic response. Both host and viral factors were compared between 138 patients with sustained HBeAg response and 40 patients whose response was not sustained. Results: The cumulative relapse rates at 1, 3, and 5 years were 15.9%, 26.4%, and 30.2%, respectively. The mean time to relapse after cessation of lamivudine was 12 months (range, 2-42). Most relapses were occurred within 2 years after discontinuation of lamivudine (35/40, 87.5%). In multivariate analysis, age ≤ 40 years, additional treatment duration over 12 months after HBeAg loss were independent factors for sustained virologic response. In conclusion, only 22.5% of patients who discontinued lamivudine after HBeAg loss experienced a relapse for 5 years follow-up. Age and additional treatment are major predictive factors for sustained HBeAg loss. Key words: chronic hepatitis B, lamivudine, treatment

949 MULTIDRUG RESISTANCE AND CROSS-RESISTANCE PATHWAYS IN HBV AS A CONSEQUENCE OF TREATMENT FAILURE

Lilly Yuen1,2, Angeline Bartholomeusz1, Anna Ayres1, Margaret Littlejohn1, Stephen Locarnini1,2; 1Victorian Infectious Diseases Reference Lab, North Melbourne, VIC, Australia; 2Evivar Medical, East Melbourne, VIC, Australia

Background/Aims: Antiviral resistance is now the single most important factor in treatment failure using nucleos(t)ide analogues (NA). Primary drug resistance mutations refer to amino acid change(s) that result in reduced susceptibility to an antiviral agent. Secondary compensatory mutations restore replication defects associated with primary drug resistance, and may be associated with low level reduced susceptibility. Several evolutionary pathways of drug resistant HBV have been observed in patients treated with NAs. It is possible that the drug resistance mutations selected with one agent may affect the efficacy of other NAs. The aim of this study was to elucidate mutation pathways associated with use of NAs and to determine the potential cross-resistance profiles selected under a particular NA. Methods: The HBV reverse transcriptase (rt) gene was amplified by PCR and sequenced from patients pre- and during-treatment. A software program (SeqHepB) was used to analyse the treatment-associated mutations (Yuen L et al. 2007. AVR;75:64). Associations between drug resistance and rt mutations found in the most recent samples from 159 patients pre- and 215 patients during failing monotherapy with either lamivudine (LMV) or adefovir (ADV) were evaluated using the Fisher’s Exact method and a pattern discovery program Magna Opus (Rule Quest Research, Australia). Results and Discussion: Therapy with LMV or Telbivudine (LdT) or entecavir (ETV) resulted in the selection of rtM204I/V. Statistical analysis identified several secondary compensatory mutations (rtL80I/V, rtV173L, rtL180M, rtT184G and rtS202I) during LMV monotherapy that can also affect response to ETV or LdT. Therapy with ADV resulted in the selection of rtN236T and/or rtA181T/V selection as well as the maintenance of rtL180M and rtM204V in a subset of patients with add-on ADV. The loss of rtL180M and/or rtM204I/V was also statistically significant among LMV resistant patients who subsequently switched to ADV monotherapy. The rtA181T/V mutation, which has been implicated with reduced sensitivity to LMV and ADV, could be either common with or separate to the “204 and 236 pathways”. Conclusion: Three major HBV evolutionary NA-resistance pathways (rtM204I/V, rtN236T and rtA181T/V) have been characterised. The rtM204V/I pathway is responsible for resistance to the L-nucleosides such as LMV, LdT and also ETV whilst the rtN236T pathway is responsible for adefovir resistance. Both are associated with clusters of secondary mutations that can affect subsequent treatment with NAs (rtT184G, rtS202I). The third pathway, rtA181T/V, is associated with resistance to LMV and ADV and is a potential multi-drug resistance pathway.

Different HBV variants carrying point mutations at level of the reverse transcriptase (rt) domain of the viral Pol gene had been detected in patients under treatment with nucleos(t)ide analogues. At present, few information is available about the occurrence of these drug-resistant mutants in untreated patients. Aim of this study was the genomic characterization of HBV isolates from individuals (1) naive for antiviral therapy or (2) who had developed lamivudine resistance. We analysed - by amplification, cloning and sequencing procedures - the entire rt-domain in viral isolates from 84 untreated (naive-group) and 49 lamivudine-resistant (Lam-group) consecutive HBsAg carriers with chronic liver disease. All the cases had serum HBV DNA levels > 20,000 UI/mL. Thirty-two of the 84 naive-group cases (38.1%) carried single or multiple mutations potentially predisposing to antiviral resistance. In particular, we found the following mutations: rtV173M in 2 cases (2.4%), rtA181D in 1 case (1.2%), rtV214A/E in 3 cases (3.6%), rtQ215S/P/H in 12 cases (14.3%), rtL217R in 8 cases (9.5%), rtS219S in 4 cases (4.8%), rtF221Y/L in 15 cases (17.8%), rtL233V in 4 cases (4.8%), rtP237T in 3 cases (3.6%), rtN238T/H/D in 4 cases (4.8%). In the Lam-group – besides the mutations typically inducing Lamivudine resistance – 28/49 (57.1%) carried single or multiple mutations conferring resistance to other antivirals. In particular, 4 cases (8.2%) had either the rtT184S or the rtM250V/L mutations favouring resistance to Entecavir, whereas various combined mutations predisposing to Adefovir resistance were detected in 26 cases: rtV84M in 1 case (2%), rtA181T/S in 2 cases (4.1%), rtA181T/S in 2 cases (4.1%), rtQ215S/E/P in 12 cases (24.5%), rtL217R in 3 cases (6.1%), rtS219A in 3 cases (6.1%), rtF221Y in 6 cases (12.2%), rtL233V in 1 case (2%), rtP237T/H in 2 cases (4.1%), rtN238T/H/D in 12 cases (24.5%). In conclusion, our study shows that HBV mutants predisposing to drug resistance may be present as major infecting population in untreated patients, and that variants emerging during Lamivudine treatment may also carry mutations potentially inducing resistance to either Adefovir or Entecavir. Thus, the genetic characterization of HBVs infecting patients undergoing treatment with nucleos(t)ide analogues may be a helpful tool for tailoring the most proper therapeutic strategy in each individual case.

951 ENTECAVIR: A RESCUE THERAPY FOR CHRONIC HEPATITIS B PATIENTS WITH A LIMITED VIROLOGICAL RESPONSE TO ADEFOVIR?

Jurrien G. Reijnders1, Robert A. De Man1, Suzan D. Pas2, Martin Schutten2, Harry L. Janssen1 1Gastroenterology & Hepatology, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands; 2Virology, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands

Background The frequency of detection of drug resistant HBV mutants correlates with the rapidity of initial decline of viral load. In treatment-naive patients with HBeAg-positive hepatitis B entecavir (ETV) achieves approximately 6log_{10} HBV DNA decline and PCR-negativity in 45% of the patients after 24 weeks of treatment. In lamivudine (LAM)-refractory patients who are subsequently switched to ETV, it has shown to be less effective. Here we describe 12 patients with chronic HBV infection and a persistently high viral replication after one year of treatment with ADV, who were switched to ETV as rescue therapy.

Methods Limited ADV response was defined as presence of HBV DNA levels greater than 5log_{10} copies/mL after 48 weeks of treatment. Patients were directly switched from ADV to ETV at a daily dose of 1 mg. ALT and HBV DNA levels were assessed at baseline and after 24 weeks of treatment (detection limit 400 copies/ mL). All subjects were screened for resistance-associated mutations within the HBV polymerase gene using Inno Lipa HBV DR v2 and v3 (Innogenetics).

Results The baseline characteristics of the 12 patients with limited ADV response were: median age 44 [range 23-73]; m/f: 9/3; 11 HBeAg+; 3 cirrhosis; genotype A: 3; B: 3; C:1; D: 5. Six patients had a prior history of LAM-resistance. Median period of ADV administration was 79 weeks [range 49-135]. HBV DNA levels ranged between 5.2 to 10.1 log_{10} copies/mL (median 7.7 log_{10} copies/mL). At baseline three patients had ADV-resistance substitutions [N236T ± A181V/T], and in only one patient also LAM-resistance was detected [M204I]. After 24 weeks of treatment the median decrease of HBV DNA was 3.7 log_{10} copies/mL [range 1.9-5.9]. There was no difference in decline between patients with or without a prior history of LAM-resistance (3.7 vs. 3.7). Median HBV DNA level at 24 weeks was 3.8 log_{10} copies/mL. None of the patients reached HBV DNA levels below the detection limit. The proportion of patients with ≤ 3 log_{10}, 3.1-5.5 log_{10}, > 5 log_{10} copies/mL was 33%, 42%, and 25%, respectively. HBeAg-seroconversion occurred in one patient after 12 weeks of treatment. After 24 weeks of treatment two patients showed LAM-resistance (M204I), no ETV-resistance substitutions were detected (I169, T184, S202, M250).

Conclusion Entecavir treatment leads to a suboptimal viral decline in patients with a limited response to adefovir, even in the absence of ADV or LAM resistance. Our finding that none of these patients achieved HBV DNA negativity by 24 weeks necessitates close monitoring for potential development of ETV resistance in ADV nonresponders.

952 COMBINATION ANTIVIRAL EFFECTS OF 2', 3'-DIDEOXY-3'-FLUOROGUANOSINE WITH NUCLEOS(T)IDE ANALOGS AGAINST HEPATITIS B VIRUS IN VITRO
Lei Lu1, Chee-Kin Hui1, Hai-ying Zhang1, Yui-Hung Yueng1, Kwok-fan Cheung1, John M. Luk2, George K. Lau1; 1Medicine, The University of Hong Kong, Hong Kong, China; 2Surgery, The University of Hong Kong, Hong Kong, China

Background & Aims: 2', 3'-dideoxy-3'-fluoroguanosine (FLG) is a nucleoside analogue which acts as an inhibitor of viral DNA polymerase and a chain terminator of viral reverse transcription. FLG has been shown to be active against wild-type and drug-resistant HBV in in vitro models (Jacquard et al 2006). In this study, we investigated the in vitro antiviral efficacy of combinations of FLG with lamivudine and clevudine, acyclic phosphate nucleotide analogues (PMEA, adefovir and PMPA, tenofovir) and carbocyclic analogues (entecavir). Methods: Using the HepAD38 cell line that expresses high levels of wild-type HBV as the in vitro cell model, we assayed the antiviral activities and cytotoxities of each drug alone and in combination with FLG (Tibotec Pharmaceuticals Ltd). Real time PCR was used for the measurement of HBV DNA generated by HepAD38, and the cytotoxicity was determined by 3-[4, 5-dimethylthiazol-2-yl]-2, 5-diphenyltetrazolium bromide (MTT) assay. Each combination experiment included 24 samples, 13 of which were controls (five doses of each drug alone plus three untreated wells) and 11 of which were drug combinations. Of the five concentrations tested for each drug, the middle dose was equal to the IC50; two higher doses (corresponding to three and six times the IC50) and two lower doses (responding to 0.16 and 0.33 times the IC50) were also tested. The combination data were analyzed through the Bliss independence model which is defined by the equation E_{xy}=E_x+E_y-E_{x+y}-E_xE_y, where E_x and E_y are the additive effect of drugs x and y as predicted by their individual effects E_x and E_y. The MacSynergy II program, version 1.0 (M. N. Prichard, University of Alabama) was used to evaluate antiviral data according to the Bliss independence model. MacSynergy II uses a nonparametric three-dimensional approach to quantify areas where observed effects are significantly greater (synergy) or less (antagonism) than those predicted from single-drug control data. Results: Analysis using the Bliss independence model indicated that FLG exerted significant synergistic antiviral effects when combined with lamivudine (V=41.51 µM2) or tenofovir (V=95.07 µM2) and additive effects when combined with adefovir (V=25 µM2). However, minor antagonism effects were displayed when FLG combined with entecavir (V=32.12 µM2) or clevudine (V=60.25 µM2). There was no evidence of cytotoxicity with any of the drugs when used alone or in combination at the tested doses. Conclusion: FLG exerted different kinds of combination antiviral effects when it was used with other nucleos[t]ide analogs. Future clinical study on FLG-related combination therapy is warranted.

953 DEMONSTRATION OF AN ASSOCIATION BETWEEN DETECTION OF IGG ANTIBODY REACTIVITY TOWARDS THE C-TERMINAL REGION OF THE PRES1 PROTEIN OF HEPATITIS B VIRUS AND THE CAPACITY TO RESPOND TO INTERFERON THERAPY IN CHRONIC HEPATITIS B
Staffan P. Sylvan1, Ulla B. Hellstrom2, Kim Krogsaard3, Magnus Lindh4; 1Dept of Communicable Disease Control and Prevention, Uppsala County Council, Uppsala, Sweden; 2Dept of Communicable Disease Control and Prevention, Stockholm County Council, Stockholm, Sweden; 3PhaseOne Trials A/S Hvidorew, University Hospital, Hvidore, Denmark; 4Dept of Clinical Virology, Gothenburg University, Gothenburg, Sweden

Background: The aim of this study was to determine the predictive value of the pre-treatment presence of circulating antibodies towards a synthetic peptide mimicking the amino acids 94-117 of the preS1 protein of hepatitis B virus (HBV) and the capacity to respond to interferon–alpha (IFN-alpha) therapy. Methods: The anti-preS1 (94-117) antibodies were measured by a peptide-based enzyme-linked immunosorbent assay (ELISA) and the response to IFN-alpha therapy was judged by the effect on the viral kinetics as measured by a quantitative polymerase chain reaction (PCR) based assay during the treatment and follow-up. Results: We found a significant (p<0.001) correlation between the pre-treatment presence of anti-preS1 (94-117) antibodies and a decrease in viral levels on follow-up after the end of IFN-alpha therapy. The combined response of HBV DNA suppression (p<0.001), HBsAg loss (p<0.0001) anti-HBe seroconversion (p<0.005) and ALT normalisation (p<0.01), was also highly associated with the pre-treatment presence of anti-preS1 (94-117) antibodies. Conclusions: The positive predictive value (PPV) of anti-preS1 (94-117) in determining a virological response was 83% and the negative predictive value (NPV) was 100%, indicating that in the absence of pre-treatment anti-preS1 reactivity virtually no patient has the capacity to respond to IFN-alpha therapy. Our findings may help to improve the efficacy of IFN-alpha therapy for chronic hepatitis B (CHB) by guiding the selection of patients to treatment and optimising the clinical management of the individual patient.

954 INCREASING ADEFOVIR AND ENTECAVIR UTILIZATION DRIVE HEPATITIS B RESISTANCE PATTERNS IN A US NATIONAL REFERENCE LABORATORY DATABASE
Ron M. Kagan, Jamie L. Platt, Hasnah Hamdan, Michael A. Lewinski; Infectious Diseases, Quest Diagnostics, San Juan Capistrano, CA

INTRODUCTION An increasing number of antivirals are available for treatment of chronic hepatitis B virus (HBV) infection. Increasing use of antivirals can affect the frequency of resistance mutations in the treated population. We surveyed a large clinical database of HBV polymerase gene sequences to assess changes in the prevalence of resistance-associated mutations for lamivudine, adefovir, and entecavir over a 5-year period. METHODS HBV pol sequences for 10,800 clinical samples obtained between June 2002 and May 2007 were compiled in a database. Genotypes were determined by phylogenetic analysis of a 348-nt pol fragment. Antiviral drug prescription utilization data were obtained from NDChEalth (http://www.ndchealth.com). RESULTS The HBV sequences submitted for resistance analysis comprised genotypes C (37%), B
Background and aim: We recently described a cross-resistance pattern to adefovir (ADV) in a patient with lamivudine (3TC) resistance (EASL 2005). We aimed to further analyse the drug susceptibility of a novel mutation pattern to adefovir (ADV) in a patient with lamivudine (3TC) and entecavir-refractory patients.

Continued surveillance of emerging antiviral resistance in the clinical population is warranted.

955 DRUG SUSCEPTIBILITY TESTING OF A NOVEL MUTATION PATTERN (A181S+M204I) CONFERRING RESISTANCE TO LAMIVUDINE AND ADEFOVIR DIPIVOXIL

Ersin Karatayli1, Selim Karayalcin2, Hayri Karaaslan2, Handan Kayhan1, Ahmet R. Turkylilma1, Fikret Sahin1, Cihan Yurdaydin1,2, A.Mithat Bozdayi1,2; 1Hepatology Institute, Ankara University, Ankara, Turkey; 2Department of Gastroenterology, Ankara University, School of Medicine, Ankara, Turkey

Background and aim: We recently described a cross-resistance pattern to adefovir (ADV) in a patient with lamivudine (3TC) resistance (EASL 2005). We aimed to further analyse the drug susceptibility of this novel mutation pattern (A181S+M204I) against 3TC, ADV, tenofovir (PMPA), clevudine (L-FMAU), and emtricitabine (FTC). Methods: Successful suppression of HBV replication by sequential therapy of 9 MU/TIW interferon (IFN) and 3TC was followed by the genotypic resistance detected at the 19th month of treatment. ADV was added to 3TC therapy on the 44th month of antiviral treatment. However, neither ALT normalization nor a stable decrease in the HBV viral load was observed although ADV was used for more than 40 months. HBV pol region was amplified from 8 serum samples obtained before and after ADV treatment. Out of 8, complete genome was amplified in 3 serum samples and was cloned into a TA vector. DNA sequencing was performed for 8 PCR products of HBV pol gene and for 9-10 clones from 3 cloned constructs. Full genome of A181S+M204I variant was also cloned into an expression vector and its in vitro susceptibility to 3TC, ADV, PMPA, L-FMAU and FTC was determined in transiently transfected Huh7 cells. Results: Of the 29 clones sequenced, A181S+M204I pattern was detected in 14. The novel A181S mutation in the reverse transcriptase gene was associated with W172C mutation in the overlapping surface antigen gene. The results of the in vitro drug susceptibility assay revealed that this mutation pattern displays more than 1000 fold resistance for 3TC and FTC, and 28.2 fold resistance to ADV. This novel mutation pattern was relatively sensitive to the effect of PMPA and L-FMAU, displaying 5.9 and 5.6 fold resistance, respectively. Conclusion: In conclusion, A181S+M204I mutation pattern is associated with reduction in the susceptibility of all antiviral agents tested. While resistance is very high to 3TC and FTC, it is moderate to ADV and relatively mild to L-FMAU and PMPA. This study underlines the potential clinical aid of drug susceptibility assays in the area of multi-resistant viral variants.

956 ADEFOVIR DIPIVOXIL PLUS LAMIVUDINE COMBINATION TREATMENT IS SUPERIOR TO ADEFOVIR DIPIVOXIL MONOTHERAPY IN LAMIVUDINE-RESISTANT HEPATITIS B E ANTIGEN-NEGATIVE CHRONIC HEPATITIS B PATIENTS

Themistoklis Vassiliadis1, Olga Giouleme1, Georgios Koumerkieridis2, Charalampos Koumaras2, Konstantinos Tzimolas2, Kaliopi Patiaoura1, Alexander Mpoumponaris1, Dimitrios Oikakis1, Konstantinos Theodoropoulos2, Nikolaos Grammatikas2, Athanasia Pandis2, Nikolaos Nikolaidis1, Nikolaos Evgenidis1; 1Gastroenterology and Hepatology Department, 2nd Propaedeutic Internal Medicine Clinic, Hippokration Hospital, Aristotle University of Thessaloniki, Thessaloniki, Greece; 2Clinical Immunology and Hepatology Department, 2nd Internal Medicine Clinic, Hippokration Hospital, Aristotle University of Thessaloniki, Thessaloniki, Greece

The aim of this study was to evaluate the long-term efficacy of adefovir dipivoxil (ADV) in patients with hepatitis B e antigen (HBeAg)-negative chronic hepatitis B (CHB) who have developed resistance to lamivudine (LAM) treatment. In addition, we aimed to assess whether LAM should be discontinued in these patients. Sixty patients with lamivudine-resistant HBeAg-negative CHB were randomized in a 3:1 ratio to receive either ADV + LAM combination treatment (Group A; n = 45) or ADV monotherapy (Group B; n = 15). Baseline characteristics did not differ between groups. After a median follow-up time of 43 months (range, 10 to 63 months), hepatitis B virus (HBV) DNA became undetectable (< 400 copies/ml; virological response) in 37/45 patients in Group A (82.2%) and in 11/15 patients in Group B (73.3%) (p = 0.079). During follow-up, transaminases’ levels normalized in 40/44 patients in Group A (90.9%) and in 8/14 patients in Group B (57.1%) (p = 0.012). ADV-resistant mutations were identified in 2/45 patients in Group A (4.4%) and in 5/15 patients in Group B (33.3%) (p = 0.011). The 2 patients with ADV-resistance (group A) were suboptimal responders and in one of two (50%) the duplication of ADV dose to 20 mg per day resulted in disappearance of HBV DNA (< 6 IU/ml) in six months later. Virological breakthrough ( reappearance of HBV DNA after its initial disappearance) did not develop in any of the 37 Group A patients with virological response. In contrast, 3/11 Group B patients with virological response (27.3%) developed virological breakthrough (p=0.011). Treatment was well-tolerated and no adverse effects
occurred. In conclusion, ADV + LAM combination treatment is superior to ADV monotherapy in patients with lamivudine-resistant HBeAg-negative CHB, in terms of both efficacy and development of resistance to ADV. Increase of ADV dose to 20mg/day may be effective in suboptimal response patients or even ADV-resistant patients.

DOES THE GENOTOXIC EFFECT OF LAMIVUDINE TREATMENT IN CHRONIC HEPATITIS B TO THE HOST DNA?

Hatice Ilgın Ruhi 1,2, Meral Akdogan 1,2, Pınar Ozkal 1,3, Sabite Kacar 1,4, Nurgül Sasmaz 2,5; 1Department of Medical Genetic, Ankara Medical Faculty, Ankara University, Ankara, Turkey; 2Department of Gastroenterology, Türkiye Yüksek İhtisas Hospital, Ankara, Turkey; 3Department of Medical Biology, Ankara Medical Faculty, Ankara University, Ankara, Turkey; 4Department of Gastroenterology, Türkiye Yüksek İhtisas Hospital, Ankara, Turkey; 5Department of Gastroenterology, Türkiye Yüksek İhtisas Hospital, Ankara, Turkey

Chronic viral hepatitis B is the main cause of chronic liver disease, cirrhosis and hepatocellular carcinoma in the world. Lamivudine, a nucleoside analog, is an inhibitor of viral DNA replication. Patients are treated with lamivudine show normalization of serum alanine aminotransferase (ALT) level, and histological improvement. However, discontinuation of therapy often leads to reactivation of HBV so long-term therapy is necessary for many patients with chronic HBV infection. The aim of this study is to detect the genotoxic effects of the long-term lamivudine treatment to the host DNA. Material and Method: Fourteen chronic hepatitis B (CHB) patients (4 women, 10 men, mean age: 44 ranges: 29-64 yrs) who were treated with lamivudine were included in this study. Blood samples were collected before the treatment and 6 months and at least sixteen months (mean 27 months) of the treatment. Peripheral blood lymphocytes of these patients were cultured to make cytogenetic evaluation by observing chromosome breakage and cytologic evaluation by micronucleus (MN) test. For each individual 100 metaphase chromosome spreads were analysed. 190-1091 binucleated cells were observed and for each individual MN scores between each period of the treatment (p>0.05). Based on this data, we concluded that lamivudine treatment in patients with chronic HBV may be chromosomal instability and this instability may increase during long-term therapy especially after one year of the treatment.

TOVFIVOR SHOWS LIMITED EFFICACY IN TREATMENT OF HBV INFECTIONS RESISTANT AGAINST ADEFOVIR

Florian van Bömmel1, Jörg Trojan2, Heinz-Hubert Feucht2, Bernd Möller2, Dietrich Hüppe3, Bertram Wiedenmann4, Thomas Berg5; 1Medizinische Klinik m. S. Hepatologie und Gastroenterologie, Charité-Universitätsmedizin Berlin, Berlin, Germany; 2Department of Internal Medicine, Wolfgang Goethe University Medical Centre, Frankfurt am Main, Germany; 3Institut für Infektionsmedizin, Universitätsklinikum Hamburg-Eppendorf, Hamburg, Germany; 4Hepatologische Schwerpunktpraxis, Berlin, Germany; 5Gastroenterologische Gemeinschaftspraxis, Heerde, Germany

Background: Genotypic HBV resistance against adefovir dipivoxil (ADV) develops rarely during the first two years of treatment. However with increasing treatment duration ADV resistant HBV mutants are selected in up to 28% of the patients after 5 years which is often associated with viral rebound. In vitro, these mutations cause a 3-14-fold decrease of ADV efficacy. Tenovifor (TDF), a nucleotide analogue approved for HIV therapy, is closely related to ADV, shows equipotent antiviral activity against HBV on molar basis and is cross resistant to ADV in vitro. However, due to the 25-fold higher dosage of TDF (300 mg/d) as compared to ADV (10 mg/d), TDF might still be effective in ADV resistant HBV infections. Methods: The efficacy of TDF monotherapy was retrospectively evaluated in 10 HBV monoinfected patients (m/f 9/1, mean age 47±11 [27-67] years, 6 HBeAg positive) with initial lamivudine resistance who had developed genotypic ADV resistance (rtN236T and/or rtA181T/V) after consecutive 1-45 [mean 24±9] months of ADV monotherapy. HBV DNA and ALT values were measured every 3 months (HBV Monitor, Roche, detection limit 400 copies/mL). In six patients, during TDF treatment the HBV polymerase gene was sequenced from codon r88 to r282 after PCR products were cloned in E. coli (TOPO-TA cloning system, Invitrogen; minimum of 10 clones sequenced each). Results: At the begin of TDF treatment (mean duration 16±3 [12-21] months), the mean HBV DNA was 7.5±1.3 [4.6-9.4] l copies/mL and nine patients had elevated ALT levels (mean 151±118 [34-358] U/mL). The mutations associated with ADV resistance N236T, A181T and combination of both were detected in 3, 2 and 5 patients. During TDF treatment, HBV DNA decreased by a mean of 3.6±1.2 [2-5] and 4.3±1.2 [2-6.2] log copies/mL at week 24 and week 48, respectively. HBV DNA was still detectable in 9, 8 and 6 patients while ALT levels remained elevated in 8, 8 and 6 patients at week 24, week 48 and at the end of observation. Subspecies analysis in six patients showed that ADV resistance mutations remained detectable throughout the whole observation period in increasing ratio as compared to HBV wild type. Combination therapy with TDF and lamivudine was started in two patients at month 12 and lead to undetectable HBV DNA and normal ALT levels after two months. Conclusion: Although TDF shows significant antiviral efficacy in patients with genotypic ADV resistance, HBV DNA can be completely suppressed only in a minority of the patients and the selection of ADV resistant mutations is not prevented. Therefore, patients with genotypic ADV resistance should receive combination treatment with TDF or ADV plus lamivudine or entecavir.

THE EFFECT OF LAMIVUDINE AND ADEFOVIR DIPIVOXIL ON PREVENTING HEPATOCELLULAR CARCINOMA IN HEPATITIS B VIRUS-RELATED LIVER CIRRHOSIS

Jong Ryul Eun1, Heon Ju Lee2, See Hyung Lee2, Tae Nyeun Kim3, Byung Il Jang4, Jae Won Choi5, Youn Sun Park5, Kyung Ok Kim5, Kyu Hyung Lee2, Hee Jung Moon6, Sang Hoon Lee7; Yeungnam University College of Medicine, Daegu, South Korea

Background/Aims: We evaluated the effect of lamivudine and adefovir dipivoxil on preventing HCC in hepatitis B virus (HBV)-related liver cirrhosis. Patients and Methods: We reviewed the medical records of the patients who were diagnosed with HBV-related liver disease at Yeungnam University Hospital from Jan 1983 to Dec 2005. The number of patients treated with lamivudine over 12 months was 570 and the number of patients treated with adefovir dipivoxil after lamivudine resistance was
284 from Mar 1997 to Dec 2005. The number of patients who could not be treated with oral antiviral agent from 1983 to 1999, followed over 12 months, was 1592. In our results using Cox regression model, 4 factors were related with HCC; gender (male, OR=1.81, p<0.001), age (≥40 years, OR=4.95, p<0.001), platelet count (<150×10^3/mm^3, OR=3.48, p<0.001), and ascites (yes, OR=1.69, p=0.009). Using SPSS program, 111 patients of the oral antiviral agent-treated group and the untreated group were randomly selected, respectively, matching an age variable, a gender variable, liver cirrhosis with Child-Pugh class A and positive HBe antigen. Results: The mean follow-up period was 4.4 years in the oral antiviral agent-treated group and 5.4 years in the control group. In oral antiviral agent-treated group, HCC occurred in 5 patients (4.5%) with an annual incidence rate of 1.02% patients/year, whereas in the control group, HCC occurred in 36 patients (32.4%) with an annual incidence rate of 6.0% patients/year. The cumulative incidence of HCC in the oral antiviral agent-treated group was lower than that in the control group (Log-rank, p=0.003). Conclusion: Oral antiviral agents, such as lamivudine and adefovir dipivoxil may reduce the incidence of HCC in patients with HBV-related liver cirrhosis.

**THE INDICATION AND LIMITATION OF INTERFERON THERAPY AS THE FIRST LINE THERAPY OF CHRONIC HEPATITIS B: FROM THE HISTOLOGICAL ANALYSIS OF 800 CHRONIC HEPATITIS B PATIENTS**

Michiko Shindo1, Kazushige Hamada2, Teruhisa Morikawa1, Yuichi Harano1, Tomoaki Nakajima1, Tadao Okuno1; 1Akashi Municipal Hospital, Akashi, Japan; 2Kyoto Institutes for Technology, Kyoto, Japan

**[AIM]** Current therapy of chronic hepatitis B does not eradicate HBV and has limited long-term efficacy. Thus, careful consideration of the patient’s age, severity of liver disease, likelihood of response, and potential adverse events is needed before treatment is initiated. The role of interferon in the first line therapy is not clearly defined. The degree of liver histology might be related to interferon’s efficacy and limitation. To prove this, we investigated the relationship between the staging score and the interferon response and durability in patients with chronic hepatitis B. [Materials and Methods] A total of 800 Japanese genotyped C treatment naive chronic hepatitis B were studied. All of them had liver biopsy before the treatment. Seven hundred patients were HBeAg positive and the remaining 100 were HBeAg negative. All patients had elevated ALT levels (>2x UNL) and increased HBVDNA (>10^6I) levels. Among these 800 patients, 269 patients with HBeAg positive chronic hepatitis B were treated with interferon alfa therapy (Sumiferon, 6 MU/d, TIW, 4 mo). The patients were stratified by age into 5 year groups beginning with 15-20 y/o until 70-75 y/o. All liver tissue specimens were obtained by needle biopsy. The grade and stage were based on international standard criteria and METAVIR. The relapse after seroconversion was defined as that HBeAg became positive again or that HBeAg remained negative but HBVDNA and ALT elevated for one year after the therapy. [RESULT] 1) The staging scores for each group were generally increased with age from 1.51 (15-20) to 2.75 (61-65), and the degree of fibrosis increased significantly especially after 30 y/o (mean, 2.2) every year at the rate of 0.04-0.06 until 45 y/o (mean, 2.54). 2) Among 269 HBeAg positive patients treated with interferon, 89 (30%) seroconverted to anti-HBe, and among them 74 (83%) had staging score either 1 or 2, and durability was 80-90%. While those with stage 3 or 4 had 50% durability. In nonresponders, the staging score was significantly higher than seroconverters (p=0.0001). [Conclusions] 1) The current study showed that progression of fibrosis appeared to increase significantly especially after 30 year old until 45 year old at the rate of 0.04 to 0.06 every year. 2) Interferon appeared to be effective in patients who had less than staging score 2 with 80-90% durability, while in patients with staging score 3 or 4, interferon did not seem to be similarly effective and the durability appeared to be poor. Thus the degree of fibrosis may be one of the important factors to indicate and limit interferon efficacy for the treatment of chronic hepatitis B.

[Background/Objective] The objective of this study was to elucidate the emergence rate of HBV DNA gene mutation related to entecavir-resistance (ETVr) in chronic hepatitis B patients participated in the phase 2 entecavir (ETV) clinical studies performed in Japan. [Method] The subjects of this study were 287 patients in total, consisted of (1) 137 nucleoside-naive patients in the ETV-047 study administered with 0.01, 0.1, 0.5 mg/day of ETV or 100mg/day of lamivudine (LVD) for 24 weeks, (2) 66 nucleoside-naive patients in the ETV-053 study administered with 0.1 or 0.5mg/day of ETV for 52 weeks, and (3) 84 LVD-refractory patients in the ETV-052 study administered with 0.5 or 1.0 mg/day of ETV for 52 weeks. After the studies, a total of 282 patients were enrolled in ETV-060 roll over study, and subsequently administered with ETV for another 2 years. Single-nucleotide-polymorphism (SNP)-PCR analysis for HBV polymerase was performed to detect the ETVr mutation for the patients who experienced viral rebound, defined as elevation in serum HBV DNA by greater than 1 log copy/mL. [Results] (Result-1: Nucleoside-naive patients). Five out of 169 nucleoside-naive patients with ETV administration (comprising 103 from ETV-047 and 66 from ETV-053), experienced viral rebound before week 148. ETV-related mutation (rtS202S/G) along with LVD-related mutation (rtL180M and rtM204V) was detected in two patients (1.2%) between week 100 and 148. The two patients who developed ETV never experienced a disappearance of serum HBV DNA. The 34 patients in ETV-047 study, who were administered with LVD for 24 weeks followed by administration with ETV 0.5mg, did not develop LVD- or ETV-related mutation throughout the study duration. [Result-2: LVD-refractory patients]. Viral rebound developed in 21 patients out of 84 in ETV-052 study, before week 148, and LVD-related mutation (rtM204I/V and/or rtL180M) along with ETV-related mutation (rtS202 and/or rtT184), was detected in 19 patients (22.6%). [Conclusions] The cumulative number of patients who developed ETVr-related mutation were 0/0/2 at years 1/2/3 in nucleoside-naive group (total n=169 at baseline), and 0/10/19 at years 1/2/3 in LVD-refractory group (total n=84 at baseline), respectively. Development of ETV-related gene mutation was rare in nucleoside-naive patients.

MUTATIONS OF THE HBV-POLYMERASE GENE ASSOCIATED WITH ADV DRUG RESISTANCE IN PATIENTS UNDERGOING A FIRST ADV THERAPY

Karine Sauné1, Florence Abraovaneli, Guillaume Martin-BlondelP, Jacques Izopet1, Laurent Alric2; 1Laboratory of Virology, Toulouse University Hospital, Toulouse, France; 2Service de Médecine Interne, Toulouse University Hospital, Toulouse, France.

Background: HBV resistance mutations have been identified for all oral antiviral agents used to treat chronic hepatitis B. Whereas the rtA181V and rtN236T mutations are associated with long-term adefovir dipivoxil (ADV) treatment, the newly discovered mutation i233V is associated with primary resistance to ADV. Aim: To assess the association between existing HBV polymerase mutations and failure of antiviral therapy in patients given ADV for the first time. Patients and methods: 86 patients began ADV therapy during 2001 and 2005 for more than 12 months, of these 6 (7%) showed no significant viral suppression (less than 1 log IU/ml) and their ALT was elevated when therapy was stopped (NR group). The HBV rt amino-acid sequences from these 6 patients were compared to those of 5 patients who had virus sensitive to ADV (R group). The HBV rt gene was sequenced with in-house protocols (ABI 3100) using sera collected at baseline and at the end of treatment. Results: Phylogenetic analysis of the rt gene HBV gave genotypes A [6/11], D [4/11] and E [1/11]. The rtA181TV and rtN236T mutations were never detected at the beginning of ADV therapy. rtM204I/V and/or rtL180M were detected in 5/11 patients (45%) because most of them had been treated with Lamivudine (LVM). Two of them had lost these LVM-resistance-associated mutations at the end of ADV therapy. Only one patient in the NR group developed rtA181TV and rtN236T mutations (17%) during the ADV treatment. The rtL233V mutation, recently associated with primary resistance to ADV was not detected in any patient and did not exist in patients whose virus was resistant to ADV. But, rtL217R was detected at baseline and at the end of treatment in 3/6 of the NR patients (50%) and in 1/5 R group patients (20%). This mutation, which is more prevalent in HBV strains with genotype A, was found in 3 patients infected with genotype A. Conclusion: HBV strains that are naturally resistant to adefovir can occur, but are not frequent. The rtL233V mutation cannot explain the failure of ADV therapy in our patients, whereas rtL217R mutation seemed to be more frequent. Further studies are needed to clarify the influence of the rtL233V and the rtL217R mutations on ADV therapy.

We evaluated the long-term sustainability of response and clinical outcome in patients treated with PEG-IFN-α 2b alone or in combination with lamivudine for 52 weeks. Methods: All 266 HBeAg positive chronic hepatitis B virus (HBV) infected patients from 41 centers enrolled in the randomized HBV99-01 study were offered participation in a long-term follow-up (LTFU) study. Initial response was defined as HBeAg negativity at the end of the initial study (26 weeks post-treatment; week 78). For the LTFU study, patients had one additional visit after the initial study (mean interval 3.0 ± 0.8 years). For analysis, retreatment was considered as non-response. Results: 172 patients (65%) from 28 centers (68%) were enrolled in the LTFU study. 91 patients (53%) received PEG-IFN-α 2b alone and 81 (47%) its combination with lamivudine. Response rates at different time points are shown in the table. At LTFU, HBeAg loss was durable in 52 of 64 initial responders (81%), of whom 67% had HBV DNA <10,000 copies/ml and 65% had normal ALT. 14 initial responders (21%) and 67 of 108 (62%) non-responders were retreated (p<0.001). HBsAg was negative in 19 initial responders (30%). Sustained HBeAg negativity was observed in 96%, 86%, 67% and 77% of initial responders with genotype A, B, C and D infection, respectively (A vs. C, p=0.04; A vs. D, p=0.07). Serum HBV DNA <10,000 copies/ml was observed in 81%, 29%, 44% and 35% of initial responders with genotype A-D, respectively (A vs. B or D, p<0.02). HBsAg negativity was observed in 58% of genotype A infected initial responders compared to 14%, 0% and 6% of those with genotype B, C or D (A vs. C or D, p<0.004). At LTFU, 3 non-responders had died and 1 developed hepatocellular carcinoma; decompensated liver disease was observed in 1 responder and none underwent liver transplantation. Conclusions: HBeAg response to PEG-IFN-α 2b ± lamivudine is durable in the majority of patients and is associated with an increase in HBeAg loss. This study further emphasizes the importance of HBV genotype in PEG-IFN therapy, with high rates of sustained virological response in genotype A infected patients. PEG-IFN should therefore particularly be considered as first line therapy in genotype A infected HBeAg positive patients.

*p<0.05 PEG-IFN-α 2b + lamivudine (PEG LAM) vs. PEG-IFN-α 2b (PEG); ND = not done

Disclosures:
The following people have nothing to disclose: Erik H. Buster, Hajo J. Flink, Yilmaz Cakaloglu, Christopher Simon, Jörg Trojan, Fahmi Tabak, Thomas M. So, Victor S. Feinman, Tomasz Mach, Ullus Akarca, Wanda C. Tieleman, Hanneke J. van Vuuren, Bettina E. Hansen, Harry L. Janssen.

PREDICTION OF LONG-TERM MAINTENANCE OF VIROLOGIC RESPONSE DURING LAMIVUDINE TREATMENT IN HBEAG NEGATIVE CHRONIC HEPATITIS B

Alexandros S. Hadziyannis1, Panagiota V. Mitsoula1, Stephanos J. Hadziyannis1,2; 1Molecular Biology Of The Liver Lab at Evgenidion Hospital, University of Athens Medical School, Athens, Greece; 2Department of Medicine, Henry Dunant Hospital, Athens, Greece

Background and Aims: It has recently been claimed that non-detectability of serum HBV-DNA by PCR after six months of treatment with telbivudine or lamivudine in chronic hepatitis B (CHB) predicts maintenance of the response after two years of treatment with a positive predictive value (PPV) for HBeAg-negative patients of > 80% The aim of the present study was to investigate in such CHB patients the relation between HBV-DNA suppression achieved during the early phases of lamivudine treatment with the long-term outcome of therapy after 4 and more years. Patients and Methods: The study included 156 patients with 56 of them (37%) in maintained virologic and biochemical responses for more than 4 years. Their virologic data was compared to those of patients who experienced a breakthrough 3 months to 5 years after starting treatment. HBV-DNA data assessed by sensitive real time PCR assays was available every 3 to 6 months and all samples negative or <1000 cp/ml were retested with the COBAS TaqMan Test (Roche Molecular Systems, CA, USA, sensitivity 50 cp/ml). Results: The positive predictive value of negative HBV-DNA after 6 months of treatment was 93% for maintenance of the response for two and 71.5% for maintenance of response for four or years more. Similar percentages were found for the results after 3 months of treatment. On the other hand, a positive result even >10,000 cp/ml at month 6 could not exclude the possibility that LAM therapy would be successful and was associated with a possibility of maintenance of response for 2 years of 36.5% and for 4 or more years of 8%, those percentages being 43.7 and 19.5% for the month three results. Overall, patients who maintained response had lower levels of HBV-DNA both at month 3 and 6 compared to patients who experienced a breakthrough. Conclusion: HBV-DNA non-detectable by sensitive PCR assays during the "early" phases of antiviral treatment of HBeAg(-) CHB are very useful in predicting maintenance of the response up to year 3 of Rx but their positive predictive value decreases to approximately 70% for response maintained longer than 4 years. Moreover their low negative predictive value cannot provide reliable information for deciding treatment discontinuation or modification.

967 AMINO ACID VARIABILITY WITHIN HEPATITIS B SURFACE ANTIGEN AND THE OVERLAPPING REVERSE TRANSCRIPTASE REGION IN HBSAG NEGATIVE/HBCAB POSITIVE PATIENTS PRESENTING HBV REACTIVATION WHILE UNDERGOING CHEMOTHERAPY AND/OR STEM CELL TRANSPLANTATION FOR CANCER

Philippe Colson1,2, Patrick Boretain2, Diane Csoo2, Aude Charbonnier4, Anne-Marie Stoppa4, Thérèse Auran2, Erwan Bories2, Anne Motte1,2, Mireille Henry1,2, Danielle Battia-Fridlund5, Catherine Tamalet1,2, Rene Gerolami3,1, Virology, Timone hospital, Marseille, France; 2CNRS UMR 6020, University of Marseilles Medical School, Marseilles, France; 3Service d'Hépato-Gastroentérologie, Centre Hospitalier Universitaire Conception, Marseille, France; 4Service d'Oncologie, Institut Paoli-Calmettes, Marseille, France

Background/Aim: Hepatitis B virus (HBV) reactivation has been described in HBsAg-/anti-Hbc+ patients (pts) undergoing immunosuppressive chemotherapy (CT). We previously reported HBV reactivation in 8.3% of pts (n=7) with HBV viremic profile indicating past infected who underwent CT and/or hematopoietic cell transplantation (HCT) for cancer. Baseline anti-HBs titer <100 IU/L was significantly associated with HBV reactivation in these pts. In the present study, we aimed to analyse the amino acid (aa) variability and mutations patterns within HBsAg and the overlapping HBV reverse transcriptase (rt) region of HBV strains from these pts to assess whether HBV reactivation might be associated with specific virological features. Patients/Methods: 7 male pts (mean age, 60 years), HBsAg/anti-Hbc+ (HBsAb+/−) prior to CT and/or HCT who presented HBV reactivation between 11/2003 and 12/2005. 4/7 pts received anti-C20. HBV HBsAg and rt genes were amplified/sequenced using in-house protocols. Newly-diagnosed HBsAg-positive pts (n=51) served as controls. Results: HBV genotype was D and C in 5 and 2 cases, respectively. Mean number of substitutions/100 aa was significantly higher vs controls within HBsAg major hydrophilic region (MHR) (8.8 vs 2.1; p<0.01), its “a” determinant (15.7 vs 2.5; p=0.003), and the HBsAg C-terminal region (7.5 vs 3.8; p=0.054). Substitutions D144AA/V and G145RA previously associated with altered S antigenicity were more frequent (from 2 pts each) than in controls (p=0.001 and p=0.004, respectively). Among genotype D sequences, substitutions at positions s116, s126, s134, and s144 within the MHR were significantly more frequent than in controls (p=0.05). No rt drug resistance mutation was detected at time of reactivation. However, within rt sub-domains B-CD that overlap HBsAg C-terminal region and where drug resistance mutations occur, the mean number of substitution/100 aa showed a tendency to be higher in the reactivation group (3.0 vs 1.3; p=0.081), and a significantly higher proportion of sequences harboured >1 substitutions (P=0.05). Mutations rtR/W153Q, known to restore HBV replication of lamivudine (LAM) resistant strains and corresponding to substitutions sG145R, were found in HBV from 1 pt. In 1 pt, LAM-resistance was detected 1 month after LAM introduction. Conclusions: Our data show an increased aa variability within HBsAg and HBV RT associated with HBV reactivation in AgHBs-/anti-Hbc-positive pts undergoing CT and/or HCT. Whether or not these virological patterns may play a role in the pathogenesis and frequency of HBV reactivation or might impact the response to antiviral treatments needs further investigations.

968 ESTIMATING THE IMPACT OF CHRONIC HEPATITIS B ON FUTURE LIVER-RELATED MORTALITY, MORTALITY AND COST IN SPAIN

Maria Buti1, Max Brosa2, Miguel A. Casado3, Magdalena Rueda4, Rafael Esteban1; 1Hospital Vall d‘Hebrón, Barcelona, Spain; 2Oblikue Consulting, Barcelona, Spain; 3Pharmacoeconomics & Outcomes Research Iberia, Madrid, Spain; 4Gilead Sciences Inc, Madrid, Spain

Background and aims: Chronic hepatitis B (CHB) is a common infection often producing progressive disease. Some studies suggest that HBV-related complications will increase in the future, impacting future disease costs. Our aim was to estimate future morbidity, mortality and costs associated with CHB infection in a cohort of patients in Spain. Methods: A Markov model was used to project HBV-related complications and costs over the next 20 years in a cohort of 132,028 patients representing the HBV-infected population in Spain. This cohort was stratified according to age (25-34, 35-44, 45-54, 55-64, 65-74 years), HBeAg status (13% HBeAg-positive and 87% HBeAg-negative), and the degree of liver disease. The probabilities of disease progression in the model were obtained from data published in the literature, and the cost of the disease and its complications were based on actual variable costs from the Spanish Health Care System. An annual 3.5% discount rate was applied to the costs. Results: A greater disease progression and morbidity will be observed in HBeAg-negative patients compared with HBeAg-positive patients, with a higher proportion of HBeAg-negative patients requiring liver transplant (9% vs. 5%) and a higher proportion of deaths (59% vs. 45%). The total cost of the HBV-infected cohort during the next 20 years will be US$5,007 million. The disease progression in HBeAg-negative patients requires an additional cost of 65% in relation to HBeAg-positive patients. The mean estimated cost in US$ per patient and the different stage of the disease distribution over the next 20 years are shown in the table below. Conclusions: In the future, HBV mortality, morbidity, and associated cost will increase. Treatment of the CHB-infected population potentially may control the infection, reduce progression, increase patient survival and reduce the need for liver transplantation.

LIVER BIOPSY: STILL ESSENTIAL IN THE MANAGEMENT OF CHRONIC HEPATITIS B

Patrick Kennedy, Lukshmy Jeyalingam, Heather Lee, Rob Goldin, Peter Karayiannis, Janice Main, Mark R. Thrusz, Ashley Brown, Belinda Smith, Howard C. Thomas; Liver and Antiviral Centre, St Mary’s Hospital, Imperial College, London, United Kingdom

BACKGROUND & AIMS: In the absence of an established role for non-invasive markers of fibrosis, liver biopsy remains the gold standard for the assessment and staging of disease in chronic hepatitis B virus (HBV). With growing numbers of chronic HBV patients attending hepatology clinics, the indications and timing of liver biopsy needs to be clearly defined. The aim of this study was to formally review all biopsies undertaken for a primary diagnosis of HBV in a tertiary referral centre and to assess how histology correlates with disease profile, in particular HBV DNA & ALT. Factors associated with more advanced disease or progression of disease on repeat biopsy were sought.

PATIENTS & METHODS: Between 1995 and 2007, 212 chronic HBV patients underwent liver biopsy. This comprised of 76 HBeAg+ patients (Group 1), 9 of whom underwent repeat biopsy and 136 anti-HBe+ patients (Group 2), 31 of whom underwent repeat biopsy. Two specialist liver histopathologists reviewed all biopsy material and determined Ishak fibrosis scores. A fibrosis score of 0-2 was designated mild disease, 3-4 moderate and 5-6 severe. Quantitative HBV DNA and ALT values [> or < twice upper limit of normal (2ULN)] at the time of biopsy were collected. RESULTS: Fibrosis score correlated with age at biopsy [p<0.01]. In Group 1, 43 patients (57%) [M:F 29:14] had mild disease on histology: median age at biopsy was 30 years [range 16-64]; 33 patients (43%) [M:F 27:6] had moderate/severe disease on biopsy with a median age at biopsy 37 years [range 16-73]; 4/14 (29%) patients with severe disease had HBV DNA >107 and normal ALT were, therefore, considered immuno-tolerant. In Group 2, 71 patients (52%) had mild disease on biopsy, [M:F 50:21] median age at biopsy 36 years [range 18-70]. The remaining 48% (65/136) had moderate/severe disease [M:F 50:15], median age at biopsy 47 years [range 23-73]; 27/65 (42%) with moderate/severe fibrosis had both HBV DNA>105 and ALT <2ULN. Repeat biopsy group Rate of fibrosis change in untreated patients undergoing serial biopsies was highly variable, ranging between improvements of fibrosis score of 0.44 points/year versus progression of one point per year (mean 0.22 points/year). Rate of progression did not correlate with eAg status, HBV DNA or ALT level. However, there was a trend towards faster progression in those with a BMI>25.

CONCLUSIONS: This study highlights the importance of liver biopsy in the diagnosis and management of chronic HBV. It emphasizes the inadequacy of quantitative HBV DNA and ALT values in reflecting underlying liver damage. We conclude that any decision not to offer antiviral therapy should be based on histological findings.

NEUTRALIZING ANTIBODIES TO INTERFERON ALPHA IN CHRONIC HEPATITIS C PATIENTS NON-RESPONDING TO Pegylated INTERFERON PLUS RIBAVIRIN TREATED TO Peg-INTERFERON α-2A AND RIBAVIRIN (ANRS GAMMATI)

Philippe Halfon1, Sophie Pérusat1, Marc Bourlière4, Jean-Pierre Bronowicki5, P. Trimoulet2, Yves Benhamou6, V. Leroy7, Patrick Marcellin8, J. Foucher6, Geneviève Chène3, Patrice Couzigou2; 1Laboratoire Alphabio, Marseille, France; 2CHU Bordeaux, Bordeaux, France; 3CHU Bordeaux, Bordeaux, France; 4SISPED, Bordeaux, Bordeaux, France; 5Hôpital Saint-Jospeh, Marseille, France; 6CHU, Nancy, France; 7Hôpital Pitié-Salpêtrière, Paris, France; 8Hôpital Beaujon, Clichy, France

Background. Neutralizing antibodies to interferon (IFN)-α may explain a lack of antiviral response (Van der Eijk and al. NEJM 2006). We aimed at assessing NAb to IFN-α and IFN levels in non responders (NR) patients retreated by Peg-interferon α-2a (PEG-IFN α-2a) + ribavirin (RIBA). Methods. NR to a first-line treatment of PEG-IFN-α2a + RIBA were included to receive PEG-IFN α-2a [180µg/week] + RIBA (weight-based dosage) for 48 weeks. HCV RNA was measured at week 12 using Taq Man Roche (lower limit of detection 15 IU/ml) in a central laboratory. IFN levels and Nab to IFN-α were retrospectively measured on stored sera at baseline, weeks 4 and 12, using a quantitative sandwich ELISA for Nab to IFN-α (Bender Med-Systems Diagnostics GmbH) with a lower limit of detection of 1.38 ng/ml (similar to Van Der Eijk study). Interferon α-2a levels were measured using a quantitative sandwich ELISA for interferon α (Bender Med-Systems Diagnostics GmbH) with a lower limit of detection of 3.3 pg/ml. Results. Among 43 NR patients with baseline mean HCV RNA 6.1 log10 IU /ml (Inter-Quartile Range 4.7 to 7.4), 85% genotype 1, 53% F3-F4 Fibrosis, HCV RNA decreased greater than 2 log10 in 20 patients at week 12. Nab titers against IFN-α and IFN α titers are shown in the table. No significant association was observed between the presence nor the titers of Nab and HCV RNA levels. Median IFN levels (interquartile range) at weeks 0, 4 and 12 (pg/ml) were < 3.3 (<3.3-to-371.4); 1532 (106.8-to-5000) in the 20 responders and 84.5 (3.3-to-277.4); 1407.4 (120.2-to-2443.4); 1620.1 (120.1-to-2287.1) in the 23 non responders. Conclusion. This study, performed in non selected consecutive NR patients, do not confirm recently published case reports. Re-treatment with PEG-IFN + RIBA is able to be associated with virological response in the presence of antibody-mediated resistance to conventional IFN treatment.

decompensation (ascitis, liver insufficiency, encephalopathy, gastro-intestinal bleeding) were retrospectively evaluated in a cohort of 336 HBeAg- patients referred to the Hepatology Department of Pitié Salpêtrière Hospital (Paris France) since 1980. Patients co-infected with HIV, HDV and HCV were excluded. Age, race, oral anti-HBV therapy (lamivudine, adefovir, tenofovir, entecavir), IFN based therapy, baseline ALT and serum HBV DNA were analyzed using Kaplan Meyer (KM) survival curves. A Cox regression analysis was performed to assess independent predictors of liver decompensation. Results: Main baseline characteristics of included patients are summarized in the table. Age, sex, race, oral anti HBV therapy, serum ALT, serum HBV DNA were significantly associated with liver decompensation in univariate analysis. Age (>35 years, RR 25.72 [3.08-214.80], p= 0.003) and high baseline serum HBVDNA (>6 log copies/mL, RR 11.97 [2.75-52.13], p<0.001) remained independently associated with the risk of liver decompensation in the Cox analysis (n=252). Conclusion: High HBV DNA (> 6 log copies/mL) and age older than 35 years strongly predict the risk of liver decompensation in HBeAg- patients. These patients should be actively considered for anti-HBV therapy independently of serum ALT level. This study was supported by IDENIX PHARMACEUTICAL.

treatment group was defined as HBe seroconversion and HBV-DNA<105 copies/ml at 24 weeks after end of treatment. Age, sex, HBe Ag, pretreatment ALT, ALT-10 and HBV-DNA levels and stage of fibrosis were examined by multivariate logistic regression analysis. Results: All patients had HBV genotype C. In LMV group, 53 patients (63.9%) [29 HBeAg +ve and 24 HBeAg –ve] achieved EVR. Pretreatment median serum IP-10 levels had no significant difference EVR between non-EVR (381 v 339 pg/ml, respectively; p=0.89). From multivariate analysis, pretreatment ALT levels (p=0.001) and negativity for HBe Ag (p=0.01) were independent predictor for EVR. Meanwhile, in sequential treatment group, 11 patients (50%) achieved SVR. Pretreatment median serum IP-10 levels had significant difference SVR between non-SVR (665 v 431 pg/ml, respectively; p=0.03). From multivariate analysis, only pretreatment ALT levels (p=0.002) was independent predictor for SVR. During sequential treatment, IP-10 levels in treated all patients showed dramatic change (median levels:pre LMV(460pg/ml), pre IFN(160pg/ml), post IFN 1week(65pg/ml), post IFN 4weeks(159pg/ml). Conclusion: Our data suggest that pretreatment serum IP-10 levels predict SVR to LMV-IFN sequential treatment in CHB. The difference of significance of pretreatment IP-10 levels predict SVR to LMV monotherapy and LMV-IFN sequential treatment may be derived from that the CHB patients with high IP-10 levels will show good IFN response which is contrary to response for IFN in CHC.

NOT HBEAG-STATUS BUT HBV GENOTYPE PREDICTS RESPONSE TO IFN IN CHRONIC HEPATITIS B
Andreas Erhardt1, Amei Ludwig2, Maurizia Brunetto3, Matei Popescu4, Florian van Bömmel Malle, Siemer5, Ortwin Adams2, Dieter Haussinger1; 1Klinik fuer Gastroenterologie, Hepatologie und Infektiologie, Heinrich-Heine-Universitaet, Duesseldorf, Germany; 2Institut fuer Virologie, Heinrich-Heine-Universitaet, Dusseldorf, Germany; 3Medicina Interna, Universita di Pisa, Pisa, Italy; 4Medizinische Kliniken, Charite, Berlin, Germany; 5Roche Pharma AG, Basel, Switzerland

Background and Aims: In contrast to HBeAg-positive hepatitis B, HBeAg-negative hepatitis B is considered to be associated with a poor sustained virological response towards interferon therapy. The present study investigated the influence of HBV genotype on the presumed HBeAg-dependence of IFN response. Patients and Methods: 399 patients with chronic replicative hepatitis B infected by HBV genotype A (n=141) or HBV genotype D (n=258) were treated with standard interferon-alpha or pegylated interferon-alpha for 4-12 months. HBV genotype was determined by direct sequencing of the HBV X or S gene. 44.4% of the patients had HBeAg-negative hepatitis B and 55.6% HBeAg-positive hepatitis B. Results: Sustained virologic response to standard interferon-alpha therapy was lower in HBeAg negative compared to HBeAg-positive patients (22.1% vs 35.6%; p<0.003). Prevalence of HBV genotype A was higher in HBeAg--positive hepatitis compared to HBeAg-negative hepatitis (59.3% vs. 16.2%; p<0.0001) and opposite to the prevalence of HBV Genotype D (40.7% in HBeAg-positive hepatitis vs. 83.8% in HBeAg-negative hepatitis). SVR was lower for HBV genotype D patients (19.8%) compared to HBV genotype A patients (43.3%; p=0.001). However, there was no difference in SVR between HBeAg-positive and HBeAg-negative patients of HBV genotype A (44.8% vs 38.9%, p=n.s.) neither for HBeAg-positive and HBeAg-negative patients of HBV genotype D (18.5% vs. 21.1%, p=n.s.). Multivariate logistic regression performed for a representative cohort of patients (n=208) identified HBV genotype A vs. D (p<0.002; 95%CI:1.485,43) and HBV DNA (<or ≥200pg/ml; p<0.04; 95%CI:1.01-3.82) but not pretreatment ALT levels (>2 x ULN) nor HBeAg-status as independent predictive parameters of IFN response.

Conclusions: The present data demonstrate that SVR to IFN in hepatitis B was not affected by HBeAg status but by HBV genotype. Therefore genotype dependence of IFN response and geographic variability of HBV genotype prevalence might explain the divergent SR to IFN between HBeAg-positive and HBeAg-negative patients. This should be taken into account for delineation of antiviral therapy in chronic hepatitis B.

INTRAHEPATIC AND SERUM MARKERS OF HBV REPLICATIVE CAPACITY AND THEIR RELATIONSHIP TO SERUM HBEAG TITRES: IMPLICATIONS FOR THE USE OF QUANTITATIVE HBEAG TESTING AS A PREDICTIVE TOOL FOR TREATMENT OUTCOME
Alex Thompson1,2, Margaret Littlejohn2, Anna Ayres3, Seng Gee Lim2, George K. Lau4, Kumar Visvanathan2, Scott D. Bowden2, Paul V. Desmond3, Stephen Locarnini2; 1Department of Gastroenterology, St. Vincent’s Hospital, Melbourne, VIC, Australia; 2Molecular Research and Development, Victorian Infectious Diseases Reference Laboratory, North Melbourne, VIC, Australia; 3Department of Medicine, National University of Singapore, Singapore, Singapore; 4Department of Medicine, University of Hong Kong, Hong Kong SAR, China; 5Department of Medicine, Monash University, Clayton, VIC, Australia

Background: HBeAg seroconversion is one of the major therapeutic endpoints used when treating HBeAg-positive chronic hepatitis B (CH-B). Data from clinical trials suggests a potential role for quantitative HBeAg titres in guiding therapy. However, a commercial assay is not available and HBeAg titres have not been well-characterized in vivo. The relationship of HBeAg titre to viral load (VL) and cccDNA in vivo remains unresolved; interpretation may be confounded by the presence of the basal core promoter (BCP) or precore (PC) variants in the quasispecies pool. Although shown to reduce/abolish HBeAg production in vitro, their impact on HBeAg titre in vivo has not been defined. Aims: 1) To define the normal range of HBeAg titres seen in patients with HBeAg-positive CH-B in the immunoequilibration phase of disease. 2) To correlate HBeAg titres with VL, liver cccDNA, viral genotype and the presence of PC/BCP mutations. Methods: A high throughput commercial HBeAg ELISA kit (Architect, Abbott Laboratories, Ill) was optimised for use as a quantitative assay using the Paul-Ehrlich (PE) reference standard. HBeAg titre was correlated with VL in all patients. Detailed virological characterization was performed in a subset; this included genotype, BCP/PC sequence, and intrahepatic cccDNA (Werle-Lapostolle, Gastro, 2004). Results: The assay was validated using a cohort of 85 untreated HBeAg-positive patients in the immunoequilibration phase of disease. Sequencing was performed in 30 patients. Intrahepatic cccDNA was measured in 17 patients. The linear range of the assay was 0.5 – 90 PE IU/ml. The observed HBeAg titres followed a log-normal distribution (median 1-14236 PE IU/ml). Median VL was 3.43x108 IU/ml. Median cccDNA was 3.65 copies/Geq. VL correlated strongly with...
cddNA (r = .81, p < .05). HBcAg titre correlated modestly with VL (r = .50, p-value < .001) and cddDNA (r = .48, p-value = .05). The lack of a stronger correlation was attributed to the presence of BCP and PC variants in the quasispecies pool (dominant virus WT/WT in 17/30, BCP/WT in 9/30, and WT/PC in 4/30; median HBcAg titres 3095, 209 and 149 respectively, p < .05 vs WT). The effect of the BCP/PC variants was independent of VL HBcAg titre did not differ between genotypes A-D. Conclusion: We have optimised a commercial HBcAg assay for use as a sensitive and accurate quantitative tool. HBcAg titres were log-normal distributed and modestly correlated with VL and cddDNA, which was due to the presence of BCP/PC variants reducing HBcAg titre independent of VL. BCP/PC sequencing should be incorporated into research protocols evaluating the utility of HBcAg titres in predicting treatment outcome.

976 DRUG RESISTANCE MUTATION ANALYSIS BY DIFFERENT METHODS IN A HIGHLY TREATMENT-EXPERIENCED CHRONIC HEPATITIS B PATIENT POPULATION

Joke Doutreligne1, Scott K. Fung2, Tony Mazzulli3, George Moussa4, Vladimir Popovic5, Erwin Sablon2; 1Infectious Diseases, Innogenetics NV, Gent, Belgium; 2Department of Medicine, University of Toronto, Toronto, ON, Canada; 3Department of Microbiology, Mount Sinai Hospital, Toronto, ON, Canada; 4Gilead Sciences Canada, Mississauga, ON, Canada

Background: Antiviral drug resistance in patients with chronic hepatitis B has become a major drawback, ultimately leading to antiviral treatment failure, subsequent biochemical breakthrough, and hepatic decompensation. To optimally monitor treatment of HBV patients, a highly sensitive assay is required that can detect resistance mutations early. Patients and Methods: 133 adult HBV patients attending the liver clinics of University Health Network (Toronto, Canada) were prospectively monitored for antiviral resistance mutations using INNO-LiPA HBV DR assays (Innogenetics, Belgium) and sequencing. The majority was Asian (78%), HBcAg positive (57%), and had mean HBV DNA upon resistance testing 5.4±2.1 log10 IU/μl. Ninety percent had received lamivudine therapy, 40% adefovir, and a few tenofovir or entecavir. INNO-LiPA HBV DR v2* probes cover mutations at codons 80, 173, 180, 181, 204 and 236; a prototype INNO-LiPA HBV DR v3 strip covers codons 184, 194, 202, 233 and 250. Sequencing and LiPA were performed on the same amplicon. Concordance between the LiPA and sequencing was calculated. Results: Viral loads ranged from 1.29-7.7 log10 IU/μl. All genotypes except F were found, with the majority being genotype C (51.1%). Interpretable LiPA patterns were obtained for 133/133 samples (100%); sequence information for 131/133 samples (98.5%). Thirty-four of the 131 samples (26%) showed no mutations at any one of the 11 codon sites with LiPA or sequencing, whereas 97 samples (74%) displayed at least one mutation with one or both methods. Of resistance mutations detected by sequencing, 70% were known mutation at codon 204 after LiPA analysis. With sequencing, 45 patients (86%) and 70 patients (92%) showed these respective mutations. Conclusions: Both LiPA and sequencing are useful and accurate methods for drug resistance mutation detection. However, LiPA enables detection of minor mutant populations as mixtures earlier than sequencing. Earlier detection of resistance mutations using LiPA followed by prompt salvage therapy could help optimize the management of patients with antiviral-resistant HBV.

977 RESTORATION OF HBV-SPECIFIC T CELL RESPONSES IN LAMIVUDINE LONG TERM RESPONDER

Elisabetta Loggi1, Florian K. Bihi2, Cinzia Fortini1, Carmela Curcari2, Elena Grandini3, Lorenzo Micco3, Annagliola Gramenzi3, Mauro Bernardi1, Christian Brandt1, Pietro Andreone1; 1Department of Internal Medicine, Cardioangiology and Hepatology, University of Bologna, Bologna, Italy; 2Division of Gastroenterology and Hepatology, University Hospital of Geneva, Geneva, Switzerland; 3Partners AIDS Research Center, Massachusetts General Hospital, Harvard Medical School, Boston, MA

Background: Hepatitis B virus (HBV)-specific T cell responses appear to play a pivotal role in infection control and disease outcome. The benefit of Lamivudine (LAM), a nucleoside analogue used for HBV treatment, is compromised by progressively increasing emergence of drug-resistant strains (up to 70% after 5 years). However, 20-30% of patients do not develop resistance despite long-term therapy. While LAM has been shown to induce early but only transient restoration of CD4 and CD8-specific T cell responses, the immunological profile of LAM long-term responders (LAM-LTR) has not yet been analyzed. Aim: To assess the HBV-specific T cell responses in LAM-LTR compared to LAM resistant (LAM-R) and to evaluate if successful long-term LAM therapy restores HBV-specific immunity. Methods: Seven LAM-LTR (male/female: 5/2; median age: 60; range: 42-67), defined by sustained HBV suppression during prolonged LAM administration (median years of treatment: 9; range: 7-11) and 13 LAM-R patients (male/female: 12/1; median age: 52; range: 30-60), defined by occurrence of viral breakthrough, were tested with a panel of overlapping peptides (18-20 mers) spanning the entire HBV sequence. The frequency and magnitude of HBV-specific T cell responses was assessed by an IFN-γ ELISPOT assay after in vitro stimulation with the synthetic HBV peptides. Results: HBV-specific immune responses were detected in all LAM-LTR (100%) and in eight of the 13 subjects with LAM-R (61%). The frequency of HBV-specific T cell responses were significantly higher in LAM-LTR compared to LAM-R (median frequency: 5 vs 1, respectively, p=0.001). Moreover, LAM-LTR presented significantly stronger IFN-γ responses (median: 2793 vs 1740 SFC/1,000,000 PBMC, p=0.03). Polymerase-specific immune responses dominated the HBV-specific T cell repertoire in both groups of patients, although LAM-LTR presented multiple responses to all four HBV proteins. Interestingly, two regions, in the core protein and in polymerase, were targeted by 3 LAM-LTR (42%), suggesting two new regions of immunogenicity. Conclusions: LAM-LTR are characterized by a multispecific pattern of HBV specific T cell responses. Moreover, the immune repertoire of responses is stronger in terms of both frequency and magnitude in long term responders than resistant ones. These results can contribute to...
better characterize HBV patients with LTR to antiviral therapy and to help for their clinical management.

TWENTY-FOUR WEEKS THERAPY WITH PEGINTERFERON ALFA-2A IS SIMILAR TO 48 WEEKS THERAPY IN PATIENTS WITH HBEAG POSITIVE CHRONIC HEPATITIS B AND GOOD PREDICTORS OF RESPONSE

Lucrecia Rezzonico1, Omar Galdame1, Bernardo Frider2, Joaquin Solari1, Alejandra Villamil1, Paola Casiato1, Maria Reig1, Juan Bandi1, Analia Alessio1, Adrian Gadano1, 1Medicine, Hospital Italiano, Buenos Aires, Argentina; 2Medicine - Hepatology, Hospital Reig, Juan Bandi, Analia Alessio, Adrian Gadano

Background: 48 week therapy with Peginterferon alfa-2a has demonstrated to be effective in about one third of patients with HBeAg-positive chronic hepatitis B. Although the recommended treatment duration for these patients is 48 weeks, there is no enough data supporting 48 weeks of therapy over 24 weeks of therapy. Treatment might be shortened particularly in patients with good predictors of response. Aim: To compare the efficacy of 48 weeks vs 24 weeks of therapy with Peginterferon alfa-2a, in patients with chronic hepatitis B who had good predictors of response. Patients and Methods: 19 patients with high baseline ALT levels (> 3 ULN) and low viral load (HBV DNA < 109 cp/ml) were treated with Peginterferon alfa-2a 180 mcg/week, during 48 weeks. Virological, biochemical and serological responses were compared with those obtained in 16 patients with similar baseline characteristics treated with Peginterferon alfa-2a for 24 weeks. All patients had a follow-up period of 24 weeks after end of therapy. Results: At end of follow-up, HBeAg seroconversion was observed in 7/19 (36.8 %) of patients treated for 48 weeks and in 6/16 (37.5 %) of patients treated for 24 weeks (p=ns). Patients treated for 48 weeks evidenced a significantly higher decrease in HBV DNA at the end of therapy than patients treated for 24 weeks (-4.8 logs vs -3.6 logs respectively, p<0.05). However, the % of patients with HBV DNA < 100.000 cp/ml was similar in both groups at the end of follow up (42.1 % vs 43.7 %, ns). No significant differences between both groups were observed regarding ALT normalization, HBSAg loss or seroconversion. Serious adverse events occurred in 1 patient from each group. Conclusion: The results from this study indicate that 24 weeks of therapy with Peginterferon alfa-2a is similar to 48 weeks therapy in patients with HBeAg positive chronic hepatitis B who have good predictors of response.

LONG-TERM FOLLOW-UP OF HBSAG CLEARANCE IN PATIENTS WITH HBEAG-NEGATIVE CHB TREATED WITH PEGINTERFERON ALFA-2A: INCREASE IN HBSAG CLEARANCE RATE FROM 3% 6 MONTHS POST-TREATMENT TO 8% AFTER 3 YEARS

Patrick Marcellin1, Maurizia Brunetto2, Ferruccio Bonino3, George K. Lau4, Patrizia Farcì5, Cihan Yurdakal6, Teerba Piratsivuth7, K. Luo8, Y. Wang9, Stephanos J. Hadziyannis10, Eva Wolf11, Matei Popescu12, 1Hôpital Beaujon, Clichy, France; 2UO Gastreonterologia ed Epatologia, Pisa, Italy; 3Foundation IRCCS Policlinico of Milan and University of Pisa, Pisa, Italy; 4Queen Mary Hospital, Hong Kong, China; 5Università di Cagliari, Monserrato, Italy; 6University of Ankara, Ankara, Turkey; 7Prince of Songkla University, Hat Yai, Thailand; 8Nanfang Hospital, Guangzhou, China; 9Xinan Hospital, Chongqing, China; 10Henry Dunant Hospital, Athens, Greece; 11MUC Research GmbH, Munich, Germany; 12Roche, Basel, Germany

Clearance of HBsAg in patients with CHB is associated with long-term clinical outcome and improved survival. It can be induced by treatment with interferon-based therapy but is extremely rare following treatment with direct antivirals. The HBsAg clearance rates 24 weeks post-treatment in patients with HBeAg-negative CHB who were treated for 48 weeks treatment with peginterferon alfa-2a, peginterferon alfa-2a plus lamivudine or lamivudine alone in a multinational randomized trial were 3%, 4% and 0%, respectively. All patients included in this trial were offered entry into an observational study of long-term response 3 years post-treatment. The proportion of peginterferon alfa-2a-treated patients losing HBsAg increased from 3% 24 weeks post-treatment to 8% at 3 years; 9 patients treated with peginterferon alfa-2a monotherapy cleared HBsAg and 9 in the combination therapy group. Loss of HBsAg was observed across all the major HBV genotypes. Eight of the 18 patients developed anti-HBs antibodies. We analyzed the quantitative on-treatment HBsAg levels using the Architect assay (Abbott Diagnostics) for 198 patients treated with peginterferon alfa-2a +/- lamivudine who were included in the long-term follow-up study for whom 3-year post-treatment follow-up data were available. An HBsAg level <10 IU at week 48 was significantly associated with HBsAg loss 3 years post-treatment (relative risk [RR] 22.8; 95% CI 8–64.9; p<0.0001). Of the 23 patients with HBsAg <10 IU/mL at week 48, 12 (52%) had cleared HBsAg by year 3 vs 4/171 patients (2.3%) with HBsAg >10 IU/mL at the end of treatment. An on-treatment reduction of >2 log IU/mL from pre-treatment level to week 48 was significantly associated with HBsAg clearance at year 3 (RR 14.6; 95% CI 5.5–38.5; p<0.0001). Of the 26 patients with an on-treatment HBsAg decline of >2 log IU/mL, 11 (42.3%) had HBsAg at year 3 compared with only 5 of 172 patients (2.9%) with an on-treatment HBsAg decline <2 log IU/mL. Despite the fact that at the end of the 48-week treatment period patients who cleared HBsAg had HBV DNA suppressed to levels <400 cp/mL, an HBV DNA level <400 cp/mL was not predictive of HBsAg clearance 3 years post-treatment. In conclusion, the ability to induce HBsAg clearance, an outcome that is associated with long-term improvement in survival, supports the use of peginterferon alfa-2a as a first-line treatment for patients with HBeAg-negative CHB. Potent HBV DNA suppression appears to be required, but is not sufficient, for subsequent clearance of HBsAg. The ability of interferon-based therapy to induce HBsAg clearance may be associated with its dual immunomodulatory and antiviral mode of action.

VERY HIGH PREVALENCE OF PRECORE (PREC) AND/OR BASAL CORE PROMOTER (BCP) MUTATIONS (MUT) IN HBEAg-POSITIVE (EAG+) AND NEGATIVE (EAG-) CHRONIC HEPATITIS B (CHB) ESPECIALLY AMONG OLDER PATIENTS

Mindie H. Nguyen1,2, Huy N. Trinh2, Ruel T. Garcia2, Jeanine Phan2, Gloria H. Nguyen2, Khanh Nguyen2, Huy Nguyen2, Emmet B. Keeffe1; 1GI and Hepatology, Stanford University Medical Center, Palo Alto, CA; 2Pacific Health Foundation, San Jose, CA

PURPOSE: Relapse is common following anti-HBe seroconversion and discontinuation of therapy for eAg+ CHB. Presence of an eAg+ HBV with preC/BCP Mut among patients who “appear” to have eAg+ CHB may be responsible for such treatment failure. Our goal is to examine the prevalence of preC and BCP Mut in eAg+ CHB patients.

METHODS: We performed a cross-sectional study of 330 CHB patients with genotypic Mut analysis done between 11/05-5/07 at a U.S. clinic. Mut analysis was performed by Quest Diagnostics, San Juan, PR. The following people have nothing to disclose: Mindie H. Nguyen, Huy N. Trinh, Ruel T. Garcia, Jeanine Phan, Gloria H. Nguyen, Khanh Nguyen, Huy Nguyen, Emmet B. Keeffe.

RESULTS: A total of 330 cases were identified and included. All but 4 were Asians. Mean age=46±14, 61% male, median ALT=35 (range:7-1070) U/L. Treatment history was as follows: naive=242 (73.3%), adefovir only=27 (8.2%), lamivudine=adefovir=57 (17.3%), and entecavir=4 (1.2%). Mean HBV DNA was lower in patients with preC/BCP Mut (3.6±107±2.7±108 vs. 1.9±108±4.2±108 IU/L, p=0.0002). Distribution of HBV genotypes was as follows: A=4%, B=67%, and C=28%. eAg+ was seen in 38% and eAg- in 62%. Overall prevalence of preC/BCP Mut was 77%, 95% in eAg- and 49% in eAg+. Mut prevalences increase with age (Figure). The majority of preC Mut detected were G1698A (87%) with G1896A/G, G1896G/A, 1839, 1841, 1845, 1874, or mixed in the remaining. The majority of preC Mut detected were A1762T(A)+G1764A(G,A/G)(90%) with the remaining having single Mut. There were no significant differences PreC/BCP Mut prevalence by gender or treatment groups.

CONCLUSIONS: The prevalence of PreC/BCP Mut is very high among CHB patients, especially among older patients. PreC/BCP Mut prevalence among eAg+ patients is 49% which also increases with age. Patients with mixed wild-type and preC-BCP Mut may be at higher risk for relapse after anti-HBe seroconversion. Baseline Mut analysis may help identify pts who would benefit from long-term therapy despite anti-HBe seroconversion.

FACTORS AFFECTING RESPONSE TO ADEFOVIR TREATMENT IN PATIENTS WITH CHRONIC HEPATITIS B AND LAMIVUDINE RESISTANCE
Sean Pritchett1, David K. Wong1, Colina Yim1, Tony Mazzulli2, E. Jenny Heathcote1; 1Division of Gastroenterology, Toronto Western Hospital, University Health Network, University of Toronto, Toronto, ON, Canada; 2Department of Microbiology, Mount Sinai Hospital, University of Toronto, Toronto, ON, Canada

Background & Aims: Adefovir (ADV) may not always gain control of lamivudine resistant (LAM-R) chronic hepatitis B (CHB). To identify factors that predict adequate ie. undetectable HBV DNA (<60 IU/mL) response to ADV in the treatment of CHB. To identify factors that predict adequate ie. undetectable control of lamivudine resistant (LAM-R) chronic hepatitis B and ADV resistance in 1 yr while on ADV.

Methods: A retrospective study of CHB with genotypic or phenotypic LAM-R treated with ADV 10mg daily in an Add To or Switch To/Add Back Lam treatment strategy. Adequate response to ADV was defined as undetectable HBV DNA (<200copies/ml or <60IU/ml) at 1 yr. Factors evaluated included eAg status, treatment strategy, pre-treatment (just prior to starting ADV) HBV DNA level (PreTxDNA), whether ADV was added at phenotypic or genotypic resistance, and rapid HBV DNA decline at 6 months, defined as >50% logarithmic decline from PreTxDNA. A multivariate analysis was performed both for all patients and for the subset with cirrhosis. Results: Only 45 of 95 (47%) patients achieved undetectable HBV DNA at 1 yr. In multivariate analysis, only PreTxDNA level and >50% decline in HBV DNA at 6 months predicted achieving undetectable HBV DNA at 1 yr. Though patients with a PreTxDNA >7 log IU/ml were only 12% (3% to 43%) as likely to achieve an undetectable HBV DNA at 1 yr compared to patients with HBV DNA <7 log IU/ml, this effect continued below this cutoff. For each 1 log IU/ml increase in PreTxDNA a patient was only 40% (25% to 64%) as likely to attain an undetectable HBV DNA at 1 yr. Patients who at 6 months had >50% logarithmic decline in HBV DNA compared to pre-treatment were 25.4 (3.1 to 206.1) times more likely to reach undetectability at 1 yr. These same factors significantly predicted response at 1 yr when only patients with cirrhosis were evaluated. Three of 21 patients with a <50% decline in HBV DNA at 6 months developed ADV resistance in 1 yr while on ADV. Conclusions: ADV should be started at the first emergence of LAM-R when HBV DNA is lowest to maximize the probability of achieving an adequate response. Assessing the 6 month rate of decline in HBV DNA may identify those who should have anti-viral therapy changed earlier.

983
PREDICTORS OF VIROLOGIC RESPONSE AND RESISTANCE TO ADEFOVIR IN PATIENTS WITH LAMIVUDINE-RESISTANT CHRONIC HEPATITIS B VIRUS INFECTION
Neung Hwa Park, Jung Woo Shin, Jin Woo Park, Seok Won Jung, In Du Jeong, Sung-Jo Bang, Do Ha Kim; Internal Medicine, Ulsan University Hospital, Ulsan, South Korea

Background: Adefovir (ADV) can be used as initial therapy in patients with HBeAg positive or HBeAg-negative chronic hepatitis B or as additional therapy in those with lamivudine (LAM)-resistant HBV. ADV resistance was common in LAM-resistant patients than in treatment-naive patients. We evaluated the virologic response to ADV in patients with LAM-resistant chronic hepatitis B virus infection, and the potential role of primary non-response in prediction of virologic response and resistance.

Methods: Liver panel, HBeAg/anti-HBe, HBV DNA PCR (COBAS Amplicor HBV Monitor assay) were measured every 2 or 3 months during ADV treatment. Genotypic mutation was detected using mass spectrometry-based genotyping assay (RFMP). Primary non-response was defined as a decrease in serum HBV DNA by < 2 log10 copies/ml at 24 weeks of therapy. Virologic breakthrough (VBT) was defined as a >1 log10 copies/ml increase in serum HBV DNA from nadir after achieving virologic response. Virologic response was defined as a decrease in serum HBV DNA to undetectable levels by PCR, and loss of HBeAg. Results: 146 HBeAg positive CHB patients with LAM resistance were received ADV for at least 12 months. Mean treatment duration was 25 months (range 12-42). Mean pretreatment HBV DNA and ALT levels were 7.7 log10 copies/ml and 357 IU/L, respectively. 115 patients were chronic hepatitis, 31 were liver cirrhosis. Serum HBV DNA became undetectable and ALT normalized in 59 (44%) and 121 (82.9%), respectively. Thirty-four (23.3%) patients represented primary non-response. Virologic response was archived in 34 (23.3%) patients. The cumulative rates of virologic response were 9, 22, and 40% at 12, 24, and 36 months, respectively. In multivariate analysis, the absence of primary non-response (OR, 3.34; 95% CI, 1.017-10.965; P<0.001), higher pretreatment ALT (OR, 100; 95% CI, 1.000-1.002; P<0.05), and lower pretreatment HBV DNA (OR, 1000; 95% CI, 1.000-1.000; P<0.05) were independently associated with virologic response. VBT and genotypic ADV resistance were observed in 24 (16.9%) and 18 (12.3%), respectively. The rtA181T, rtN236T, and rtA181V and rtN236T were detected.

Predictive Factors For Effective ADV Therapy In LAM-R CHB (Multivariate Analysis)

>50% decline at 6 months
25.1 (3.1-206.1)\(^c\) | 24.6 (2.4-290.3)\(^c\) |
The cumulative rates of genotypic ADV resistance at 12, 24, and 36 months were 3, 13, and 26%, respectively. In multivariate analysis, the predictive factor associated with VBT was only the presence of primary non-response (OR, 2.46; 95% CI, 1.089-5.547; P<0.05). Conclusions: Primary non-responder to ADV for LAM rescue therapy showed not only lower rate of virologic response, but also higher rate of virologic breakthrough than those of primary responder.

MANAGEMENT OF CHRONIC HEPATITIS B VIRUS (HBV) INFECTION BY PRIMARY CARE PHYSICIANS IN URBAN HOSPITALS AND CLINICS IN NEW YORK CITY

Henry Pollack1, Keija Wan1, Thomas Miyoshi1, Sonali Tawdekar1, Paige Baker1, Dean McEwen2, Cindy Weinbaum3, Stephanie R. Bialek4, George Fryer1, Ronald Low4; 1Pediatrics, NYU School of Medicine, New York, NY; 2Denver Health, Denver, CO; 3Division of Viral Hepatitis, Center for Disease Control and Prevention, Atlanta, GA; 4NYC Health and Hospitals Corporation, New York, NY

Current primary care physician practices with respect to the management of persons with chronic HBV infection are largely unknown and comprehensive recommendations directed to primary care physicians are lacking. In this pilot study we examined chronic hepatitis B disease management practices in primary care settings in New York City HHC South Manhattan Network Hospitals and clinics. Analysis was conducted, retrospectively, through electronic medical record review. We present preliminary results for patients 19-49 years of age who first visited primary care clinics in affiliated facilities during January 2003-December 2006. For the purposes of this analysis, chronic HBV infection was defined as a positive test for hepatitis B surface antigen (HBsAg). The minimum adequate evaluation for chronic HBV infection was defined as testing for HBsAg, VL and ALT. Among the 18,457 patients, 42.4% (7,826) were screened for HBsAg. 893 were HBsAg+. The mean age of HBV-infected patients was 31.8 ± 7.4 years. 57.8% were men. The HBV-infected patients were overwhelmingly APIs (83.9%), followed by Blacks (7.8%), Hispanics (3.6%), and Whites (0.9%). 97.9% of HBV-infected persons were tested for ALT, 71.0% for HBeAg, 68.2% for viral load, and 63.6% for AFP. The rates of testing for HCVAb, HAVAb, HDVAb and HIV were 52.0%, 47.3%, 3.8% and 22.8%, respectively. Approximately one third of the patients (37.8%) received an abdominal ultrasound exam, 9.9% had a CT scan and 0.6% had a MRI. 564 patients (63.2%) had HBeAg, VL and ALT measurements and 306 patients (34.3%) had all three measurements and an ultrasound exam. 83.1% of those with abnormal ALTs had HBeAg and VL tests, higher than 58.5% among those with normal ALTs, p<0.01. Management practices did not differ by patient sex (p=0.51), race/ethnicity (p=0.07), age (p=0.18) or country of birth (p=0.82). Patients at hospital facilities were more likely to receive the minimum adequate evaluation (68.6%, and 64.9%, respectively), compared to patients at community clinics (45.5%, and 29.3%, respectively), p<0.01. In conclusion, the management of patients with chronic HBV infection by primary care physicians in this study was suboptimal according to practice guidelines established by the AASLD. Additional education and training of primary care physicians in the proper management of these patients needs to be implemented and evaluated in order to decrease the long-term morbidity and mortality of persons chronically infected with HBV.

Background: Clevudine therapy in chronic HBV patients resulted in a significant reduction of serum HBV DNA level. The purpose of this abstract is to determine if reduction of HBV DNA with clevudine therapy may lead to decrease of serum hepatitis B surface antigen (HBsAg). Methods: A total of 50 naive patients with chronic hepatitis B received clevudine 30 mg daily for 24 weeks followed by clevudine 10 mg daily for another 24 weeks. Serum HBV DNA was determined by Digene hybrid capture II assay [limit of detection of 4700 copies/ml] and Amplicor PCR assay [limit of detection of 300 copies/ml]. Serum HBsAg was quantified by the ARCHITECT HBsAg assay. Results: Based on the level of HBsAg titer at baseline, patients were stratified into four groups: group I (n = 18), < 10,000 IU/ml; group II (n = 15), 10,000 – 20,000; group III (n = 9), 20,000 – 40,000; group IV (n = 8), > 40,000. Median baseline HBV DNA were 6.1, 7.1, 8.1 and 9.0 log 10 copies/ml and baseline HBsAg levels were 2922, 14577, 25200 and 102605 IU/ml in the group I, II, III and IV, respectively. During first 24 weeks of clevudine treatment, HBsAg titers of group II, III and IV except group I showed a rapid decrease which showed the similar pattern of HBV DNA suppression. At the end of 1-year treatment, median HBV DNA reduction from baseline was 3.6, 4.6, 5.6 and 4.9 log 10 copies/ml and the change of HBsAg level from baseline of 1061, -2887, -5573, and -83909 IU/ml in the group I, II, III, and IV, respectively. Particularly, median serum HBsAg level in group IV at week 48 dropped to 18.2% of pretreatment level. Combined data of HBsAg reduction from group II, group III and group IV at week 48 showed statistically significant decrease (P = 0.002). Con-

A HEPATITIS B VIRUS MUTANT IMPLICATED IN NON-RESPONSE TO SEQUENTIAL TREATMENT WITH ADEFOVIR, LAMIVUDINE AND ENTECAVIR SHOWS CROSS-RESISTANCE TO MULTIPLE ANTIVIRAL AGENTS

Tim Shaw1, Tina Sozzi1, Fee Wong1, Stephen Locarnini1,2; 1Victorian Infectious Diseases Reference Lab, North Melbourne, VIC, Australia; 2Evisar Medical, East Melbourne, VIC, Australia

Background: Development of safe and effective nucleos(t)ide analogue reverse transcriptase inhibitors (NRTI) has revolutionised chemotherapy for chronic hepatitis B (CHB), but prolonged treatment engenders viral resistance and sequential treatment with different NRTI can promote the emergence of multi-drug resistant mutants, which are refractory to continuing therapy and may be cross-resistant to new drugs. Consequently, control of multi-drug resistant HBV is becoming a major challenge. We describe the phenotype of an HBV mutant isolated from a patient with CHB who responded poorly to sequential treatments with adefovir, lamivudine, and entecavir. Isolates from this patient were genotype D and HBeAg negative due to the presence of the precore [pc] G1896A mutation and encoded multiple substitutions in the polymerase region including rtA181T, rtI233V, rtM250L and rtM250L. Cloning established that these were encoded on a single genome. Aims: To determine antiviral drug resistance phenotype of the putative multi-drug resistant rtA181T/rtI233V/rtM250L mutant, and determine how rtI233V and rtM250L influence phenotype. Methods: Mutant HBV clones encoding rtI233V, rtM250L, rtA181T/rtI233V/rtM250L and rtA181T/rtI233V/rtN236T/rtM250L were generated by site-directed mutagenesis from a wild type (WT) genotype D HBV isolate. WT and derived clones harboured the [pc] G1896A mutation, which may increase replication efficiency but does not significantly affect drug resistance. The phenotypes were determined by comparing viral replication in transfected HuH-7 cells. Virus replication and its inhibition were monitored by measuring changes in the amounts of intracellular core-associated viral DNA in cell lysates using a commercial assay kit (Bayer Versant HBV 3.0). Results: The rtA181T/rtI233V/rtN236T/rtM250L substitutions in combination imparted a severe replication defect but conferred high level resistance to all L-nucleosides (lamivudine, telbivudine, clevudine and emtricitabine) as well as high level resistance to the deoxyguanosine analogues diaminopurine, 2',3'-dideoxy-3'-fluoroguanosine and abacavir, and conferred lower level, but still significant, resistance to adefovir and tenofovir. The rtI233V and rtM250L substitutions in isolation did not confer significant drug resistance and significantly reduced replication capacity in the absence of selection pressure, but presumably act to compensate for the replication defects associated with acquisition of drug resistance. Conclusions: Sequential treatment with NRTI promotes multi-drug resistance. It is likely that development of multi-drug resistance could be reduced by combination therapy optimised to individual viral phenotypes.

987
COST-EFFECTIVENESS OF NEW TREATMENT PARADIGMS FOR E-AG NEGATIVE CHRONIC HEPATITIS B

Ahmad Kamal1,2, Lauren B. Gerson1, Aijaz Ahmed1; 1Gastroenterology and Hepatology, Stanford University School of Medicine, Stanford, CA; 2Gastroenterology, Santa Clara Valley Medical Center, San Jose, CA

BACKGROUND: A number of new drugs for chronic hepatitis B have become available in recent years, and several studies show that treatment with either interferon or the oral nucleos(t)ide analogs is cost-effective compared with no treatment. However, the cost-effectiveness of recent treatment algorithms has not been evaluated. METHODS: We considered the base case of a forty year old patient with newly-diagnosed, treatment-naive, e-Ag negative chronic hepatitis B. Using a decision analysis model, we examined seven treatment strategies: (1) no treatment (natural history arm), (2) Adefovir (ADV) with switch to entecavir (ETV) upon emergence of resistance (3) ETV with switch to ADV upon emergence of resistance, (4) ADV with addition of lamivudine (LAM) upon emergence of resistance, (5) ETV with addition of ADV upon emergence of resistance, (6) ADV with addition of ETV upon emergence of resistance, and (7) Peginterferon alfa-2a for one year. We examined the cost-effectiveness of each option from a third-party payer perspective, using a sixty year time horizon and an annual discount rate of 3%. We then separately considered the case of a similar patient with pre-existing LAM resistance. RESULTS: All treatment options yielded more quality-adjusted life years (QALY’s) than the “no treatment” arm. The oral agents demonstrated extended dominance over pegylated interferon. For treatment-naive patients, the most cost-effective option was initial ADV with switch to ETV upon emergence of resistance, yielding an incremental cost effectiveness ratio (ICER) of $6,697 over the next most cost-effective strategy. Among the “add-on” regimens, initial ETV with addition of ADV was a dominant strategy, giving the highest number of QALY’s at the lowest cost. For patients with pre-existing LAM resistance, adding ADV was preferred over switching to ADV or ETV, with an ICER of $37,118 per QALY gained. CONCLUSION: New treatment recommendations for the treatment of e-Ag negative chronic hepatitis B are cost-effective. Initial ADV with switch to ETV upon emergence of ADV resistance is the most cost-effective treatment strategy. Initial ETV with ADV add-on is superior to other “add-on” strategies due to a relatively longer allowable period of monotherapy. In patients who have already developed LAM resistance, adding ADV is cost-effective compared with switching to ADV or ETV, due to a lower rate of subsequent resistance.

HBV reactivation is needed for clinicians treating patients with chronic HBV as pre-emptive therapy against reactivation. Current practice among oncologists is unknown in regard to screening and prophylaxis strategies for HBV. Aims: To assess the practice of oncologists in screening and management of HBV prior to initiating chemotherapy. Methods: A survey was sent to AMA registered oncologists in the United States assessing practice demographics and HBV screening practices. Fischer’s exact test was used for analysis. Results: Responses were obtained from 265 individuals: 38% (n=101) from an office-based practice, 55% (n=145) from a university/academic/research institution, and 6% (n=17) from other practice setting. Office-based physicians were less likely to screen for HBV prior to chemotherapy (p<0.001). Years in practice varied: 51% with <5 years (n=136), 29% with 5-15 years (n=77), and 18% with >15 years (n=49). No difference was found in screening practices based on years of experience (p=NS). Surveyors screen for HBV as follows: never-20% (n=54), abnormal liver tests-30% (n=80), risk factors or history of hepatitis-38% (n=101), randomly-11% (n=28), always-13% (n=35). Most oncologists used HB surface antigen as a screening test (76%), in conjunction with surface antibody (64%), and core antibody (46%). In pts with HBV, 75% (n=201) of oncologists refer to specialists and 7% (n=18) initiate therapy themselves, while 15% (n=39) do not refer or initiate therapy, most of whom are in an office setting (p=0.02). Conclusions: 20% of oncologists never screen for HBV prior to initiating chemotherapy, and fewer than 40% screen even if patients have risk factors or a history of hepatitis. Screening practices were not influenced by years in practice, however office-based physicians were less likely to screen, treat, or refer to a specialist prior to chemotherapy. Greater education and awareness regarding risk of HBV reactivation is needed for clinicians treating patients with immunosuppressive therapies.

PROFILES OF HBV DNA, ALT AND HBEAG STATUS AFTER STOPPING LAMIVUDINE IN PATIENTS WITH HBEAG SEROCONVERSION

James Fung1, Ching Lung Lai1, Yasuhito Tanaka2, Masashi Mizokami3, John Yuen1, Danny Wong1, Man-Fung Yuen1; 1Department of Medicine, University of Hong Kong, Hong Kong, China; 2Department of Clinical Molecular Informative Medicine, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan

Aim: To determine the virological and biochemical relapse rates in Chinese CHB patients with lamivudine-induced HBeAg seroconversion after stopping lamivudine therapy, and to identify significant viral or biochemical factors predictive of subsequent relapse. Methods: All patients from all Hepatology Clinic with lamivudine-induced HBeAg seroconversion with subsequent cessation of lamivudine therapy were recruited. Liver biochemistry, HBeAg, anti-HBe, and serum HBV DNA by PCR (COBAS Taqman) was determined at the time of stopping lamivudine, at 3 months, 6 months, 1 year, and yearly thereafter. Results: Twenty-two patients were included, of which 16(73%) were male with a median age of 32 years (range, 21-55). The median duration of follow-up was 104 months (range, 31-150). Six (27%) patients had undetectable HBV DNA by PCR at the time of stopping lamivudine treatment. In total, 7(32%) patients had subsequent flare (as defined by ALT >2x upper limit of normal), with associated virological rebound of HBV DNA (as defined by 1 log increase from time of stopping therapy). The cumulative incidence of flare at 5 years was 44%, all occurring before 25 months. There was no significant difference in the cumulative incidence of flares between those patients that continued lamivudine for 6-12 months, 1-2 years and over 2 years after HBeAg seroconversion (p=0.58). In patients who had normal ALT and undetectable HBV DNA, their cumulative incidence of flare was not significantly different to those that had detectable HBV DNA or abnormal ALT at time of stopping lamivudine (p=0.73). Two patients underwent HBeAg seroconversion at 5 and 10 months, with resulting flares. The cumulative incidence of HBeAg seroconversion after stopping lamivudine was 9% at 5 years. Fourteen (64%) patients underwent virological rebound, with a cumulative incidence of 82% at 4 years. There was no significant difference in the cumulative incidence of virological rebound in patients with detectable HBV DNA at the time of stopping lamivudine therapy compared to those with detectable HBV DNA. Of those with virological rebound, 8(57%) had HBV DNA >10^5 copies/ml. Neither patient age or gender, genotype, presence of precore or core promoter mutations were significant factors in subsequent flare or virological rebound after stopping lamivudine therapy. Conclusion: Despite the high sustained HBeAg seroconversion (81%) after stopping lamivudine, HBV DNA rebound occurred in 64%, of which 57% had HBV DNA >10^5 copies/ml and 32% had ALT flares. Patients who had both normal ALT and undetectable HBV DNA by PCR at the time of stopping lamivudine therapy did not have a lower cumulative incidence of flares.

REDUCTION IN SERUM HBsAg LEVEL IN PATIENTS WITH CHRONIC HEPATITIS B INFECTED WITH GENOTYPE D INDUCED BY (PEGYLATED)INTERFERON ALFA-2A ALONE OR IN COMBINATION WITH NUCLEOS(T)IDE ANALOGS: A LONG-TERM SINGLE CENTRE COHORT STUDY

Maurizio Brunetto1, F. Moriconi1, D. Cavallone1, F. Oliveri1, A. M. Maina1, P. Ciccossi1, P. Columbatta1, B. Coco1, G. Moscato2, Ferruccio Bonino2, 1UO Gastroenterologia ed Epatologia, Pisa, Italy; 2Laboratorio Centrale, Azienda Ospedaliera Universitaria Pisana, Pisa, Italy; 3Foundation IRCCS Policlinico of Milan and University of Pisa, Pisa, Italy

In patients with CHB undergoing antiviral therapy, clearance of serum HBsAg appears to be associated with better long-term clinical outcome. In clinical practice, quantification of serum HBsAg might provide a valuable tool to identify the best therapeutic strategy for individual patients. We quantified serum HBsAg (Architect, Abbott Diagnostics) in a total of 80 consecutive HBV genotype D patients treated at our chronic viral hepatitis reference center. The patients received interferon (IFN) alfa-2a [recombinant or pegylated] monotherapy (11 patients), PEG-IFNα-2a + lamivudine [LMV] (24 patients), LMV or adefovir [ADV] monotherapy (6 patients) or LMV + ADV (39 patients). Of the 80 patients, 45 were resistant to LMV; we treated 39 of these with LMV + ADV and 6 with LMV + PEG-IFNα-2a). Baseline characteristics such as gender, HBeAg, viral load and ALT level were not significantly different between the 2 groups of patients receiving (PEG)-IFN +/- nucleos(t)ide analogs (NA) or NAs alone. Patients treated with NAs had lower HBsAg baseline levels (mean 3.39 vs 3.77 log IU/mL, p=0.025) and were older (mean 57 vs 45 years, p<0.001). Patients were followed up for a mean duration of 40 months (24–84 months). The overall serum HBsAg delta variations (log decline from baseline to last observation) according to treatment group are reported in the Table. Almost all patients treated with NAs alone had no or minimal reduction in HBsAg level and none of these cleared HBsAg during follow-up. In contrast, the majority of patients who received interferon-based therapy showed a reduction in HBsAg level of at least 0.5 log and 4 patients achieved HBsAg clearance. In conclusion, IFNα-2a (conventional or pegylated) appears to be more effective in suppressing serum HBsAg independently of baseline host and virologic features, also in patients who are resistant to LMV therapy. Quantification of serum HBsAg could provide a useful tool to predict the long-term outcome of interferon-based therapy and its ability to induce HBsAg clearance in CHB patients infected with genotype D.

HIGH RATES OF HBsAg SEROCONVERSION IN CHRONIC HEPATITIS B PATIENTS RESPONDING TO INTERFERON THERAPY: A LONG TERM FOLLOW-UP STUDY

Anneke Korevaar1, Rami Moucari1,2, Tarik Asselah1,2, Olivier Lada2, Nathalie Boyer1,2, Michèle Martinot-Peignoux1, Pierre Bedossa2, Patrick Marcellin1,2; 1Gastroenterology, Beaujon Hospital, Clichy, France; 2INSERM U773-CRB3, Beaujon Hospital, Clichy, France; 3Pathology, Beaujon Hospital, Clichy, France

Background and Aim Loss of HBsAg with seroconversion to anti-HBs is the most desired treatment endpoint in chronic hepatitis B (CHB), and can be considered a complete response indicating resolution of hepatitis B. The difficulty is that HBsAg loss is rare, occurring spontaneously in less than 1% per year in inactive carriers and in patients receiving a one-year course of nucleos(t)ide analogue therapy. HBsAg loss is more frequent with interferon based therapy, occurring in up to 8% of patients three years post-treatment. The aim of this study was to assess the long term HBsAg response in a cohort of HBsAg-positive CHB patients treated with interferon. Patients and Methods All consecutive patients with HBeAg-positive CHB treated with conventional interferon between 1987 and 2000 were retrospectively evaluated. There were 97 patients. Sustained virological response (SVR) was defined as persistent HBsAg seroconversion and undetectable HBV DNA in serum 24 months after treatment discontinuation and during the follow-up period. Cumulative incidence of HBsAg seroconversion was assessed during the follow-up period and compared between patients with and without SVR. Results The baseline characteristics of the study population were: male gender (88%), mean age (39±13 years), mean ALT level 4.5±3.5 ULN, mean serum HBV DNA level 7.3±0.9 log10 copies/ml. Liver histology showed moderate-severe necroinflammation (META VIR A2-A3) in 42%, and severe fibrosis (META VIR F3-F4) in 44% of patients. SVR was achieved in 25 patients (26%). At multivariate analysis, SVR was independently associated with age > 45 years (p=0.008, OR=4.6) and serum HBV DNA level < 6 log10 copies/ml (p=0.002, OR=9.4). During a median follow-up period of 11 years (4.20), HBsAg seroconversion developed in 28 patients (29%), and was significantly more frequent in patients who achieved SVR than in those who failed interferon treatment (64% vs. 17%, p<0.0001). The cumulative incidence of HBsAg seroconversion was significantly higher in patients who developed SVR compared with those who failed interferon treatment during the whole follow-up period (40% vs. 8% at year 5, and 60% vs. 18% at year 10 and 80% vs. 30% at year 15). Five patients developed hepatocellular carcinoma (HCC) after a median period of 7 years (5-12) post interferon treatment. None of these patients had developed HBsAg seroconversion (p=0.02). Conclusion Patients with HBsAg-positive CHB achieved a 26% SVR rate following treatment with conventional interferon. Long-term follow-up showed that SVR was associated with a very high rate of HBsAg seroconversion (60% at 10 years) and a significant decrease in the incidence of HCC.

HBSAG SEROCONVERSION: DIFFERENT KINETICS OF SERUM HBSAG LEVEL DECREASE IN INACTIVE CARRIERS AND CHRONIC HEPATITIS B PATIENTS TREATED WITH INTERFERON

Rami Moucari1,2, Vincent Mackiewicz3, Olivier Lada2, Agnes Devergne4, Nathalie Boyer1, Tarik Asselah1,2, Michèle Martinot-Peignoux2, Michel Vidaud4, Marie-Hélène Nicolas-Chanoine3, Patrick Marcellin1,2, 1Hepatology, Beaujon Hospital, Clichy, France; 2INSERM U773-CRB3, Beaujon Hospital, Clichy, France; 3Microbiology, Beaujon Hospital, Clichy, France; 4Biochemistry, Beaujon Hospital, Clichy, France

Background and Aim HBsAg is used typically as a qualitative serological marker for diagnosing an ongoing HBV infection. HBsAg clearance is the most desired treatment endpoint in hepatitis B and considered as resolution of disease. Recently, a quantitative, fully automated chemiluminescent microparticle immunoassay (Abbott Architect HBsAg QT) has become available for the quantitation of HBsAg at a wide range of concentrations. The aim of this study was to assess the kinetics of HBsAg level decrease in serum of patients who have cleared HBsAg spontaneously or following interferon therapy. Patients and Methods 22 HBV-infected patients who have cleared HBsAg have been retrospectively studied. Five patients were inactive carriers while 17 have been successfully treated with interferon. HBsAg clearance occurred after a median period of 6 years (2-14) after treatment discontinuation. Serum samples collected at yearly interval up to 4 years prior to HBsAg clearance and adequately kept frozen were retrospectively analysed. Samples were diluted 1:20 and 1:500 with the Architect HBsAg diluent in order to expand the upper limit of quantitation in serum at wide range of concentrations. These data also suggest that interferon treatment accelerates HBsAg clearance. Further studies are ongoing to explore the clinical relevance of HBsAg quantitation for the monitoring of patients treated either with interferon or analogues.

HIGH PREVALENCE OF SIGNIFICANT HISTOLOGIC DISEASE IN PATIENTS WITH CHRONIC HEPATITIS B (CHB) AND NORMAL ALT

Mindie H. Nguyen1,2, Huy N. Trinh2, Ruel T. Garcia2, Jeanine Phan2, Gloria H. Nguyen2, Gerald Weiss3, Huy Nguyen2, Emmet B. Kefee1, 1GI and Hepatology, Stanford University Medical Center, Palo Alto, CA; 2Pacific Health Foundation, San Jose, CA; 3Pathology, San Jose Regional Medical Center, San Jose, CA

PURPOSE: Current guidelines recommend therapy for CHB with elevated ALT. However, many patients presenting with “normal” ALT may not have persistently normal levels on f/u. Our goal was to define the spectrum of histologic findings in such patients. METHODS: We performed a retrospective cohort study of all patients with active CHB (HBV DNA≥10000 copies/ml) & ALT<UNL during liver biopsy at a GI clinic. Significant histology was stage II or grade 2+ stage I or higher. RESULTS: Of the 136 potential cases, we excluded 4 with +anti-HCV and 3 with significant EtOH use and included 129 cases. Mean age=45±11, mean weight =62±14 kg, 65%=male, 28%=smokers. 6% had DM, 40% had hyperlipidemia, 18% had FH of liver CA/liver-related death. All were Asian: 58% were HBeAg+. At biopsy, mean HBV DNA=6.2±1.9 log10 copies/ml and mean ALT=45±18 U/L. Average number of ALT levels per patient =4.1±2.5 over a median f/u of 17 months (range:1-113), when 38% had at least one ALT>UNL. Mild steatosis was seen in 28% and moderate in 11% but this finding was not a significant predictor. The overall prevalence of significant histology was 43.4% & increased with age (Figure): 31% in those with persistently normal ALT and 63% in those without. On univariate analysis, predictors of significant histology were age, weight, HBeAg negativity, & abnormal ALT on f/u. On multivariate analysis, predictors were elevated ALT (OR=5.1, p=0.0001) and age (OR=5.2, p=0.037 for age 35-49; OR=11.2, p=0.005 for age 50-64; & OR=28.0, p=0.007 for age≥65). CONCLUSION: Only 62% of patients with normal ALT at evaluation have persistently normal levels on follow-up, a third of whom can still have significant histology. Older age starting at 35 is the strongest independent predictors of significant histology. Asian patients with normal ALT should be followed closely and histologic evaluation should be considered if patients are ≥35 or if ALT becomes elevated.

BASELINE PARAMETERS PREDICT BOTH EARLY Virologic RESPONSE AND LONGER TERM OUTCOMES FOR TELBIVUDINE-TREATED PATIENTS WITH CHRONIC Hepatitis B (THE GLOBE STUDY)

Stefan Zeuzem1, Maria Buti2, Edward J. Gane3, Yun-Fan Liaw4, Adrian M. Di Bisceglie5, E. Jenny Heathcote6, Nikolai V. Naoumov7, Jens Rasenack8, Seng Ge Lim9, Jin Lin Hou10, Xin-Jian Qiao11, Karin Gilil11, Johann Wolfgang Goethe University, Frankfurt, Germany; 2 Vall d’Hebron University Hospital, Barcelona, Spain; 3 University of Auckland, Auckland, New Zealand; 4 Chang Gung Memorial Hospital and University, Taipei, Taiwan; 5 Saint Louis University School of Medicine, St. Louis, MO; 6 Toronto Western Hospital, Toronto, ON, Canada; 7 Novartis Pharmaceuticals, East Hanover, NJ; 8 University of Virginia Health Science Center, Charlottesville, VA; 9 National University Hospital, Singapore, Singapore; 10 Nanfang University of Medical Science, Guangzhou, China; 11 Indenix Pharmaceuticals, Cambridge, MA

Background: Viral load at 24 weeks of telbivudine treatment has been linked to efficacy outcomes after 1 and 2 years. Studies have shown that pretreatment, elevated ALT and low HBV DNA levels predict higher responses to interferon, however few corresponding data are available for nucleos(t)ide therapies for hepatitis B. Here we report that baseline disease variables predict virologic responses to telbivudine at 24 weeks, which in turn predict efficacy outcomes at 2 years. Methods: The GLOBE trial enrolled 1,367 HBeAg+ and HBeAg- hepatitis B patients with HBV DNA >6 log10 copies/mL, ALT 1.3-10 xULN, and compensated liver disease, randomized to receive telbivudine or lamivudine for 2 years. The influence of baseline parameters and early HBV DNA suppression on subsequent efficacy outcomes and resistance were evaluated by univariate and multivariate regression analyses. Results: Pretreatment serum HBV DNA and ALT levels were significant predictors of virologic response at Week 24 and of efficacy outcomes and viral breakthrough at Week 104. Among HBeAg+ telbivudine recipients with ALT ≥2 xULN and HBV DNA <9 log10 copies/mL, 47% and 14% experienced HBeAg seroconversion and viral breakthrough at Week 104, respectively, vs. 30% and 29% among all HBeAg+ telbivudine recipients. 71% of patients in this subset were PCR-negative after 24 weeks of telbivudine, vs. 44% of HBeAg+ telbivudine recipients overall. HBV genotype had minor, generally nonsignificant effects on outcomes. Similar relationships were observed in HBeAg- patients with elevated ALT and serum HBV DNA <7 log10 copies/mL at baseline, however due to the higher overall rate of viral clearance in this group, baseline parameters had a less pronounced effect on virologic responses at Weeks 24 and 104, compared with HBeAg+ patients. After initiation of treatment, multivariate analyses showed a diminished impact of baseline parameters on subsequent outcomes, and confirmed viral load at Week 24 as the most significant predictor of outcomes at Week 104. Among patients with HBV DNA <9 log10 copies/mL and elevated ALT at baseline, PCR negativity at Week 24 resulted in 52% HBeAg seroconversion and 3.6% viral breakthrough at 2 years. Conclusions: High rates of efficacy responses after 2 years of telbivudine, and low resistance, occurred in patients with elevated ALT and HBV DNA <9 log10 (HBeAg+ patients) or <7 log10 (HBeAg patients) copies/mL pretreatment, coupled with optimal viral load reduction at Week 24. These results define patient characteristics associated with optimal responses to telbivudine and may contribute to on-treatment patient management strategies.

995
ON-TREATMENT Virologic SUPPRESSION AT WEEK 24 DECREASES THE RISK OF HISTOLOGIC PROGRESSION AT 1 YEAR; DATA FROM THE GLOBE TRIAL

Yves Benhamou1, Adrian M. Di Bisceglie2, Zachary D. Goodman3, Pietro Lampertico4, Michael P. Manns5, Pamela Vig6, Xin-Jian Qiao1, Hospital Pitie Salpetriere, Paris, France; 6 Saint Louis University School of Medicine, St. Louis, MO; 2 Armed Forces Institute of Pathology, Washington, DC; 4 University of Milan, Milan, Italy; 5 Medizinische Hochschule Hannover, Hannover, Germany; 6 Indenix Pharmaceuticals, Cambridge, MA

Background: Serum HBV DNA and ALT level have been correlated with active liver disease in patients with chronic hepatitis B (CHB). However, on-treatment predictors of liver disease progression have been inadequately studied. Objective: To identify on-treatment predictors of worsening of HBV-related liver disease. Methods: The GLOBE trial enrolled 1367 compensated CHB patients with baseline HBV DNA >6 log10 copies/mL, ALT 1.3-10 xULN. Patients were randomized 1:1:1 to treatment [telbivudine (600 mg/d PO) or lamivudine (100 mg/d PO)] and stratified by HBeAg status and baseline ALT level. Predictors of histologic progression at Week 52 (WS52) were evaluated using baseline (BL) and 24-week (W24) data from the GLOBE trial. Progressors (P) exhibited [1-unit increase in Ishak Fibrosis Score (IFS)] OR [2-unit increase in Knodell Necroinflammatory Score (KNS)] with no decrease in IFS at WS52. All other patients were deemed non-progressors (NP). Stepwise logistic regression analysis of data from 349 telbivudine patients and 535 lamivudine patients compared P (n=142) to NP (n=942) after 52 weeks of treatment; p-values and odds ratios of being P at W52 were calculated. Factors were entered into the model using α=0.25, and retained in the model using α=0.1. BL factors included IFS, KNS, viral load, e-antigen status, genotype, ALT, BMI, age, gender, and treatment assignment. On-treatment factors were viral load reduction, ALT decline, and PCR negativity (all at week 24). Results: BL IFS (OR=5.0) and KNS (OR=2.7) were the only significant factors predicting P (p<0.0001 for both), with lower scores being more predictive of P than higher scores, possibly due to higher IFS and KNS responding better to antiviral treatment. The only significant on-treatment predictor of P (p≤0.05) was failing to achieve a decline in HBV DNA of ≥5 log10 copies/mL by W24 (p=0.0058), which increased the likelihood of P by 57%. Genotype, baseline BMI and treatment arm were retained in the model but were not significant at p<0.05. However, significantly more telbivudine-treated patients achieved ≥5 log10 decline in HBV DNA compared with lamivudine (69% vs. 55%, p<0.05). Conclusion: Although baseline histology status was the most important predictor of disease progression at 1 year, the only significant on-treatment factor found to reduce the likelihood of progression was attaining HBV DNA decline ≥5 log by W24. These data suggest that using a more potent antiviral agent can result in histologic improvements over periods as short as one year. Longer term studies are needed to evaluate the effects over time. IMPACT OF ADEFOVIR DIPIVOXIL ON LIVER FIBROSIS AND ACTIVITY ASSESSED WITH FIBROTEST-ACTITEST IN PATIENTS INFECTED BY HEPATITIS B VIRUS
Thierry Poynard¹, Yen Ngo¹, Patrick Marcellin³, Stephanos J. Hadziyannis², Vlad Ratziu³, Yves Benhamou⁴, Carol Brosgart⁵; ¹APHP CHPS, Paris, France; ²Gilead, Foster City, CA; ³APHP Beaujon, Paris, France; ⁴Henri Dunant Hospital, Athens, Greece

Background: The aim was to assess the usefulness FibroTest-ActiTest (FT-AT) as surrogate markers of histological features in patients with chronic hepatitis B based on a correlation analysis with biopsy data in pivotal studies with adefovir dipivoxil.

Methods: Patients with chronic hepatitis B randomized in two pivotal trials of adefovir versus placebo, with available paired liver biopsy and FT-AT at baseline and after 48 weeks of treatment were included. Fibrosis and Activity were assessed blindly according to ISHAK scoring system. Diagnostic value of FT-AT was assessed using the area under the receiver operating characteristic curves (AUROCs) for the diagnosis of bridging fibrosis, cirrhosis, and moderate-severe necro-inflammatory activity; sensitivity analyses take into account race, length of biopsy, HBsAg status and sample date. The impact of treatment versus placebo was assessed on liver injury according to baseline stage, and virological response at 48 weeks. For baseline discordant cases, 48 weeks repeated estimates in adefovir virological responders and placebo non-responders permitted to estimate the ratio due to FT-AT or biopsy failures. Findings: 462 patients were included, 304 treated with adefovir and 158 received placebo with paired FT-AT and biopsies. The analysis of 924 estimates showed for the diagnosis of bridging fibrosis, cirrhosis, and moderate-severe necro-inflammatory activity very significant FT-AT AUROCs: 0.76±0.02, 0.81±0.02 and 0.80±0.01 respectively. Similar impacts on liver fibrosis and activity were observed both with biopsy and FT-AT, with greater efficacy in patients with baseline advanced fibrosis, treated with adefovir and virological responders. The discordances analyses suggested that 66% of discordances were attributable to biopsy failure and 34% to FT-AT failure. Conclusion: In patients with chronic hepatitis B, FibroTest-ActiTest is a simple and non-invasive quantitative estimate of liver fibrosis and necroinflammatory activity, which could be used as a surrogate marker to reduce the need for liver biopsy.

LONG-TERM FOLLOW-UP OF ENTECAVIR TREATED PROTOCOL-DEFINED NON-RESPONDERS IN ROLLOVER STUDY ETV-901
Morris Sherman¹, Mario Rizzetto², Ching Lung Lai³, Yun -Fan Liaw⁴, Adrian Gadano³, Ira M. Jacobson⁵, Eugene R. Schiff⁶, Joanna Yang⁷, Richard Colombo⁸, Bruce Kreuter⁹, Robert Hindes¹⁰; ¹Toronto General Hospital, Toronto, ON, Canada; ²Ospedale S. Giovanni Battista, Turin, Italy; ³Queen Mary Hospital, University of Hong Kong, Hong Kong, China; ⁴Linkou Chang Gung Memorial Hospital, Taoyuan, Taiwan; ⁵Hospital Italiano Regional del Sur, Buenos Aires, Argentina; ⁶University of Miami, Miami, FL; ⁷Bristol-Myers Squibb Pharmaceutical Research Institute, Wallingford, CT; ⁸Bristol-Myers Squibb Pharmaceutical Research Institute, Princeton, NJ; ⁹Department of Medicine, Weill Medical College of Cornell University, New York, NY

Background: Entecavir’s (ETV) efficacy in nucleoside naïve HBeAg(+) [ETV-022] and HBeAg(-) [ETV-027] patients with chronic hepatitis B (CHB) has been demonstrated.¹,² Protocol-defined patient management criteria dictated that ‘Non-Responders’ in ETV-022 and ETV-027 discontinued study therapy. However, ‘Non-Responders’ who enrolled in rollover study ETV-901 continued to be monitored and are reported here.

Methods: 679 nucleoside-naïve HBeAg(+) and HBeAg(-) patients were enrolled and treated with ETV in studies ETV-022 and ETV-027. Patients who failed to achieve HBV DNA <0.7 MEq/mL by bDNA at week 48 or during year-2 were classified as ‘Non-Responders’, discontinued study and were offered continued entecavir (1 mg) treatment in rollover study ETV-901 or at the discretion of the investigator, alternative off-study anti-HBV therapy. The proportions of patients with HBV DNA <300 copies/mL by PCR assay, ALT normalization and HBeAg seroconversion were assessed during long-term follow-up in ETV-901. Results: At 48 weeks, 19 HBeAg(+) and 3 HBeAg(-) ETV-treated patients were classified as ‘Non-Responders’ (3%). Among patients treated during year-2, 8 additional HBeAg(+) patients became ‘Non-Responders’ (8/269 [3%]). Twenty-one HBeAg(+) patients from ETV-022 enrolled in ETV-901. Median HBV DNA and ALT at entry into ETV-901 were 3.3 log₁₀ copies/mL and 37 IU/L respectively. The table below shows proportions of patients who achieved HBV DNA <300 copies/mL by PCR, ALT normalization and HBeAg seroconversion as well as the proportions of patients who maintained these endpoints at their last observation. Four patients experienced a virologic breakthrough. However, genotypic and phenotypic analysis failed to show any evidence of resistance. No patients discontinued due to adverse events. Conclusions: Fewer than 5% (30/679) of nucleoside-naïve HBeAg(+) and HBeAg(-) patients treated in ETV-022 and ETV-027 met protocol-defined criteria of ‘Non-Response’. Substantial proportions of ‘Non-Responders’ subsequently achieved undetectable HBV DNA and ALT normalization in ETV-901. Approximately one third of patients also experienced HBeAg seroconversion. PROGNOSTIC FACTORS THAT ASSOCIATED WITH HEPATITIS B VIRUS DNA BREAKTHROUGH IN CHRONIC HEPATITIS B PATIENTS WITH LAMIVUDINE TREATMENT
Zheng Zeng, Guobao Tian, Di Tian, Jianjun Cui, Haiying Lu; Peking University First Hospital, Beijing, China
Objective: To early determine the prognostic factors associated with hepatitis B virus DNA breakthrough in chronic hepatitis B patients with lamivudine treatment. Methods: Clinical data, YMDD genotyping, HBV DNA loads, ALT level, HBeAg titer and lamivudine-resistant HBV mutant ratio, before and during therapy collected from 64 patients throughout lamivudine treatment 48 weeks were retrospectively analyzed by using non-parametric test and logistic regression model test. HBV DNA viral loads were determined by real-time PCR, ALT level were determined by automatic biochemistry analysis system, HBeAg titer were measured by microparticle enzyme immunoassay, and the lamivudine-resistant HBV ratio were determined by Pyrosequencing. Results: the ratio of YMDD and rtL180M mutants were significantly higher in patients who developed HBV DNA breakthrough after lamivudine therapy than before, although they were not significantly associated with HBV DNA breakthrough, for 24 weeks data, multivariate logistic regression analysis revealed that HBeAg titer (24 weeks) was the independent factor for HBV DNA breakthrough (p=0.004, 48w), and was correlated with HBV DNA loads(r=0.493). Conclusions: Pre-existing lamivudine-resistant HBV ratio was not the prognostic factors associated with hepatitis B virus DNA breakthrough, while HBeAg titer after 24 weeks of lamivudine treatment was the independent factor that influenced HBV DNA breakthrough after 48 weeks of lamivudine treatment. 1000 ADEFOVIR DEPIVOXIL FOR DECOMPENSATED LIVER CIRRHOSIS PATIENTS WITH LAMIVUDINE-RESISTANT HEPATITIS B: MULTI-CENTER LONG-TERM RESULTS
Hyun Young Woo1, Jong Young Choi1, Seung Woon Paik1, Dong Jin Suh2, Seung Woon Paik3, Kwang Hyub Han4, Soon Ho Um5, Byung Ik Kim6, Heon Ju Lee7, Meng Cho8, Chun Kyon Lee9, Dong Jun Kim10, Jae Seok Hwang11, 1The Catholic University of Korea, Seoul, South Korea; 2University of Ulsan College of Medicine, Seoul, South Korea; 3Samsung Medical Center, Seoul, South Korea; 4Yonsei University College of Medicine, Seoul, South Korea; 5Korea University College of Medicine, Seoul, South Korea; 6Kangbuk Samsung Hospital, Seoul, South Korea; 7Yeungnam University College of Medicine, Daegu, South Korea; 8Pusan National University College of Medicine, Pusan, South Korea; 9National Health Insurance Corporation Ilsan Hospital, Koyang, South Korea; 10Hallym University College of Medicine, Chuncheon, South Korea; 11Keimyung University College of Medicine, Daegu, South Korea

Background/Aim: The effect and safety of adefovir dipivoxil for patients with decompensated cirrhosis were not well known. Long-term efficacy and safety of adefovir dipivoxil in decompensated cirrhosis patients with lamivudine-resistant hepatitis B (HBV) were studied. METHODS: One hundred nineteen cirrhotic patients who developed hepatic decompensation (any cirrhosis complication or Child-Pugh (CP) score ≥ 7) after lamivudine treatment were enrolled from eleven university hospitals and treated with 10 mg of adefovir dipivoxil for a median 33 months between January 2003 and October 2006. Lamivudine was switched to adefovir dipivoxil with or without overlap period (median 2 months). We evaluated the overall survival...
HBV reactivation usually occurs on patients with HBsAg positive, with HBsAg positive developed abnormal liver function easily and especially those with higher viral load. HBV reactivation delayed on the NHL patients with HBsAg negative and anti HBc-IgG positive or even with anti HBsAb positive. Our results suggest that the importance of HBV viral load and liver function surveillance routinely during chemotherapy and necessity of prophylactic antiviral therapy to patients with hepatitis B carriers at the onset of chemotherapy.

1001 CLINICAL FEATURES OF LYMPHOMA CHEMOTHERAPY ASSOCIATED HEPATITIS VIRUS B REACTIVATION
Dongmei Shi, Qing Xie, Honglian Gui, Hui Wang, Nina Jia; Department of Infectious Diseases, Ruijin Hospital, Shanghai Jiaotong University School of Medicine, Ruijin Hospital, Shanghai, China

Objective: Investigate the incidence of Hepatitis Virus B reactivation and its related severity of hepatitis after the Non-Hodgkin’s Lymphoma (NHL) patients had been administered with chemotherapy, recognize the significance of detecting HBV DNA and employing prophylactic antiviral therapy. Methods: Retrospective study was conducted on 252 NHL patients who had received chemotherapeutics, among which 166 cases with HBV serologic test negative, 86 cases with HBV positive (60 with HBsAg positive, 26 with HBsAg negative and anti HBc-IgG positive). Results: After these 252 NHL patients received chemotherapy, 56 cases occurred hepatitis biochemical abnormality, among which 11 with HBV negative (6.6%), 45 with HBV positive (52.3%), there was a statistically significant difference between these 2 groups (P<0.01). In addition, within the HBV positive group, 39 cases with HBsAg positive (65.0%) and 6 cases with HBsAg negative and anti HBc-IgG positive (23.1%). There was also a statistical difference between these 2 groups (P<0.05). The prevalence of HBV reactivation in patients with HBsAg positive was much higher when compared with those with HBsAg negative and anti HBc-IgG positive (53.3% vs. 7.7%, P<0.01). 32 among 39 patients with HBsAg positive occurred liver function abnormal within three cycles of chemotherapy, nevertheless 4 among 6 patients with HBsAg negative and anti HBc-IgG positive occurred liver function abnormal following five cycles of chemotherapy. Conclusions: NHL patients with HBV positive have a higher incidence of hepatic biochemical abnormality than those with HBV negative. Patients with HBsAg positive developed abnormal liver function easily than those with HBsAg negative and anti HBc-IgG positive. HBV reactivation usually occurs on patients with HBsAg positive and especially those with higher viral load. HBV reactivation delayed on the NHL patients with HBsAg negative and anti HBc-IgG positive or even with anti HBsAb positive. Our results suggest that the importance of HBV viral load and liver function surveillance routinely during chemotherapy and necessity of prophylactic antiviral therapy to patients with hepatitis B carriers at the onset of chemotherapy.

1002 PREDICTING SUSTAINED HBEAG LOSS AFTER TREATMENT WITH PEGINTERFERON ALPHA-2B: DEVELOPMENT AND VALIDATION OF A PRACTICAL MODEL
Erik H. Buster1, Bettina E. Hansen1,2, Stefan Zeuzem3, Solko W. Schalm1, Ewout W. Steyerberg2, Harry L. Janssen1; 1Gastroenterology & Hepatology, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands; 2Department of Epidemiology and Biostatistics, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands; 3Medizinische Klinik I, Klinikum der Johann Wolfgang Goethe-Universität, Frankfurt am Main, Germany; 4Department of Public Health, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands

We developed and validated a model based on readily available factors for the prediction of response to peginterferon in individual patients. Methods: Patients randomized to PEG-IFN α-2b 100µg alone (n=136) or in combination with lamivudine 100mg (n=130) for 52 weeks were analyzed. Univariate logistic regression analysis, followed by backward stepwise selection was used to identify predictors of HBeAg loss at 26 weeks post-treatment among the variables age, sex, HBV genotype (A-D), serum HBV DNA, ALT, GGT, treatment allocation and previous antiviral therapy. Interactions between variables and nonlinear relationships were investigated. Discrimination was quantified by the area under the receiver-operating characteristic curve (AUC). Bootstrap sampling was used for internal validation to reduce overfit bias. Results: 23 patients were excluded because of missing values or infection with HBV genotype other than A-D, leaving 233 patients for analysis. HBV genotype, serum HBV DNA, GGT and previous IFN therapy were found to be independent predictors of HBeAg loss (p<0.05). Since the influence of ALT was dependent on HBV genotype, an interaction between these variables was included (p=0.03). A multivariable model based on the above mentioned variables had adequate discriminative ability (AUC 0.73). After bootstrapping, the discriminative ability of the model was found to be somewhat lower (AUC 0.69). A nomogram was generated from the logistic regression formula (figure). The probability of HBeAg loss is calculated by drawing a vertical line from each of the 4 variable axis to the top Points axis. The sum of these 4 points is put on the Total score axis, from which a vertical line is drawn to the Chance of HBeAg loss axis. Conclusion: A multivariable model based on HBV genotype, serum HBV DNA, ALT, GGT and previous IFN therapy provides an adequate prediction of PEG-IFN induced HBeAg loss and will be a useful tool to guide treatment choice of PEG-IFN vs. nucleos(t)ide analogues in individual patients.
1003
THREE-YEAR ASSESSMENT OF ENTECAVIR RESISTANCE IN GENOTYPE C CHRONIC HEPATITIS B PATIENTS IN JAPAN REVEALS DIFFERENT CLINICAL OUTCOMES REGARDING BREAKTHROUGH HEPATITIS PREDICTED BY THE RESISTANCE SUBSTITUTIONS USING RECENTLY DEVELOPED INNO-LIPA HBV ASSAY

Motakazu Mukaida, Yasuhiro Tanaka, Etsuro Orito, Fuat Kurbanoğlu, Kenichi Fukai, Osamu Yokosuka, Michio Sata, Tatsuya Ide, Karino Yoshiyasu, Kohsaku Sakaguchi, Masashi Mizokami.

Background/Aim: Currently, entecavir (ETV) is being considered as a first- or second-choice treatment for nucleoside-naive or lamivudine (LVD)-refractory chronic hepatitis B patients. To assess frequency of ETV-resistance (ETVr) and the specific substitutions associated with breakthrough hepatitis (BTH) during 3-years ETV therapy, recently developed INNO-LIPA HBV DR v2 and ETV TDF assay was applied. Methods: Forty-five patients including 25 chronic LVD-refractory genotype C patients (n=22/23, mean age: 41.6 yrs, ALT: 129.1 HBeAg: 36 and HBV-DNA (TMA): 6.98) and 20 naïve patients were enrolled. Drug resistance was assessed by detection L80I, V173L, M204I and L259F for LVD and T184A/C/G, A194T, S202G/C for ETV. Results: In 25 LVD-refractory patients, the ETVr substitutions (SCGA184, ILMF184, G202, C202, VL250) were present in 3/25 (12.5%) at baseline and emerged in 5/25 (20.8%), and 7/25 (29.4%) and 5/17 (29.2%) at weeks 48, 96, and 144, respectively, versus 8%, 8%, 0%, and 13% in naïve patients, respectively. Five of the 25 LVD-refractory (20%) patients treated with 1.0 mg ETV had evidence of BTH after 72 to 136 weeks of the therapy. Of the all BTH patients, LVDr substitutions (M180 and V204) were detected at baselines, and an additional G202 ETVr substitution occurred (0-96 weeks), resulting in BTH 40-72 weeks later. Other substitutions emerged during ETV therapy, but none of them seemed to affect susceptibility to ETV or associated to BTH. Conclusions: INNO-LIPA is useful in early ETVr detection. In LVD-refractory, genotype C, Japanese patients, LVD (M180 and V204) plus G202 ETVr substitutions resulted in BTH. High and long-term efficacy of ETV was demonstrated in naïve patients, whereas adefovir add-on LVD should be considered as a first-, or second-line treatment option for LVD-refractory chronic hepatitis B patients.

Table 1. ETVr associated substitutions emerged in LODr cohort during follow up

THE EFFECTS OF α-GALACTOSYLCERAMIDE ON CHRONIC HEPATITIS B INFECTION IN A RANDOMIZED PLACEBO CONTROLLED PHASE I/II TRIAL

Background: The glycosphingolipid alpha-galactosylceramide (α-GalCer) has been shown to have an immunomodulatory effect mediated via the activation of natural killer T (NKT) cells and is able to inhibit hepatitis B virus replication in HBV transgenic mice. Aim: The aim of this dose-escalating randomized placebo-controlled phase I/II trial was to investigate the antiviral activity and safety of α-GalCer as a novel class of treatment for chronic hepatitis B patients. Methods: Twenty-seven patients were allocated to a α-GalCer dose of 0.1 μg/kg (n=8), 1 μg/kg (n=9), 10 μg/kg (n=6) or to placebo (n=10). All patients had an HBV DNA level above 10^5 copies/ml at screening and ALT values >1.2 times the upper limit of normal. The treatment period consisted of intravenous injections with α-GalCer activated NKT cells are able to inhibit hepatitis B virus replication in HBV transgenic mice. Aim: The use of this dose-escalating randomized placebo-controlled phase I/II trial was to investigate the antiviral activity and safety of α-GalCer as a novel class of treatment for chronic hepatitis B patients. Methods: Twenty-seven patients were allocated to α-GalCer dose of 0.1 μg/kg (n=8), 1 μg/kg (n=9), 10 μg/kg (n=6) or to placebo (n=10). All patients had an HBV DNA level above 10^5 copies/ml at screening and ALT values >1.2 times the upper limit of normal. The treatment period consisted of intravenous injections with α-GalCer at 0, 4 and 8 weeks. Thereafter, patients were monitored for an additional 16 weeks. Results: Although some patients showed an HBV-DNA decrease after administration, no clinically relevant suppression of viral replication was observed. Four patients exhibited a more than 0.5 log_{10} copies/ml decrease in HBV DNA fol-
following the first administration (1 µg/kg n=2, 10 µg/kg n=2) with a median decline in the first week of 1.1 log_{10} copies/mL (range 0.5 – 3.0) from baseline, but this decline was not sustained and also not observed after the second and third administration of α-GalCer. There were no clear changes in ALT levels. In three patients of the highest dose level, a rise in IL-6 production in serum was observed four hours after drug administration. In four patients (1 µg/kg n=1, 10 µg/kg n=3) α-GalCer was discontinued prematurely because of an episode of fever and severe rigors shortly after drug administration. Otherwise there were no significant side effects. Conclusion: α-GalCer used as monotherapy for chronic hepatitis B infection at the doses (0.1-10 µg/kg) used in this trial had no clear effect on HBV DNA and ALT levels, was poorly tolerated, and is unlikely to provide an alternative as monotherapy for the current treatment of peg-IFN and nucleos(t)ide analogs.

1005 CROSS-RESISTANCE CHARACTERIZATION OF THE MAIN HBV DRUG RESISTANT MUTANTS
Stephanie Villet1, Fabien Zoulim1,2; 1INSERM U871, Lyon, France; 2Hospices civils de Lyon, Lyon, France

Introduction - Currently, four nucleoside analogues are approved for the treatment of chronic hepatitis B: lamivudine, adefovir, entecavir and telbivudine. They suppress viral replication through inhibition of HBV DNA polymerase and chain termination. However, prolonged treatments with these analogues result in the emergence of resistant virus harbouring mutations within the HBV polymerase gene which are associated with resistance to treatment. Objectives - We isolated and cloned HBV DNA genomes from patients who developed viral resistance following various therapies. We determined in vitro the antiviral susceptibility of the main resistance mutants to nucleoside analogues approved for chronic HBV treatment, and tested new nucleoside analogues on these mutants. Results - A bank of mutants, constructed by site directed mutagenesis or from patients serum samples were intensively analyzed. We could observed that all the mutants harbouring the rtM204V substitution, except the rtM204V mutation alone, showed a >1000 fold decrease in susceptibility to lamivudine as compared to wild-type (wt) HBV. We also characterized different mutants harbouring the rtA181V mutation and all these mutants were >2.7 fold less sensitive to adefovir than wt HBV. This in vitro decrease in susceptibility to adefovir seems to be sufficient to induce in vivo viral breakthrough. Concerning entecavir, all the mutants harbouring the rtS202G substitution, but only in addition to rtL180M+M204V main lamivudine resistance mutations showed a >200 fold resistance to this drug in comparison with wt HBV. Tenfovir seems to be one of the most efficient drugs on these mutants, since only two of them (rtN236Ts and rtL180M+M204V+N236T) showed a decrease in susceptibility to tenofovir as compared to wt HBV. We also tested new nucleoside analogues for their capacity to inhibit replication of drug resistant mutants and demonstrated that PMEO, a novel pyrimidine analogue, showed a better activity than adefovir on all the tested mutants except the rtN236T mutant. Phenotypic characteristics of additional complex mutants were also determined. Conclusion - These data on antiviral susceptibility of the main HBV polymerase mutants observed in patients provide useful information to guide anti-HBV therapy.

1006 DETECTION OF HEPATITIS B VIRUS YMDD MUTANTS BY MULTIPLEX-PCR USING DUAL PRIMING OLIGONUCLEOTIDE (DPO)
Park Ji Young1, Lee Tae Hoon1, Park Jeong Hoon1, Kim Sang Gyun21, Park Do Hyun1, Lee Suck Ho1, Jang Jae Young1, Kim Young Seok1, Chung Il Kwon1, Kim Hong Soo1, Park Sang Heum1, Kim Sun Joo1, Kim Seok Hyun2, Lee Heon Young2, Kim Chang Jin3, Jeong Dong Jun1; 1Gastroenterology, Soon Chun Hyang University Hospital, Cheonan, South Korea; 2Gastroenterology, Choong Nam University Hospital, Dae Jeon, South Korea; 3Pathology, Soon Chun Hyang University, Cheonan, South Korea

Background: The mutants of hepatitis B virus (HBV) emerge selectively during long-term lamivudine therapy. Since lamivudine resistance has cross-resistance with other antiviral agents, initial choice of antiviral agents for prevention of multi-drugs resistance is very important. According to recent studies, early detection of HBV mutants at 3 months is useful to predict the long-term outcomes of lamivudine therapy. In addition, predominance of mutants is significantly associated with viral DNA breakthrough. Therefore, early detection and periodical testing of HBV mutants is needed. However current methods of detecting mutants are time-consuming and labor intensive which require multiple steps and expensive instruments. Aims: To determine the effect of recently developed YMDD genotype method using Multiplex-PCR technology, we compared this method with restriction fragment mass polymorphism (RFMP) and direct sequencing method. Patients and Methods: Total eighty chronic hepatitis B patients treated with lamivudine more than 6 months participated in this study. YMDD mutants were genotyped by RFMP using MALDI-TOF mass spectrometry, sequencing and Multiplex-PCR using dual priming oligonucleotide (DPO). Results: The Multiplex-PCR method with DPO was available for sensitive, specific and simultaneous detection of 4 types of HBV mutants (rtM204V/I/S, rtL180M) by only one time PCR. Additionally, this assay enabled to estimate relative abundance of mutants in variant/variant mixed or variants/wild type mixed serum by agarase gel electrophoresis. The Multiplex-PCR assay detected as few as 1000 copies/mL of HBV genome plasmids, also detected as little as 2% mutant plasmids. The total protocol was carried out easily within 4 hours. The patients with breakthrough (virologic or biochemical), early viral response to lamivudine therapy, HbeAg positivity, HBV-DNA >100,000 copies/ml and elevated ALT (>2 times upper limit of normal) had higher mutation rate. For these patients, Multiplex-PCR with DPO was the most sensitive method for detection of the mutants (especially mixed variants). Interestingly, 18 of 80 patients (22.5%) had single or mixed variants, these mutants only detected by the Multiplex-PCR, but not by RFMP or sequencing. These results indicate that Multiplex-PCR with DPO is more sensitive than RFMP and sequencing to detect variants. Conclusions: Multiplex-PCR with DPO is rapid, sensitive and cost-effective method for detection of the YMMD mutants and relative quantitation as well. Therefore, this method can be useful diagnostic tool for early detection of HBV mutants and estimate their predominance, thereby preventing drug resistance and early rescue therapy.

Disclosures:
The following people have nothing to disclose: Park Ji Young, Lee Tae Hoon, Park Jeong Hoon, Kim Sang Gyun, Park Do Hyun, Lee Suck Ho, Jang Jae Young, Kim Young Seok, Chung Il Kwon, Kim Hong Soo, Park Sang Heum, Kim Sun Joo, Kim Seok Hyun, Lee Heon Young, Kim Chang Jin, Jeong Dong Jun
Background/Aims: The growing number of HBV nucleos(t)ide inhibitors, the widening of anti-HBV sequential and/or combination therapies, and the viro-clinical impact of drug resistance mutations warrant surveys of HBV genotypic drug resistance. Therefore, we performed a 5-year retrospective survey during the 2002-04/2007 period aiming to analyse the prevalence and dynamic of HBV reverse transcriptase (rt) drug resistance mutations patterns in patients (pts) chronically-infected with HBV followed-up in Marseilles public hospitals. Patients/Methods: 381 HBV rt sequences from 312 pts (70% male; mean age, 47) were analysed. 39 pts have been tested twice, and 12 pts >2 times. For each year from 2002 to 2007, only one sequence per >18 year-old pt was selected. Serum HBV DNA direct sequencing was performed using in house protocols. 25 amino acid (aa) positions within domains A-E of HBV rt and previously associated with drug resistance were analysed, which included all positions at which association of aa substitution with drug resistance is clearly established. Results: A nearly 1.7-time increase of the number of HBV sequences was observed in 2006 (n=96) as compared to 2002-2003 (55 and 57, respectively). The mean number of aa substitutions per sequence ranged between 2.1 in 2003 and 1.7 in 2007, without significant change. The proportion of non-A HBV genotypes increased from 53.54% in 2002-2003 to >60% in 2006-04/2007 (p=0.24). The proportion of sequences harbouring >3 aa substitutions was significantly higher for genotypes A vs genotypes D or non-A/non-D (23% vs 11 and 9%, respectively; p<0.05). In contrast, the proportion of aa substitutions was significantly higher at positions 80, 181, 215, and 237 for genotypes D vs genotypes A (p<0.02). The most variable aa positions were rt204 and rt180. Substitution rtM204I/V was found in 71 sequences (19%), associated with L180M in all but one case for M204V and with A181V/T in two cases. Substitution rtA181V/T was found in 4.7% of sequences (n=17) and 6.4% in 2007. The proportion of mutated sequences significantly increased between 2002 and 2007 at positions 236, 237, and 238 (p<0.05). Substitution rtN236T was observed in 6 sequences (1.8%), always associated with rt204 wild-type aa, and was significantly associated with rtA181V and rt169L (in 2 sequences each; p<10-3). Conclusions: Our data underline the changing pattern of HBV drug resistance mutations and the association or exclusion of rt aa mutations in the setting of emerging nucleos(t)ide inhibitors and combination and/or sequential anti-HBV therapies. They also suggest that genotypic drug resistance patterns might differ according to the HBV genotype.

ECTOPIC EXPRESSION OF NEURAL AUTOANTIGEN IN LIVER SUPPRESSES AUTOIMMUNE NEUROINFLAMMATION BY INDUCING ANTIGEN-SPECIFIC CD4+ CD25+ FOXP3+ REGULATORY T CELLS

Johannes Herkel1, Stefan Lüth1, Samuel Huber1, Christoph Schramm1, Thorsten Buch2, Stefan Zander1, David C. Wraith3, Ansgar W. Lohse1; 1Department of Medicine I, University Medical Centre Hamburg-Eppendorf, Hamburg, Germany; 2Department of Neurology, University Medical Center Zurich, Zurich, Switzerland; 3Department of Pathology and Microbiology, University of Bristol, Bristol, United Kingdom

CD4+ CD25+ Foxp3+ regulatory T cells (Treg) are important mediators of immune tolerance to self-antigens, and their inactivation may cause autoimmune disease. Therefore, immunotherapy for autoimmune diseases may aim at restoring or expanding autoantigen-specific Treg activity. Here we report that Treg-mediated suppression of autoimmune disease could be achieved in vivo by taking advantage of the liver’s ability to promote immune tolerance. Ectopic expression of the neural autoantigen myelin basic protein (MBP) in the liver, which was accomplished constitutively in liver-specific MBP-transgenic mice, or transiently after hydrodynamic gene transfer to liver cells in vivo, induced protection from experimental autoimmune encephalomyelitis (EAE), a mouse model for human multiple sclerosis. A role of central tolerance in the observed resistance to EAE was excluded by neonatal thymectomy. Protection from EAE was mediated by MBP-specific CD4+CD25+Foxp3+ Treg cells, as demonstrated by adoptive transfer to non-transgenic mice and by their ability to suppress conventional CD4+CD25- T cells after antigen-specific stimulation with MBP in vitro. Our findings indicate that autoantigen expression in the liver may generate autoantigen-specific Treg cells. Thus, targeting of autoantigens to hepatocytes may be a novel therapeutic approach to prevention or treatment of autoimmune diseases.

A) Transient hepatic MBP expression facilitated by hydrodynamics-based gene transfer to hepatocytes with MBP-encoding pcDNA3.1 expression vector (black circles, unbroken line), but not by empty control vector (white circles, broken line) suppresses EAE.

B) Protection of wild-type mice from autoimmune encephalomyelitis by adoptive transfer of 10^5 splenic CD25+ CD4+ T cells from MBP-transgenic mice (black circles, unbroken line), but not by transfer of 10^5 splenic CD25- CD4+ T cells from MBP-transgenic mice (white squares, broken line).

CRITICAL ROLE FOR CD1D-RESTRICTED Vα14 INKT CELLS IN STIMULATING INTRAHEPATIC CD8 T CELL RESPONSES TO LIVER-EXPRESSED ANTIGEN

Dave Sprengers1,2, Fenna C. Sillé2, Gurdyal S. Besra3, Harry L. Janssen1, Eckart Schott4, Marianne Boes2,5; 1Department of Gastroenterology & Hepatology, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands; 2Department of Dermatology, Brigham and Women’s Hospital and Harvard Medical School, Boston, MA; 3School of Biosciences, The University of Birmingham, Birmingham, United Kingdom; 4Medizinische Klinik mit Schwerpunkt Hepatologie und Gastroenterologie, Charité Universitätsmedizin Berlin, Berlin, Germany; 5Department of Immunology, University Medical Center Utrecht, Utrecht, Netherlands

Background and aims. Activation of CD1d-restricted Vα14 invariant (i) NKT cells rapidly induces their secretion of effector cytokines. As Vα14 iNKT cells are localized in peripheral tissues such as the liver rather than lymphoid tissues, their role in modulating the stimulation of conventional, MHC-restricted T cell responses has remained ambiguous. We here describe a role for Vα14 iNKT cells in modulating conventional T cell responses to antigen expressed in liver, using transferrin-mOVA (Tf-mOVA) mice. Methods. Naïve ovalumin-specific Class I MHC-restricted T cells (OTI) were adoptively transferred into Tf-mOVA mice in the presence or absence of CD1d-ligand α-galactosylceramide, after which their priming, antigen-specific cytokine production and liver damage were analyzed. Results. Transfer of OTI cells resulted in robust intrahepatic, antigen-specific proliferation of T cells. OTI T cells were activated in liver, and IFNα production by OTI T cells was stimulated by co-activation of Vα14 iNKT cells using αα-galactosylceramide. This stimulation was absent in CD1d-/- Tf-mOVA mice, which lack Vα14 iNKT cells. OTI T cells induced hepatitis and liver damage was corroborated by α-galactosylceramide injection. Conclusion. CD1d-restricted Vα14 iNKT cells stimulate intrahepatic antigen-specific effector CD8 T cell responses. Our findings elucidate a previously unknown intervention point for targeted immunotherapy to autoimmune and possibly infectious liver diseases.

CTS-1027, A POTENT MMP INHIBITOR, PROTECTS AGAINST TNFα- AND α-FAS-INDUCED LIVER INJURY

Patricia C. Contreras, Karen Valentino; Conatus Pharmaceutical, San Diego, CA

Background. CTS-1027 is an orally bioavailable small molecule that is a potent inhibitor of MMP-2, 3, 8, 9, 12, 13 and 14, but not MMP-1. In the liver, in response to a variety of insults, excessive MMP activity may play a role in destruction of the extracellular matrix, and recruitment of inflammatory cells. CTS-1027 was previously evaluated in an extensive phase 2 clinical trial in which a well tolerated chronically administered dose was identified. Thus, it was of interest to evaluate a MMP inhibitor whose safety profile was known in models of acute liver injury in mice. Methods. CTS-1027 (0.001-30 mg/kg) was administered PO to male mice (C57BL/6), 30 minutes prior to treatment with TNFα/D-Galactosamine (D-Gln) or the Fas activating antibody (α-Fas). Six hours later, animals were anesthetized with Nembutal and blood taken by cardiac puncture. Plasma ALT activity was determined using a commercially available kit. For survival studies, mice were observed up to 24 hours post-injection. Pharmacokinetic analysis of CTS-1027 was
conducted in treatment-naive mice to determine plasma and liver levels. **Results:** CTS-1027 dose-dependently decreased plasma ALT activity in the TNFαr model. The average ED50 from 4 studies was 0.26 ± 0.08 mg/kg. Twenty-hour survival was also increased by CTS-1027 (10 mg/kg). The average 24 hour survival from 3 studies was 27 ± 7.3% and 55 ± 7.6% (p = 0.03) in the TNFαr/D-Gln control mice and CTS-1027-treated mice, respectively. CTS-1027 (10 mg/kg; PO) was also protective against α-Fas, significantly (p<0.05) reducing the elevation in plasma ALT activity in 2 independent studies by an average of 49%. In a separate group of mice, PK analysis of CTS-1027 in plasma vs. liver indicated that CTS-1027 was rapidly absorbed with Tmax of 0.25-0.5 hour in liver and plasma. AUCs increased in a dose-dependent manner and were 1.7-fold greater in liver than plasma. The AUC in plasma at the αED50 dose in the TNFαr/D-Gln model (~0.3 mg/kg) was 13-fold lower than the AUC at a dose previously determined to be well tolerated in man. **Conclusions:** CTS-1027 potently antagonized the liver toxicity induced by treatment with TNFαr/D-Gln or α-Fas as indicated by reductions in plasma ALT and/or lethality/morbidity at doses lower than the well tolerated dose in man. CTS-1027 is an attractive candidate for further development and is expected to enter clinical trials in patients with liver disease by the end of 2007.

**1012 INVESTIGATING THE ROLE OF AUTOACTIVE CD8+ AND CD4+ T CELLS IN THE PATHOGENESIS OF AUTOIMMUNE HEPATITIS IN A TRANSGENIC MOUSE MODEL**

M. Zierden, E. Kühnen, M. Odenenthal, H. P. Dienes; Institute for Pathology, University Hospital of Cologne, Cologne, Germany

Autoimmune hepatitis (AIH) is a chronic active liver disease of unknown cause. Autoreactive lymphocytes are thought to mediate the liver injury but the pathogenesis of AIH remains poorly understood. To investigate liver-specific CD4+ and CD8+ T cell responses and the role of autoreactive T lymphocytes in the pathogenesis of AIH, we have generated transgenic mice that express the influenza virus hemagglutinin (HA) neoantigen in the liver under the control of albumin regulatory elements (Alb-HA mice). Adoptive transfer of HA-specific naive CD8+ T cells into Alb-HA mice leads to an activation of autoreactive CD8+ T cells in the liver or in liver-draining lymph nodes and elicits a transient hepatitis characterized by portal and lobular inflammation and elevated serum level of alanine aminotransferase (ALT). Adoptive transfer of HA-specific naive CD4+ T cells into Alb-HA mice leads to an activation of autoreactive CD4+ T cells in liver-draining lymph nodes or in the spleen and causes mild transient necroinflammatory lesions of the liver. These data suggest that both, CD8+ and CD4+ T cells play an active role in the pathogenesis of AIH and that tolerance mechanisms keep autoreactive T lymphocytes specific for a liver antigen normally in check.

1014 DELETION OF CD39 INHIBITS DEVELOPMENT OF METASTATIC LIVER CANCER
Xiaofeng Sun, Yan Wu, Mika Ogawa, Keiichi Enjoji, Eva Cszmadia, Guido Beldi, Simon C. Robson; Liver Center, Department of Medicine, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA

New vessel formation and tumor infiltrating lymphocytes (TIL) influence host responses to malignant tissues. Extracellular adenosine-mediated pathways promote both vascular endothelial cell proliferation and inhibit cytotoxic T cells, thereby potentiating cancer growth. CD39 is the dominant ectonucleotidase of vascular and T regulatory cells and has the potential to generate high levels of adenosine locally. We have previously shown that deletion of Cd39 results in angiogenic failure and T regulatory cell dysfunction with loss of immune suppressive functions. Aim: Investigate impact of CD39 upon development of hepatic metastases. Methods and Results: We studied the development of metastatic liver deposits following portal vein infusion of 1.5x105 melanoma B16/F10 cells, with luciferase expression, in wild type and Cd39-null C57BL/6 mice (n=24). Tumor formation in liver was directly examined and animals imaged at days 7-17 after tumor cell implantation. As predicted, the formation of hepatic malignant foci was markedly suppressed in Cd39-null mice, at all time points examined. To test whether the major impact of Cd39-deletion was upon neo-vasculature formation or immune responsiveness, adoptive transfer experiments were conducted. Bone marrow transplants (BMT) from Cd39-null or wild type BL/6 mice were placed in lethally irradiated control and/or null mice, in a crossover manner (total n=24 for each group, respectively). Eight weeks post-adoptive transfer, melanoma cells were infused via portal vein as before and tumor growth studied. The Cd39-null mice that received wild type BMT mirrored the wild type phenotype with progressive tumor growth observed (n=8 per time point; p=0.015). In contrast, metastases were significantly inhibited in both number and size and ultimately became necrotic in the wild type mice that had received Cd39-null BMT. Conclusions: Bone marrow derived cells mediate the major inhibitory effects of Cd39 deletion on tumor growth. Pharmacological inhibition of CD39 may find utility as an adjunct therapy in the management of hepatic malignancy.

1015 EVIDENCE FOR ALTERNATIVE- AND CLASSICAL-PATHWAY INDEPENDENT ACTION OF COMPLEMENT FACTOR C3 DURING LIVER REGENERATION
Amelia Clark, Alexander Weymann, Eric Hartman, Yumirle P. Turmelle, Dennis Hourcade, David Rudnick; Washington University School of Medicine, St. Louis, MO

The liver regenerates itself following injury. Recently, the complement pathway has been implicated as important for the regenerative response. For example, both complement factor C3 and C5-null mice show impaired hepatic regeneration that can be rescued by exogenous supplementation of the respective factors. However, the specific mechanism by which complement pathway signaling is activated during liver regeneration (classical, alternative, or lectin-dependent) has not been defined. The classical and lectin dependent pathways of complement activation are absolutely dependent on complement factor C4, while the alternative pathway of activation requires factor B. In the studies reported here we investigated whether either C4 or factor B is required for normal liver regeneration using the mouse partial hepatectomy model. Methods: 2-3 month old wildtype (WT) C57Bl/6 and C3-, Factor B-, and C4-null mice on C57Bl/6 backgrounds were subjected to partial hepatectomy (PH) or sham surgery, allowed to recover, and then sacrificed for plasma and tissue harvest. 3-6 animals were examined per time point and genotype. Liver tissue was formalin-fixed, paraffin-embedded, and stained with H&E or for bromo-deoxyuridine (BrdU). Cyclin D1 protein expression was assessed by protein immunoblot. Results: Compared to WT mice, C3-null mice had reduced hepatocellular proliferation and delayed peak proliferation, as well as suppressed induction of hepatic cyclin D1 protein expression. At 48h after PH, hepatocellular mitotic body frequency was significantly reduced in C3-null mice, compared to WT mice. In contrast, both C4-null and Factor B-null mice showed normal hepatocellular BrdU incorporation, cyclin D1 expression, and mitotic body frequency. Neither C3-, C4- nor Factor B-null mice had increased mortality or increased liver tissue injury. Conclusion: Our results suggest that neither the C4-dependent classical or the lectin-dependent pathways nor the factor B-dependent alternative pathway of complement cascade activation is absolutely required for normal liver regeneration. These data raise the possibility that other mechanisms exist by which C3 and C5 can be activated during the regenerative response.

1016 HEPATOCYTE SURVIVAL IN ACUTE HEPATITIS IS DUE TO C-JUN/AP-1-DEPENDENT EXPRESSION OF INDUCIBLE NITRIC OXIDE SYNTHASE
Peter Hasselblatt1, Martina Rath1, Yukoslav Komnenovic1, Kurt Zatloukal2, Erwin Wagner1; 1Research Institute of Molecular Pathology, Vienna, Austria; 2Institute of Pathology, Medical University of Graz, Graz, Austria

Analysis of the molecular factors determining hepatocyte survival or death in response to inflammatory stimuli is essential for understanding the pathogenesis of inflammatory liver disease and for identifying novel therapeutic approaches. Jun N-terminal kinase (JNK) is a major mediator of cytokine-induced cell death during hepatitis, but the signaling pathways downstream of JNK remain less well defined. Here we show that the transcription factor c-Jun/AP-1, a prototypic target of JNK, is strongly expressed in the liver of patients with acute liver injury of viral or toxic etiology. The contribution of c-Jun to cell death was further analyzed in mice using the Concanaavalin A (ConA) model of TNFα-dependent hepatitis. Mice lacking c-Jun in hepatocytes display increased liver cell death and mortality upon ConA injection. This phenotype is due to impaired expression of inducible nitric oxide synthase (nos2, also known as iNOS), which we identified as direct transcriptional target of c-Jun during hepatitis, and reduced production of hepatoprotective nitric oxide (NO). The increased hepatotoxicity and hepatocyte necrosis in mutant mice are likely caused by hypoxia and oxidative stress and can be rescued pharmacologically by liver-specific delivery of NO or by the antioxidant N-Acetylcysteine. These findings demonstrate that c-Jun/AP-1 mediates hepatocyte survival during acute hepatitis by regulating nos2 expression and thus functionally antagonizes the cell death-promoting functions of JNK. Moreover, our data provide a strong rationale for further exploring NO-based therapies for the treatment of severe liver injury.
EFFECTS OF COPY NUMBER VARIANTS (CNVS) OF THE CHEMOKINE GENE CCL3L1 ON Susceptibility to HCV INFECTION

Frank Grünhage1, Olav A. Gressner1, Hildegard Keppeler1, Hermann E. Wasmuth2, Margarete Odenthal3, U. Dreberger3, Hans P. Dienes3, Claus Hellerbrand4, Tilman Sauerbruch1, Frank Lammer1;
1Department of Internal Medicine I, University Hospital Bonn, Bonn, Germany; 2Department of Medicine III, University Hospital Aachen, Aachen, Germany; 3Institute of Pathology, University of Cologne, Cologne, Germany; 4Department of Internal Medicine I, University of Regensburg, Regensburg, Germany

Recently a novel class of genomic diversity, copy number variants (CNVs), of the CCL3L1 gene have been associated with susceptibility to HIV infection (Gonzales et al. Science 2005;307:1434-40). The chemokine CCL3L1 is a potent ligand for CCR5, which plays a central role in anti-viral lymphocyte activity. Of note, CCR5 deficiency has been associated with differences in susceptibility to hepatitis C virus (HCV) infection and the hepatic fibro-inflammatory reaction. Hence, variation in the gene dose of CCL3L1 due to CNVs may also contribute to differences in the overall susceptibility to HCV infection and/or the inflammatory response. Thus, our aims now were to compare the CCL3L1 CNV distributions between patients with chronic HCV infection, HCV/HIV co-infection and non-infected controls, and to test for association with histological grades of inflammation and stages of fibrosis in patients with chronic HCV infection.

Patients and methods: Patients with chronic HCV infection (n=254), HCV/HIV co-infection (n=144) and non-infected controls (n=210) were recruited. CNVs of the CCL3L1 gene were determined using a real-time fluorescent-dye labelled PCR adapted from Gonzales et al. (Science 2005;307:1434-40), and CNVs were compared between groups using tests and non-parametric Mann-Whitney-U tests. Results: Copy numbers of the CCL3L1 gene are in line with previously published data for non-Africans, ranging from 0 to 12 copies (mean 2.5 ± 1.4 copies). Consistent with previous studies, CCL3L1 copy numbers of HCV/HIV co-infected patients are significantly lower compared to HCV patients (2.2 vs. 2.6; P < 0.01) and controls (2.2 vs. 2.9; P < 0.001). Of note, CCL3L1 copy numbers of HCV mono-infected patients are also significantly lower compared to controls (2.6 vs. 2.9; P = 0.011). Accordingly, CNV distributions are shifted to lower copy numbers in HCV mono-infected patients compared to controls (P = 0.036) and in HCV/HIV co-infected patients compared to HCV mono-infected patients or controls (both P < 0.01). Patients with two or less copies of the CCL3L1 gene are over-represented in the HCV cohort compared to controls (OR = 1.54; 95% CI 1.07 - 2.55; P = 0.02). HCV/HIV patients show a similar over-representation of less than two or two CCL3L1 copies (OR = 3.42; 95% CI 2.18 - 5.38; P < 0.001). However, no association is found between CCL3L1 CNVs and grades of inflammation or stages of fibrosis in HCV mono-infected patients. Conclusions: HCV patients carry lower CCL3L1 gene copy numbers than non-infected controls. Our findings indicate for the first time that susceptibility to HCV infection might be influenced by copy number variation within the host’s genome.

INHIBITION OF NKT CELL ACTIVATION AND THE DEVELOPMENT OF HEPATITIS BY A GLYCOSAMINOGLYCAN-BINDING DEFICIENT RANTES MUTANT

Maureen N. Ajuebor1, Amanda Proudfoot2, Cory Hogaboam2, Tai Le2, Mitch Kronenberg3, Mark Swain2; 1Dept of Molecular and Cellular Physiology, Louisiana State University, Shreveport, LA; 2Merck Serono Research Ceter, Geneva, Switzerland; 3Dept of Pathology, University of Michigan Medical School, Ann Arbor, MI; 4Developmental Immunology, La Jolla Institute for Allergy and Immunology, San Diego, CA; 5Dept of Medicine, University of Calgary, Calgary, AB, Canada

Background: Hepatitis is associated clinically with an increase in hepatic chemokine expression, including RANTES/CCL5, as well as the activation of NKT cells within, and recruitment of lymphocytes to, the liver. Recently, a glycosaminoglycan-binding deficient mutated version of CCL5 has been developed (GAG-CCL5) and demonstrates anti-inflammatory properties, via a mechanism which remains unclear. Methods/Results: Concanavalin A-induced hepatitis is a well characterized murine model of T cell mediated hepatitis which is critically dependent upon hepatic NKT cell activation. Using this model we have documented a significant inhibition of hepatitis in mice treated with GAG-CCL5 prior to concanavalin A (con A) administration, as reflected by serum ALT levels and histology [serum ALT 8 hrs post-con A: veh 8186 ± 489[SEM] U/L vs GAG-CCL5 1514 ± 230; p<0.01;n=5/group]. This inhibition of hepatitis was associated with a significant suppression of hepatic NKT cell activation as reflected by a > 50% reduction in the number of hepatic NKT cells producing either IL-4 or IFNγ in GAG-CCL5 vs vehicle treated mice receiving Con A (p<0.05 vs respective controls for both; NKT cell cytokine production determined by flow cytometry). We then used the specific in vivo NKT cell activator α-galactosylceramide (given as an intraperitoneal injection) to confirm that GAG-CCL5 was directly inhibiting the activation of hepatic NKT cells (as reflected by a > 65% reduction in hepatic NKT cell IFNγ production in GAG-CCL5 treated vs vehicle treated mice, as determined by flow cytometry; p<0.05). We next examined the effects of GAG-CCL5 in acetaminophen (APAP)-induced hepatitis which is known to be dependent upon both hepatic NKT cell activation and NK cell recruitment into the liver. In this model, GAG-CCL5 again significantly suppressed hepatitis [serum ALT 24 hrs post-APAP: veh 2378±275 vs GAG-CCL5 1094±145; p<0.05;n=4/group] and inhibited hepatic NKT cell activation (reflected by a >50% reduction in the numbers of IFNγ-producing hepatic NKT cells in GAG-CCL5 vs vehicle treated mice which received APAP; p<0.05) and also significantly inhibited the recruitment of NK cells, and IFNγ-producing NK cells, into the liver (>50% reduction in number of NK cells/liver in GAG-CCL5 treated mice vs vehicle treated mice receiving APAP; p<0.05). Conclusion: In summary, GAG-CCL5 inhibits the development of experimental hepatitis by preventing hepatic NKT cell activation, indicating that GAG-CCL5 may represent a novel therapeutic approach for the treatment of patients with hepatitis by targeting the innate immune system within the liver.

1019 CONTRIBUTION OF TRIF TO SECRETION OF MATURE IL-1β AND IL-18 VIA THE TLR-MEDIATED CASPASE-1 ACTIVATION DURING EXTRACELLULAR BACTERIAL INFECTION IN MICE

Michiko Imamura, Koubun Yasuda, Jiro Fujimoto, Shizuo Akira, Hiroko Tsutsui, Kenji Nakashima. 1st Department of Surgery, Hyogo College of Medicine, Nishinomiya, Japan; 2nd Department of Immunology & Medical Zoology, Hyogo College of Medicine, Nishinomiya, Japan; 3rd Department of Microbiology, Hyogo College of Medicine, Nishinomiya, Japan; 4th Department of Innate Immunity, Research Institutes for Microbiological Diseases, Osaka University, Suita, Japan

Innate immune cells (such as macrophages) participate in early host defense against pathogens by production of proinflammatory cytokines. We previously reported that Propionibacterium acnes-primed mice are highly susceptible to LPS and develop endotoxin shock or liver failure by their hyper-production of and hyper-responsiveness to TNF, IL-1β and IL-18. Both IL-1β and IL-18 are synthesized as precursor form and become active after being cleaved with caspase-1. Caspase-1 is also produced as precursor form and become enzymatically active when innate cells are stimulated with LPS or other appropriate stimuli. Two distinct pathways are activated for caspase-1-dependent release of IL-1β- and IL-1β- by stimulation with LPS. LPS alone induces caspase-1-dependent release of IL-1β- and IL-18 via activating extracellular sensor, TLR4 but independently of MyDD8. On the other hand, LPS plus ATP can induce those responses through activating intracellular sensor NOD-like receptors (NLRs), but not TLR4, which is due to intracellular influx of LPS by ATP. Since TRIF and TRAM are responsible for transducing MyDD8-independent signaling, we investigated whether these common signal adaptors are involved in LPS-induced caspase-1 activation. LPS stimulation of wild type Kupffer cells accelerates caspase-1 activation, while TRIF or TRAM deficient Kupffer cells fail to do it, indicating that both adaptors are essentially required. However, LPS plus ATP could induce activation of caspase-1 in TRIF-deficient Kupffer cells, indicating the dispensability of TRIF. After infection with Escherichia coli, extracellular bacterium, wild-type mice, but not tlr4-/-, trif-/- or caspase 1-/- mice, showed elevated serum levels of IL-18, indicating the importance of TLR/TRIF-mediated caspase-1 activation in vivo. These results demonstrate that mammalian host equips two caspase-1 activation machineries, i.e. TLR-mediated TRIF-dependent and NLR-mediated TRIF-independent pathways, and that TRIF links extracellular bacterial pathogen with caspase-1 activation would provide new regimen for the treatment of inflammatory liver diseases associated with aberrant activation of caspase 1.

1020 ALCOHOL CONSUMPTION INDUCES EXPRESSION OF SOCS3 AND SOCS1 AND INHIBITS SIGNALING VIA STAT3 AND STAT1 PATHWAYS IN HUMAN MONOCYTES

Oxana Norkina, Angela Dolganicu, Karen Kody, Pranoti Mandrekar, Gyongyi Szabo. UMass Med School, Worcester, MA

Introduction: Acute alcohol consumption is associated with downregulation of pro-inflammatory responses to various pathogens, induction of immunoinhibitory cytokines, and poor responses to IFNα treatment in HCV infection. We previously reported that alcohol activates JAK1-STAT3 signaling leading to IL-10 induction. The JAK-STAT pathway also activates its own negative regulator, suppressors of cytokine signaling, SOCS1 and SOCS3. SOCS proteins are inducible inhibitors that negatively regulate STAT3/STAT1 signaling pathways induced by cytokine, IL6 or IFNα. Aim: To explore the effect of alcohol on induction of SOCS1/SOCS3 and regulation of STAT3/STAT1 pathways induced by IL6 or IFNα in human monocytes in vitro and in vivo. Methods: Monocytes were isolated from blood samples of treatment-naive patients with chronic hepatitis C infection. Blood samples from normal volunteers were collected before and 24 hours after consumption of 2 ml vodka/kg body weight. In vitro experiments human monocytes were treated with 25-50mM of alcohol with or without cytokines for 45 min-5 h. Whole cell lysates were analyzed by western blot, nuclear proteins by EMSA, mRNA by real time RTPCR. Results: Alcoholic treatment of monocytes for 48h downregulated SOCS3 mRNA expression in monocytes. Alcohol treatment resulted in increased phosphorylation of STAT3 at tyr705 and ser727 residues and increased STAT3 DNA binding. Activation of STAT3 has been shown to induce expression of SOCS1 and SOCS3. We hypothesized that induction of SOCS proteins by alcohol may also lead to modulation of cytokine signaling through STAT1 and STAT3. Indeed, we observed significant downregulation of both IL6- and IFNα-induced STAT3 and STAT1 DNA binding when alcohol was added to monocytes 3 hours prior to the cytokine stimulation. To address whether inhibition of IL6-induced STAT3 DNA binding had downstream effects, we measured mRNA levels of IL6-dependent genes, MCP-1 and ICAM-1. We detected significant inhibition of IL6-induced expression of MCP-1 and ICAM mRNA in monocytes after acute alcohol exposure. Finally, we found increased baseline as well as inducible STAT1 and STAT3 DNA binding in monocytes of patients with chronic HCV infection compared to normal controls. Importantly, acute alcohol inhibited both IL6- and IFNα-induced STAT1/3 activation in monocytes of HCV patients. Conclusion: Alcohol activates STAT3 signaling pathway and induces SOCS3 and SOCS1 levels in monocytes, thus leading to downregulation of IL6- and IFNα-induced signaling via STAT1/STAT3 pathways. These mechanisms may be involved in attenuated responses to IFNα therapy after alcohol use in HCV infection.

1021 ACTIVATION OF CYCLIC-AMP RESPONSE ELEMENT BINDING PROTEIN CONTRIBUTES TO ADIPONECTIN-STIMULATED INTERLEUKIN-10 EXPRESSION IN RAW 264.7 MACROPHAGES

Pil-Hoon Park, Honglian Huang, Kathryn Bryan, Megan R. McMullen, Laura Nagy, Megan R. McMullen, Laura Nagy. 1Gastroenterology, Cleveland Clinic, Cleveland, OH; 2Pathobiology, Cleveland Clinic, Cleveland, OH

Adiponectin, an adipokine predominantly secreted from adipose tissue, has potent insulin-sensitizing effects in liver and muscle, as well as potent anti-inflammatory properties in macrophages. Adiponectin concentrations in the circulation are decreased in response to chronic ethanol feeding; treatment with adiponectin during chronic ethanol exposure protects mice from the development of ethanol-induced liver injury (Xu, et al., 2003). The mechanisms for the protective effects of adiponectin are likely complex. However, recent data suggests that adiponectin's anti-inflammatory properties play a critical role in its protective effects against ethanol-induced liver injury, since adiponectin treatment normalizes LPS-stimulated TNFα produc-
tion by isolated Kupffer cells after chronic ethanol exposure. We have recently reported that increased production of interleukin-10 (IL-10), a potent immune-modulatory cytokine, is involved in the anti-inflammatory actions of adiponectin in macrophages (Park, et al., 2007). Here we have further investigated the molecular mechanisms by which adiponectin increases IL-10 production in macrophages. Globular adiponectin (gAcrp) increased IL-10 promoter activity and IL-10 mRNA accumulation in RAW 264.7 macrophages. Deletion of the sequences from –416 and –369 in the IL-10 promoter, containing a cyclic AMP-response element binding protein (CREB) binding site, prevented gAcrp-induced IL-10 promoter activation. Treatment of RAW 264.7 macrophages with gAcrp increased the phosphorylation of CREB at Ser133, as well as enhanced the DNA binding activity of CREB. Further, overexpression of a dominant negative form of CREB prevented gAcrp-stimulated transcriptional activation of IL-10. gAcrp-stimulated CREB phosphorylation was mediated by the activation of both ERK1/2- and PKA-dependent pathways. Inhibition of either ERK1/2 or PKA activity prevented gAcrp-stimulated CREB phosphorylation, as well as gAcrp-stimulated IL10 promoter activation. Taken together, these data identify gAcrp-stimulated CREB as a key transcription factor responsible for gAcrp-induced IL-10 promoter activation. Supported by NIH AA11975 and AA013868.

1022 TRIMMING OF BRANCHED OLIGOSACCHARIDE STRUCTURES ON HBV INHIBITS DC-SIGN BINDING
Marjoleine L. Op den Brouw1, Marein A. de Jong2, Renate G. van der Molen1, Theo B. Geijtenbeek2, Harry L. Janssen1, Andrea M. Woltman1; 1Gastroenterology & Hepatology, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands; 2Molecular Cell Biology & Immunology, VU University Medical Center, Amsterdam, Netherlands

Background: Currently, a high affinity receptor for Hepatitis B virus (HBV) is still unknown. For HCV, both DC-SIGN, a mannose recognizing lectin expressed on dendritic cells, and L-SIGN, a liver expressed homologue, are known to bind glycoprotein E2. The oligosaccharide structures on HBV surface antigen (HBsAg) may also allow DC-SIGN/L-SIGN interaction. Therefore, we aimed to investigate the role of both DC-SIGN and L-SIGN in binding of HBV. Methods: Interaction between HBV or HBsAg and DC-SIGN/L-SIGN was studied by ELISA, using recombinant DC-SIGN-Fc and lysates of DC-SIGN/L-SIGN transfected Raji cells. Specificity was determined by blocking with mannan (100 µg/ml) or EGTA (10 mM). As a positive control, HCV virus like particles (VLP) were used. Highly mannosylated HBV was generated by treating HBV producing HepG2.215 cells with the mannosidase inhibitor kifunensin (5 µg/ml). Upstream of HBsAg by DC-SIGN/L-SIGN transfected Raji cells was studied by flow cytometry and compared to lectin mediated uptake of dextran-FITC. Results: DC-SIGN-Fc specifically interacted with HCV VLP, but no interaction with either HBsAg or HepG2.215 derived HBV was detected. HBV binding to DC-SIGN was observed after kifunensin treatment, indicating that HBV oligosaccharide trimming inhibits interaction with DC-SIGN. In theory, the recombinant DC-SIGN-Fc protein might be misfolded, therefore binding of HBsAg to native DC-SIGN/L-SIGN was also studied with lysates of transfected Raji cells. No interaction was observed between HBsAg and either DC-SIGN or L-SIGN. Also, cultured transfected Raji cells did not bind HBsAg. In contrast, both Raji DC-SIGN/L-SIGN showed mannan sensitive binding of dextran-FITC. Conclusions: Although both DC-SIGN and L-SIGN are known receptors for HCV, they do not seem to play a role in recognition of HBV. Inhibition of mannos trimming during HBV replication renders the virus susceptible to recognition by DC-SIGN. Whether HBV might use mannos trimming as a way to escape recognition by DC-SIGN and L-SIGN remains to be elucidated.

1023 CONCANAVILIN A-INDUCED HEPATITIS IS DEPENDENT ON TOLL-LIKE RECEPTOR 4 (TLR4) SIGNALING PATHWAYS
Beth L. Mallard1, Jacqui Harper2, Ayako Mabuchi1, Antony M. Wheatley1; 1Department of Physiology, University of Otago, Dunedin, New Zealand; 2Malaghan Institute of Medical Research, Wellington, New Zealand

Background: Concanavalin A (Con A) administration in mice leads to T cell mediated hepatitis, which involves cytokines interferon (IFN)-γ and tumor necrosis factor (TNF)-α. Lipopolysaccharide (LPS)/TLR4 signaling pathway has been shown to be involved in underlying mechanism in a number of liver pathologies ([L/R]-induced injury, alcohol-induced hepatitis). Involvement of TLR4 in T-cell mediated hepatitis has not been elucidated. In the current study the impact of TLR4 gene deletion (TLR4-/- mice) and a defective TLR4 (C3H/HeJ mice) was investigated. Methods: Mice with normal TLR4 (C3H/HeN and C57BL/6), C3H/HeJ and TLR4-/- were injected with Con A (20 mg/kg). Plasma ALT was measured to assess liver injury. Plasma TNF-α and IFN-γ were measured. Results: Following Con A administration, C3H/HeN and C57BL/6 mice developed a severe liver injury indicated by increased increased plasma ALT (Fig). However, no ALT increase was seen in C3H/HeJ or TLR4-/- mice. Histological examination confirmed signs of necrosis following Con A in the wildfire animals that was absent in the C3H/HeJ and TLR4-/- mice. TNF-α was significantly elevated at 2 hours post-Con A in C3H/HeN (1478±160 pg/ml) and C57BL/6 mice (7302±3500 pg/ml) but not in C3H/HeJ mice (347±199 pg/ml). IFN-γ levels were significantly higher in C3H/HeN (770±160 pg/ml) and C57BL/6 mice (113±15 pg/ml) compared to C3H/HeJ mice (40±30 pg/ml). Conclusions: Our results show that Con A causes liver injury and proinflammatory cytokine production in mice with functional TLR4. In the absence of TLR4 signaling pathway, cytokine production is attenuated and injury is prevented (C3H/HeJ) and TLR4-/-.
were revealed to be responsible for the suppression. These mechanisms may contribute to the clinical persistency of HCV infection and might constitute a novel antiviral therapeutic target.

1025 EXPRESSION OF HEPATITIS C VIRUS PROTEINS IS SUFFICIENT TO INDUCE RECOGNITION BY RESIDENT HEPATIC AND INVARIANT CD1D-RESTRICTED T CELLS

Kazuhiko Yanagisawa1, Roulie Wang1, Wenyu Lin2, Rachel Baden1, Khadija Iken1, Stanley M. Lemon3, Raymond T. Chung2, Lucy Golden-Mason4, Hugo R. Rosen4, Margaret J. Koziel1, Mark A. Exley1; 1Hematology / Oncology, Beth Israel Deaconess Medical Center, Boston, MA; 2Gastrointestinal Unit, Massachusetts General Hospital, Boston, MA; 3University of Texas Medical Branch at Galveston, Galveston, TX; 4Colorado Health Sciences University, Denver, CO

BACKGROUND: The liver is selectively enriched for innate immune cells, including natural killer T cells (‘NKT’), defined by co-expression of NK markers and T cell antigen receptor. The corresponding presenting molecule for a diverse subset of NKT, CD1d, is expressed at very low levels in healthy liver, but is specifically up-regulated in certain inflammatory conditions, including chronic HCV infection. The CD1d:NKT system is highly conserved across mammalian species. CD1d-restricted NKT are a major rodent hepatic subset and we identified analogous but distinct pro-inflammatory Th1 human populations. NKT cells positively or negatively regulate immune responses, partly through cytokine production. Their activation can be protective against certain viral and other infections, but excessive stimulation causes liver damage. METHODS: Human intrahepatic lymphocytes (IHL) and hepatocytes were isolated from subjects with HCV or other conditions along with hepatocytes from HCV transgenic mice. Blood-derived ‘invariant’ NKT served as control effectors and hepatocytes and other CD1d+ cells were used as targets. Responses of hepatic NKT were measured ex vivo and in vitro by cytokine production. An HCV-expressing Huh-7 hepatocyte line was also used as stimulator. CD1d expression was monitored on potential target cells. RESULTS: IHL CD1d-reactive NKT could be readily detected ex vivo, particularly in chronic hepatitis C, confirming their presence as a major population. Hepatocyte surface CD1d was specifically up-regulated in chronic HCV infection. Expression of HCV proteins in a hepatocyte cell line was sufficient for CD1d-dependent recognition by human IHL as well as blood invariant NKT. Furthermore, human and murine peripheral as well hepatic NKT responded efficiently to HCV transgene-expressing murine hepatocytes, suggesting a direct role for HCV protein expression in activating these cells in disease. CONCLUSIONS: HCV protein expression by hepatocytes can induce CD1d+ for surveillance by resident Th1 hepatic CD1d-restricted NKT. While potentially of benefit in acute hepatotropic infections, HCV appears to have evolved to exploit this system, thereby facilitating chronic inflammation.

1026 PROSPECTIVE ANALYSIS OF HEPATIC CD1D-RESTRICTED T CELLS IN ADVANCED HCV LIVER DISEASE

Roujie Wang1, Lyly Tran1, Kristin K. Snow2, Karen L. Lindsay3, Margaret J. Koziel1, Mark A. Exley1, 1Medicine, Beth Israel Deaconess Medical Center, Boston, MA; 2New England Research Institute, Watertown, MA; 3Medicine, University of Southern California, Los Angeles, CA

BACKGROUND: The liver is selectively enriched for innate immune cells, including natural killer T cells (NKT), defined by co-expression of NK markers and T cell antigen receptor. The corresponding presenting molecule for a diverse subset of NKT, CD1d, is expressed at low levels in healthy liver, but is specifically up-regulated in certain inflammatory conditions including chronic hepatitis C. The CD1d:NKT system is highly conserved across mammalian species. CD1d-restricted NKT are a major rodent hepatic subset with analogous but distinct pro-inflammatory Th1 human populations. NKT cells can control immune responses, partly through cytokine production, and their excessive stimulation causes liver damage. To test for a role in HCV-mediated liver disease progression, we performed prospective analysis of hepatic CD1d-restricted NKT in advanced HCV-mediated liver disease from samples obtained within the HALT-C trial. METHODS: Human intrahepatic lymphocytes (IHL) were expanded from up to 3 biopsies over 48 months from HALT-C subjects and tested for CD1d responses. Blood-derived ‘invariant’ NKT served as control effectors. Responses of hepatic NKT were measured by cytokine production. RESULTS: There was an increase in hepatic NKT cell Th2 pro-fibrotic IL-4 production (5±2.5 vs 6; 6±6 at tested again at Month 48) but not IFNγ from hepatic CD1d-restricted NKT. Cross-sectional analysis of samples from a total of 19 subjects to date with 1 or more time point analyzed for IL-4 also support an increase in this prototypical Th2 cytokine over time. Notably, in the non-seral samples also, there was at least as much IFNγ at Month 48. Whether treatment (in this by definition treatment refractory cohort) selectively impacts hepatic CD1d-restricted NKT IFNγ responses is under study. However, unlike the steady (likely treatment refractory) IL-4 rise for 5/6 subjects, IFNγ dropped at Month 24 (4/4 informative subjects; most proximal point post-therapy) in those who actually received ribavirin / IFNa and then rebounded to baseline biopsy level at the Month 48 biopsy. Other pro- and anti-fibrotic cytokines are being analyzed. CONCLUSIONS: HCV infection of treatment refractory patients was associated with a switch from Th1 hepatic CD1d-restricted NKT toward mixed Th1 and Th2 cytokine production. While potentially of benefit in control of HCV infection, NKT cells may facilitate HCV-mediated liver disease progression.

1027 BLyS/BAFF RECEPTOR-LIGAND SYSTEM IN HCV INDUCED B-CELL CLONAL DISORDERS

Dan Landau1,2, David Saadoun1,2, David Klatzmann2, Michelle Rosenzwaig3, Patrice Cacoub1,2, 1Service de Médecine Interne, Hôpital Pitié-Salpêtrière, Paris, France; 2Laboratoire de Biologie et Thérapeutique des Pathologies Immunitaires, CNRS/UPMC UMR 7087, Hôpital Pitié-Salpêtrière, Paris, France

Background & Aims: Chronic hepatitis C virus (HCV) infection induces B lymphocytes clonal disorders, including mixed cryoglobulinemia (MC)-vasculitis and B-cell non-Hodgkin’s lymphoma (B-NHL). The aim of this study was to examine the activity of the B-Lymphocytes Stimulator (BLyS) receptor-ligand system in HCV-induced B-cell disorders. Methods: A group of 94 patients with chronic HCV infection (28 HCV+ without MC, 23 HCV+ with asymptomatic MC, 35 HCV+ MC-vasculitis and 9 HCV+ B-NHL) and 15 healthy volunteers participated in this study. BLyS studies included serum BLyS measurement, membrane bound BLyS (mBLyS) staining on PBMC, BLyS binding capacity on CD19+ cells, BLyS receptors staining on CD19+ cells, CD3+ cells and clonal Vh1-69+ population and BLyS anti-apoptotic and proliferative culture studies. Finally, we evaluated BLyS measurement following treatment with interferon-alpha and Ribavirin (64 patients) or Rituximab (14 patients). Results: Serum BLyS concentration was elevated in HCV induced MC-vasculitis and B-NHL compared with HCV+ patients without vasculitis or healthy controls (p<0.05). Healthy controls and HCV patients without MC-vasculitis had similar levels of mBLyS expression with a trend towards lower expression in HCV-induced MC vasculitis. Compared with healthy controls BLyS binding to CD19+ cells was decreased in HCV patients without vasculitis, with a further decrease in patients with HCV-induced MC vasculitis (MFI, 41±6.7, 20±8±1.9, and 7.9±4.3, respectively, p<0.01 and p<0.05, respectively). BR3 staining showed a step wise decrease with highest values in healthy controls and HCV+ without MC, and lowest in HCV-induced B-NHL (p<0.0001). BR3 staining levels were further decreased in Vh1-69+ clonal B-cells. BLyS anti-apoptotic effects were maintained in culture despite this decrease in BR3 staining. Complete clinical remission in HCV-induxed MC-vasculitis or B-NHL was associated with a decrease in serum BLyS concentration, as well as with a marked increase in BR3 staining on CD19+ cells. Rituximab treatment in HCV induced MC-vasculitis or B-NHL was associated with a remarkable five-fold increase in serum BLyS concentration (p<0.001). This increase mirrored the depletion of CD19+ cells. BR3 staining in repopulating B-cell sub-populations was significantly decreased from 19.8±2.5 to 6.9±2.5 (p<0.005). Conclusion: The results of this study suggest that BLyS is significantly involved in HCV-induced B-cell clonal disorders.

1028 HCV-SPECIFIC CELLULAR RESPONSES IN ANTIBODY NEGATIVE, HCV RNA NEGATIVE INJECTION DRUG USERS

Marija Zeremski, Queenie B. Brown, Marla A. Shu, Brian R. Edlin, Andrew Talal; Division of Gastroenterology, Department of Medicine, Center for the Study of Hepatitis C, Weill Medical College of Cornell University, New York, NY

Background & Aims: Hepatitis C virus (HCV) infection resolves spontaneously in 15-50% of adult patients, while the remainder becomes persistently viremic. However, growing evidence suggests that some people exposed to HCV may develop adaptive cellular immune responses without becoming viremic or developing antibodies. The aim of this study was to examine the prevalence of HCV-specific interferon (IFN)-γ cellular responses in high-risk individuals that are both HCV RNA and HCV antibody negative. Methods: We evaluated HCV-specific T-cell responses in 13 HCV RNA and HCV antibody negative young injection drug users (IDUs, aged 18-35 years) by IFN-γ enzyme-linked immunospot (ELISPOT) assay using 429 overlapping HCV peptides that cover the entire HCV genome. Peptides were pooled in 21 mixes before incubation with patients’ peripheral blood mononuclear cells. Nine IDUs who were HCV antibody
positive and HCV RNA negative (who had presumably spontaneously resolved HCV infection) were used as positive controls. Fourteen people at low-risk for HCV acquisition were used as negative controls. Responses >2 standard deviation above the mean of the 14 controls for each respective mix were considered positive. Results: HCV-specific cellular responses in IDUs negative for both HCV RNA and HCV antibodies were similar to those measured in spontaneous resolvers. While we detected very strong responses to nearly all peptide mixes in 3/13 (23%) patients, 4/13 (31%) additional patients had moderately strong responses to at least 7 antigenic combinations. Conclusions: Intermediate to strong IFN-γ responses to multiple HCV epitopes were detected in approximately half of analyzed patients, suggesting their prior exposure to HCV despite the lack of detectable HCV antibodies. The high frequency of cellular responses against HCV in seronegative IDUs supports the hypothesis that multiple low-level exposures to HCV may promote the development of cellular immunity without the development of viremia as has been shown previously in older IDUs, and suggests that this immunity may develop after a shorter duration of exposure. The potential protective role of these immune responses remains to be determined. *Drs. Edlin and Talal have contributed equally to the project.

1029 DETECTION OF CD4+ T CELL RESPONSES IN PATIENTS WITH ACUTE HCV INFECTION IRRESPECTIVE OF CLINICAL OUTCOME

Julian C. Schulze zur Wiesch,1,2 Victoria Kasprowicz,2 Arthur Y. Kim,2 Steve Longworth2, Brian Nolan2, Thomas Kuntzen2, Barbara McGovern2, Lia Lewis-Ximenes2, Raymond T. Chung3, William Kwok4, Bruce D. Walker2,2,7, Georg M. Lauger2, Medizinische Klinik I, Universitaetsklinikum Hamburg Eppendorf, Hamburg, Germany; 2Partners Aids Research Center, Massachusetts General Hospital, Boston, MA; 7Howard Hughes Medical Institute, Chevy Chase, MD

Background and aims: HCV specific proliferative CD4+ T-cell responses have been demonstrated to be associated with the outcome of acute HCV infection. In contrast, little is known about the frequency and phenotypic properties of the HCV-specific CD4+ T cell response. Direct characterization of circulating CD4+ T cells has represented a significant challenge in human immunology, despite the recent development of MHC Class II tetramers. The purpose of this study was to longitudinally study CD4+ responses directly ex vivo by class II tetramer staining and by expanded CD4+ T cell lines. Methods: Multicolor ex vivo class II tetramer analysis was performed in a large cohort of 39 subjects with acute HCV infection. In a subset we were able to track the HCV specific CD4+ responses longitudinally. Additionally, we assessed the breadth of the response using expanded HCV specific short term lines of these subjects. Results: Using novel class II tetramers we could analyze HCV-specific CD4+ T cells directly ex vivo. We were able to track up to 3 different specificities by class II tetramers in a single patient. The frequency of tetramer positive cells reached up to 1/250 of all CD4+ cells during acute infection and declined significantly after resolution of HCV. Surprisingly, we found specific CD4+ cells by ex vivo Tetramer stainings or after short-term stimulation with IL2 also in most subjects with chronically evolving HCV, despite the absence of a proliferative response. These responses disappeared over time, but were occasionally preserved in patients in whom treatment with Interferon-alpha was started early. Preliminary phenotypic studies also did not reveal a T-cell marker clearly associated with the outcome of infection. Discussion: HCV specific CD4+ T cells are detectable at early timepoints of HCV infection in the vast majority of subjects, irrespective of clinical outcome and independent of the results in standard proliferation assays. Direct ex vivo analysis of those cells using class II tetramers will be a powerful tool to understand the mechanisms by which CD4+ T cells fail to control HCV infection and to elucidate the fate of the T cell response when HCV persists.

HIGHER PERCENTAGES OF INTRA-HEPATIC REGULATORY T CELLS ARE PRESENT IN CHRONIC HEPATITIS B PATIENTS WITH A HIGH VIRAL LOAD

Jeroen N. Stoop1, Andrea M. Waltman1, Rekha S. Binda1, Johannes G. Kusters1, Pieter E. Zondervan2, Ernst J. Kuipers1, Harry L. Janssen1, Renate G. van der Molen1; 1Gastroenterology & Hepatology, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands; 2Pathology, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands

CD4+CD25+FoxP3+ regulatory T cells (Treg) play a key role in the impaired immune response observed in patients with a chronic hepatitis B virus (HBV) infection. Most studies concerning Treg and HBV are performed with cells isolated from peripheral blood, while the liver is the main site of infection. To gain more insight in the role of Treg in chronic HBV we have monitored intra-hepatic Treg. Peripheral blood and liver biopsy samples were obtained from 40 patients with a chronic HBV infection. The liver tissue was collected in culture medium and was digested with collagenase for 15 minutes to create a single cell suspension. The percentage of Treg was determined by flowcytometry using antibodies to CD4, CD25 and FoxP3. The results show that patients with a high viral load of >1 x 10^5 geq/ml have a significantly higher percentage of intra-hepatic Treg as compared to patients with low viral load <1 x 10^5 geq/ml (8.20% ± 0.50% vs. 6.18% ± 0.54% respectively; p< 0.05), while the percentage of peripheral blood Treg was similar in both groups (9.38% ± 0.39% vs. 8.94% ± 0.43% respectively). When patients were divided into two groups based on liver inflammation, indicated by their serum ALT levels (ALT < 2 x ULN and ALT > 2 x ULN) no differences in percentages were observed between the two patient groups for intra-hepatic Treg (7.61% ± 0.56% vs. 7.03% ± 0.52% respectively) as well as for peripheral blood Treg (9.34% ± 0.31% vs. 8.89 ± 0.60% respectively). There was also no relation observed between the proportion of Treg and the Metavir Fibrosis score. Next to CD4+CD25+FoxP3+ Treg the liver also contained a large population of CD4+CD25-FoxP3+ cells (2.40% ± 0.21% (intra-hepatic) vs. 0.89% ± 0.06% (peripheral blood); p < 0.05). Additionally, approximately 40% of liver Treg expressed the immunoregulatory marker programmed death-1 (PD-1) while peripheral blood Treg hardly express PD-1. PD-1 expression does not seem to be specific for Treg, since the liver contains more PD-1+CD4+ T cells compared to peripheral blood. In conclusion: Liver CD4+ T cells have a higher expression of the immunoregulatory receptor PD-1. There was no relation between previous liver damage or liver inflammation and the presence of Treg. On the other hand, an increased proportion of intra-hepatic Treg was observed in patients with a high viral load, suggesting the importance of Treg in HBV tolerance and persistence of viral replication.

ANTIGEN-PULSED DENDRITIC CELLS ARE CAPABLE OF INDUCING BOTH INNATE AND ADAPTIVE IMMUNITY: A LESSON LEARNT FROM CROSS TALK BETWEEN NATURAL KILLER CELLS AND DENDRITIC CELLS AND THEIR APPLICATION FOR IMMUNE THERAPY OF CHRONIC HEPATITIS B VIRUS INFECTION

Osamu Yoshida, Sk. Md. Fazle Akbar, Teruki Miyake, Maho Hamada, Yoichi Hiasa, Kojiro Michitaka, Morikazu Onji; Department of Gastroenterology and Metabolism, Ehime University Graduate School of Medicine, Toon, Japan

Purpose: The magnitudes of both innate and adaptive immunities are decreased in chronic infections and cancers. Accordingly, immune therapy against these diseases have been formulated to activate innate immunity targeting natural killer (NK) cells and adaptive immunity targeting dendritic cells (DC). This study was conducted to develop insights about crosstalk between NK cells and DCs and to assess if antigen-pulsed DCs can activate both innate and adaptive immunity. Methods: Both normal C57BL/6 mice and hepatitis B virus transgenic mice (that express hepatitis B surface antigen (HBsAg), HBV DNA, and hepatitis B e antigen) were used. NK cells were depleted by administrating anti-asialo GM1 antibody, 100 microliter/mouse, intraperitoneal, twice at an interval of 48 hours. Normal C57BL/6 mice and NK-depleted mice were immunized with hepatitis B vaccine containing HBsAg, intraperitoneally and the levels of antibody to HBsAg (anti-HBs) and HBsAg-specific T cells were estimated 28 days after immunization. Spleen DCs from normal C57BL/6 mice and hepatitis B virus transgenic mice were cultured with HBsAg to prepare HBsAg-pulsed DCs and administered to NK-depleted mice, twice, at an interval of 2 weeks. We assessed if HBsAg-pulsed DCs activated innate immunity in NK-depleted mice by inducing proinflammatory cytokines (interleukin-12p70, interferon-gamma, tumor necrosis factor-alpha, and interleukin-6), 3 days after administration of HBsAg-pulsed DCs. Also, we evaluated if HBsAg-pulsed DCs induced anti-HBs and HBsAg-specific lymphocytes in NK-depleted mice. Results: Flow cytometric analyses revealed that injection with anti-asialo GM1 in mice resulted in depletion of >90% NK cells from liver, spleen and bone marrow. Compared to normal C57BL/6 mice, DCs from NK-depleted normal C57BL/6 mice produced significantly lower levels of all proinflammatory cytokines (p<005) and could not activate HBsAg-specific lymphocytes in vitro indicating that NK cells are essential for proper functioning of DCs. High levels of anti-HBs were detected in the sera of all normal mice (10 of 10, 100%), but very low levels of anti-HBs were found in only 2 of 10 NK-depleted mice due to immunization with HBsAg (p<0.05). Also, the levels of HBsAg-specific T cells were significantly lower in NK-depleted mice compared to those in normal C57BL/6 mice (p<0.001). Administration of HBsAg-pulsed DCs induced higher levels of all proinflammatory cytokines, anti-HBs and HBsAg-specific lymphocytes in NK-depleted mice. Conclusions: This study provides the rationale for using antigen-pulsed DCs for treatment of chronic infections when both innate and adaptive immunities are impaired.

1033 HLA CLASS II AND RACE-DEPENDENT DIFFERENCES IN IMMUNE RESPONSE TO HCV, SUSCEPTIBILITY TO CHRONIC INFECTION, AND RESPONSE TO THERAPY
Tony N. Marion1, Yanming Xing1, Zhimin Liu1, Ann Madey2, Jaquelyn F. Fleckenstein2; 1Molecular Sciences, University of Tennessee Health Science Center, Memphis, TN; 2Medicine-Gastroenterology, University of Tennessee Health Science Center, Memphis, TN

A hallmark of HCV infection is its tendency to develop into chronic disease. The response to therapy is more effective for Caucasian (CAU) than African American (AA) patients. The goals of the present study within the University of Tennessee Cooperative Hepatitis C Research Center have been to identify HLA associated genotypic differences among chronically infected AA and CAU patients that are 1) correlated with susceptibility to chronic infection, 2) correlated with response to combination therapy, and 3) determine class II-dependent immune responses by patient PBMC. HLA genotypes have been accumulated for 57 CAU and 85 AA patients. All patients had genotype 1a or 1b and received pegylated interferon-alpha2b and weight-based ribavirin. The difference in inheritance of HLA-DRB1*11 among African Americans (AA) chronically infected with HCV and the inheritance of DRB1*11 among AA in the Southeast is highly significant (Binomial Probability p = 0.000097). There is no DRB1*11-dependent significant difference in response to therapy among AA enrolled in our study. Among chronically infected Caucasians (CAU), we have observed a highly significant difference in the frequency of inheritance of HLA-DRB1*03 (Binomial Probability p = 0.00022). Both associations have been reported. What has not been reported is the difference in response to therapy among CAU with DRB1*03. Among CAU patients, 34% initially responded to therapy with elimination of circulating virus to below detectable levels for at least 24 consecutive weeks only to relapse to pre-therapy levels of viremia. More than half (53%) of relapsing CAU patients were DRB1*03 (p = 0.027, Fisher). Prior to therapy most chronically infected patients had relatively poor in vitro T cell proliferative and interferon-gamma responses to HCV, compared to mitogen or tetanus toxoid (TT). Immune responses to HCV were significantly higher (p = 0.007) in patients that remained virus free 24 weeks after the end of therapy compared to patients in which virus was not eliminated or who had viral relapse. A very surprising finding was that T cell responses were significantly higher to tetanus toxoid (TT) than HCV proteins (p = 0.011) for non-DRB1*11 AA but not DRB1*11 AA (p = 0.307). This result suggests that HLA-DRB1 inheritance may have a remarkable impact on immune potential to HCV and may explain in part why DRB1*11 AA are more prone to chronic infection. This result may also implicate an influence of Treg in susceptibility to chronic HCV, a hypothesis currently under investigation. This research was supported by NIH grants NIAID U19AI066316 and NCRR R016949, RR022465, and M01 RR002011.

1034 ADHESION OF IN VITRO GENERATED DENDRITIC CELLS TO HUMAN HEPATIC ENDOTHELIUM UNDER CONDITIONS OF SHEAR STRESS
Stuart Curbishley, Janine Youster, Vincent W K Lai, David H. Adams; Liver Research Group, Queen Elizabeth Hospital, University of Birmingham, Birmingham, United Kingdom

The incidence of hepatocellular carcinoma (HCC) is rising as a consequence of the increased prevalence of cirrhosis. Despite the presence of large numbers of tumour-infiltrating lymphocytes in HCC, effective killing of tumour cells is not achieved. Tumour-pulsed dendritic cells (DCs) can induce effective T cell responses in animals and early clinical trials are promising. However little is known about the mechanisms that regulate the recruitment of adoptively transferred DCs to the tumour. Aims: To determine the molecular regulation of DC trafficking to the human liver and hepatocellular carcinoma. Methods: Liver-derived DCs (LDC) were isolated from patients with HCC. Monocyte derived DCs (MoDC) were generated in vitro in the presence of GM-CSF and IL-4, before being matured with macrophage conditioned media. Primary hepatic sinusoidal endothelial cells (HSEC) isolated from human liver were cultured in glass capillary tubes before being perfused with DCs at physiologically relevant shear stress. Results: LDCs from livers containing HCC expressed maturation markers including CD86 and Class II but expressed higher levels of CCR5 than CCR7 suggesting only partial activation. Under conditions of fluid flow anti-CD40/FcR antibodies reduced adhesion of immature MoDCs to TNF-α stimulated HSEC by around 40%, though no significant variation was seen with mature MoDCs. Inhibition of CX3CCL1 on HSEC reduced total adhesion of both immature and mature MoDC by 60% and 40% respectively and transmigration by up to 70% in both cases. Similar inhibition of adhesion and transmigration was seen when pertussis toxin was used to block GI protein linked signalling. Conclusion: These data demonstrate that MoDCs use a unique combination of adhesion molecules comprising CX3CCL1, ICAM-1 and VCAM-1 to bind HSEC from flow. This data has allowed us to set up a small clinical study to visualise MoDC homing to the human liver following administration peripherally or via the hepatic artery, the results of which we will present at this meeting.

1035 INTRAHEPATIC REGULATORY T CELLS DIFFER PHENOTYPICALLY FROM THEIR CIRCULATING COUNTERPARTS IN CHRONIC THERAPY NAIVE HCV PATIENTS
Mark Claassen, Rob J. de Knecht, Harry L. Janssen, Andre Boonstra; Laboratory of Gastroenterology and Hepatology, Erasmus MC - University Medical Centre Rotterdam, Rotterdam, Netherlands

BACKGROUND: Regulatory T cells (Treg) play a significant role in the hampered immune response against HBV, as we have shown previously. Similar findings have been suggested for Treg in chronic HCV infection. This may explain the weak HCV specific T cell response in these patients. The immune response at the primary site of infection, the liver, is likely to play a critical role in HCV persistence. METHOD: Minimally invasive aspiration biopsies enabled us to repeatedly study intrahepatic and peripheral Treg in parallel. RESULTS: In 20 chronic HCV therapy naive patients, CD8+ lymphocytes were more frequent in the liver than in blood (22.8% and 13.6% respectively, p<0.001). In contrast, the proportion of CD4+ lymphocytes was lower intrahepatically than peripherally (26.34% and 31.57% respectively, p<0.05). Careful analysis of CD4+CD25hi cells and FoxP3+CD4+CD25+ cells revealed a smaller proportion of Treg in the liver (8.1% against 9.6%). Preliminary data suggest that Treg in liver and in blood predominantly consist of a memory phenotype (a.o. CD45RO). Our findings indicate that a significant proportion of CD4+ lymphocytes infiltrating the liver are Treg. However, the ratio Treg to total CD4+ lymphocytes and total CD8+ lymphocytes was lower than in peripheral blood. CONCLUSIONS: Our data
indicate that the chronicity of HCV can not be solely explained by an increased ratio of Treg to effector T cells in the liver. We are currently further investigating phenotypical and functional differences between liver and blood Treg. This could delineate the contribution and possible mechanism of intrahepatic Treg to the attenuated HCV immunity.

1036 THE ROLE OF NANOBACTERIA IN CHOLECYSTITIS AND CHOLELITHIASIS

Somaia Shehab Eldeen, Linda k. Green, Vladimir Khaoustov, Boris Yoffe; Departement of Medicine, Michael E. Debaky VAMC, Baylor College of Medicine, Houston, TX

Background: Recently discovered sub-microscopic blood particles known as nanobacteria, have a special characteristic no other blood particles have been known to possess: they form calcium phosphate shells. They have been found in human blood, arterial wall plaques, psammoma bodies of ovarian tumors and nephrolithiasis. The clinical trials demonstrated that the eradication of nanobacteria reduced the calculations in coronary arteries. The aim of this study is to access the relation between nanobacteria and cholecystitis.

Materials & Methods: Twenty-six surgically resected gallbladders with cholecystitis were tested for the presence of nanobacteria by immunohistochemical staining using primary antibody (NanoVision Antibody 8D10, Nanobac OY, Finland) and super sensitive link-label immunohistochemical detection system (QA000-5L, BioGenex, San Ramos, CA). The formalin fixed tissue link-label immunohistochemical staining system Antibody 8D10, Nanobac OY, Finland) and super sensitive immunohistochemical staining using primary antibody (NanoVision Antibody 8D10, Nanobac OY, Finland) and super sensitive link-label immunohistochemical detection system (QA000-5L, BioGenex, San Ramos, CA). The formalin fixed tissues were imbedded in paraffin, sectioned at 50 microns and stained. The control slides (provided by Nanobac OY, Finland) included cell cultures with and without nanobacteria inoculation. The stained tissue slides were reviewed blindly and graded from 0 to 4+ in staining intensity and location of staining. The results were then compared to the clinical, gross pathology and histological findings. Results: The initial evaluation revealed that 25 out of 26 cases were stained positively for nanobacteria. Following intensity of staining was observed: 0 (1 case), 1+ (5 cases), 2+ (13 cases), 3+ (6 cases) and 4+ (1 case). The one case that did not stain was a gangrenous gallbladder with no normal epithelium remaining for evaluation. No staining was observed when the primary antibody was omitted. Six out of 13 cases with gross lithiasis, have staining intensity 3+ or more compared to one out of 13 without lithiases, suggesting a strong association between nanobacteria and cholelithiasis. Nanobacteria were detected within the gallbladder epithelium, inflammatory debris, calculi, surface sludge and focal arterioles. The stain was present in the arteriole intima and was not observed in the venules within the same slide. Conclusions: Nanobacteria were found in 25 out of 26 gallbladders with cholecystitis. It was present within the epithelium, inflammatory debris, stones and sludge of cholecystitis with and without lithiasis. The presence and intensity of staining were associated with well-formed gross lithiasis. This observation suggests the contributing role of nanobacteria in gallstones formation. It is conceivable that a specific therapy for nanobacteria may prevent cholecystitis and reduce the need for surgical interventions. Further assessment of additional specimens is underway.

1037 CRITICAL ROLE OF CD44 IN HEPATOTOXIN-MEDIATED LIVER INJURY

Kiminori Kimura1,2, Masahito Nagaki2, Kazuhiro Kakimi1, Hisataka Moriwaki2; 1Department of Immunotherapeutics, The University of Tokyo, Bunkyo-ku, Japan; 2First Department of Internal Medicine, Gifu University School of Medicine, Gifu-shi, Japan

Purpose. Blocking of adhesion molecules is considered to be one of the therapeutic strategies for inflammatory diseases, although it remains unclear whether this strategy is beneficial. Here, we evaluated role of CD44, which is one of the adhesion molecules against liver injury using carbon tetrachloride (CCL4). Methods. We injected CCI4 into CD44 deficient mice (CD44KO) or wild type mice and sacrificed mice at several time points after injection and analyzed serum ALT activity and cell number in intrahepatic leukocytes by FACS and cytokine, chemokine expression in the liver by RNAase protection assay. To determine which cell subpopulation produce cytokine we analyzed intrahepatic leukocytes by intracellular cytokine stain.

1038 INCREASED ACETYLATION OF ALPHA-TUBULIN AND DECREASED EXPRESSION OF FIBROCYSTIN ARE SENSITIVE MARKERS OF CELLULAR DAMAGE AND ACTIVATION IN INFLAMMATORY LIVER DISEASE

Sarah Blair-Reid1, Gary Reynolds1, Jane Hartley2, Deirdre A. Kelly2, Stefan Hubscher2, Peter C. Harris2, Colin A. Johnson2, Christopher J. Ward2, Simon Afford1; 1Liver Research Group, University of Birmingham, Birmingham, United Kingdom; 2Pathology, University of Birmingham, Birmingham, United Kingdom; 3Paediatrics and Child Health, The Childrens Hospital, Birmingham, United Kingdom; 4The Leeds Institute of Molecular Medicine, Leeds, United Kingdom; 5Division of Nephrology, The Mayo Clinic, Rochester, MN

Background. Primary cilia are highly conserved chemosensory organelles present in normal renal and hepatic ductular epithelium that determine cell polarisation, proliferation and activation. Alpha-tubulin is a constitutive structural component of the cytoskeleton, basal body and axoneme of primary cilia. Acetylation of alpha-tubulin (acAT) is necessary for microtubule stabilisation during primary ciliary formation, cellular proliferation and activation, however, hyper-acetylation of AT has been associated with hepatocyte damage in ethanol fed mice. Fibrocystin is a receptor protein, of unknown function, that also localizes to primary cilia. Mutations of fibrocystin cause a structural dysfunction of primary cilia associated with polycystic kidney and liver disease. Aims. To investigate acAT and fibrocystin expression in human liver tissue during cellular activation associated with inflammatory/malignant disease. Methods. Routine paraffin embedded liver tissue subjected to low temperature epitope retrieval was probed with a commercially available mouse monoclonal antibody to acAT or an antibody raised to the c–terminus of wild type human fibrocystin. Antigen localisation was visualised using a ChemMate Envision detection system (Dako). The cohorts were:- Adult polycystic liver disease (PLD); PBC; PSC; Allograft Rejection (AR) Autoimmune Hepatitis (AIH); HCV; Chronic Alcoholic Liver Disease (ALD); alpha-1-AT deficiency (AAT); Biliary Atresia (BA); Hepatocellular Carcinoma (HCC). Normal liver tissue (NL) surplus to transplantation was visualised using a ChemMate Envision detection system (Dako). The cohorts were:- Adult polycystic liver disease (PLD); PBC; PSC; Allograft Rejection (AR) Autoimmune Hepatitis (AIH); HCV; Chronic Alcoholic Liver Disease (ALD); alpha-1-AT deficiency (AAT); Biliary Atresia (BA); Hepatocellular Carcinoma (HCC). Normal liver tissue (NL) surplus to transplantation required was used as a control. (n=5 for each group). Results. acAT- normal donor liver was consistently negative. All other disease groups showed very strong acAT staining of bile ducts particularly in perisepal regions of ductular reactivity. Periseptal/periportal hepatocytes and bile ducts were very strongly +ve in ALD, HCV and HCC. Staining of cystic epithelium in PLD was variable and frequently +ve whereas tumour cells in HCC were frequently +ve. acAT staining was very strong in perivenular hepatocytes and surrounding inflammatory cells in AR. Fibrotic and cirrhotic lesions contained strongly positive inflammatory and stromal cells. By contrast, most bile ducts in normal tissue were strongly +ve for fibrocystin whereas staining was frequently low or absent in all diseased liver tissue. Conclusions. Acetylation of alpha tubulin is a sensitive marker of cellular activation in most common inflammatory liver diseases and the absence of fibrocystin staining reflects ongoing damage to the intrahepatic biliary tree, rather than a phenomenon specific to the so called ciliopathies.

1039 CRITICAL ROLE OF EARLY GROWTH RESPONSE-1 TO GALACTOSAMINE / LIPOPOLYSACCHARIDE-INDUCED ACUTE LIVER INJURY IN MICE

Michele T. Pritchard1, Sanjoy Roychowdhury1, Megan R. McMullen1, Luping Guo2, Gavin E. Arteel2, Laura Nagy1; 1Pathobiology, Cleveland Clinic, Cleveland, OH; 2Pharmacology and Toxicology, University of Kentucky health Sciences Center, Louisville, KY

Early growth response-1 (Egr-1) is a transcription factor that functions as a master regulator of gene expression in response to proinflammatory signals and cellular stress and plays a critical role in the pathology of ischemia/reperfusion injury, cholestasis, atherosclerosis, pancreatitis and ethanol-induced fatty liver in mouse models. The purpose of this study was to test the hypothesis that Egr-1 is also involved in the development of galactosamine/lipopolysaccharide (GalN/LPS)-induced acute liver injury. GalN/LPS exposure bi-phasically increased hepatic Egr-1 mRNA accumulation at 1h and then at 4-5.5h after treatment. The effects of GalN/LPS were next compared in wild type and egr-1 -/- mice. Within 4-5.5h after GalN/LPS exposure, wild type mice exhibited evidence of hepatocyte injury, cell death, and extensive areas of hemorrhage; these parameters were attenuated egr-1 -/- mice. Liver to body weight ratios and ALTs were lower in egr-1 -/- mice 5.5h post GalN/LPS administration compared to wild type mice. The initial proinflammatory response to GalN/LPS administration in egr-1 -/- mice was similar to wild type, with no differences in TNFα, IL-1β, IL-8, MCP-1 or ICAM-1 mRNA or protein between genotypes at 1h. However, expression of these genes was lower in the livers of egr-1 -/- mice at subsequent time points. The observed decrease in the hepatic inflammatory milieu was associated with a decrease in neutrophil extravasation from hepatic sinusoids into the liver parenchyma in egr-1 -/- mice, compared to wild type mice, 4h after GalN/LPS. In addition, there were fewer TUNEL positive cells in livers from egr-1 -/- mice 5.5h post GalN/LPS. Finally, the decreases in inflammatory and chemo tactic responses in egr-1 -/- mice were associated with increased survival in egr-1 -/- mice after GalN/LPS. In conclusion, these data demonstrate, for the first time, that Egr-1 plays a critical role during later phases of GalN/LPS-induced acute liver injury. Supported by NIH grants AA015833 to MTP, AA003624 to GEA and AA0138868 to LEN

1040 INHIBITION OF THE KUPFFER CELL INCREASES SERUM HMGB1 LEVELS AND THE MORTALITY IN A RAT SEPTIC PERITONITIS MODEL

Hiroshi Kono, Kenichi Ishii, Naohiro Hosomura, Nobuyuki Tanaka, Masanori Matsuda, Hideki Fuji; First Department of Surgery, University of Yamanashi, Chuo, Japan

High-mobility group protein 1 (HMGB1) is a nonhistone nuclear protein whose function depends on cellular location. Inside the cell, HMGB1 modulates a variety of important cellular processes, including transcription, whereas outside the cell, HMGB1 acts as an inflammatory cytokine and mediator sepsis in animal models. In in vitro studies, proinflammatory molecules can induce HMGB1 release from macrophages. Since the Kupffer cell (KC), the resident hepatic macrophage, is a predominant population of macrophage lineage, the specific purpose of this study was to investigate whether inhibition of the KC affect the expression of HMGB1 in sepsis. Rats were given saline or
gadolinium chloride (GdCl₃), a KC toxicant, 24 hours before cecal ligation and puncture (CLP). Survival was assessed for 7 days after CLP. Liver tissues and blood samples were harvested, and the expression of inflammatory mediators was assessed. Inhibition of the KC increased significantly the mortality 7 days after CLP. Plasma endotoxin and serum TNF-α levels were significantly greater in the GdCl₃ than in the control group 12 hours after CLP. Furthermore, serum HMGB1 levels were significantly greater in the GdCl₃ group than the control group. To assess the expression of HMGB1 in the liver after CLP, immunohistochemical staining for HMGB1 was performed. The expression of HMGB1 was detected on cells in the hepatic sinusoid 12 hours after CLP. These cells recognized morphologically as KCs. Furthermore, the number of the HMGB1-positive KCs was significantly greater in the GdCl₃ group than the control group. The mRNA expression of HMGB1 in the liver was assessed by RT-PCR each time after CLP. The expression was significantly greater in the GdCl₃ group compared with the control group after CLP. It was reported that GdCl₃ eliminates ED1- and ED2-positive macrophages, which were morphologically large KCs, and ED1-positive and ED2-negative KCs were still observed after treatment of GdCl₃. Therefore, the mRNA expression of HMGB1 was assessed in each subpopulation of the KC. The Kupffer cells were isolated by a counterflow centrifugal elutriation to separate cells based on cell size and density. The expression of HMGB1 was greatest in the small KCs, which were ED1-positive and ED2-negative cells assessed by flow cytometry, compared with large KCs, which were ED1- and ED2-positive cells. Thus, the large KC plays a beneficial role on the host defense during sepsis. Furthermore, the small KC, which may include infiltrating cells into the liver, is a predominant source of HMGB1 in the liver.

MRNA EXPRESSION ANALYSIS OF IMMUNOREGULATION, APOPTOSIS AND FIBROSIS IN LIVER DISEASES
Georgios Germanidis¹,², Gedeon Loules, Ioannis Kouvelis, Vaios Karanikas, Eleutherios Giannoulis, Konstantinos Ritis, Anastasios Germenis, Matthaios Speletas.¹, Immunology and Histocompatibility, University Hospital of Larissa, Thessaly Medical School, Larissa, Greece; ²First Dept. of Internal Medicine, Aristotle University of Thessaloniki, AHEPA Hospital, Thessaloniki, Greece; ³First Department of Internal Medicine, Democritus University of Thrace, Alexandroupolis, Greece

Background: T-regulatory cells (Tregs) are important mediators of immune suppression. Their presence prevents self-immune reactions by inducing regulatory signals to APCs and/or effector T-cells. In previous studies the persistence of viral infection in liver has been associated with the expansion of Tregs in the peripheral blood of the affected patients. Our aim was to study, at the transcriptional level, the presence of Tregs in liver tissues of patients with various diseases. Patients and methods: Liver biopsies from 20 patients (7 with chronic HBV hepatitis and/or cirrhosis, 4 with chronic HCV hepatitis and/or cirrhosis, 6 with NASH, 2 with metotrexate related toxicity and 1 with autoimmune cirrhosis) were studied. Total RNA was extracted and cDNA was synthesized using standard protocols. Quantitative real-time PCR analysis was performed for the detection of mRNA expression of: Foxp3 (determinant of the presence of natural Tregs), TGF-β1 and IL-10 (cytokine determinants of inducible Tregs – Th3 and Tr1, respectively), TGFβRII, TGFβRI, Smad2, Smad3, Smad4, Smad7 (receptors and mediators of TGF-β signaling) and TRAIL, Fas, FasL (mediators of apoptosis). REST software was used for the statistical analysis. Results: Irrespective of the type of liver damage (viruses, drugs, NASH, autoimmune) an expansion of natural Tregs was present, evident through the dramatic increase of Foxp3 expression (for HBV OR: 28.025, 95%CI: 3.01 - 255.78, p<0.002, for HCV OR: 16.11, 95%CI: 3.837 - 96.625, p<0.025, for NASH OR: 20.194, 95%CI: 4.603 - 165.843, p<0.01), for methotrexate-related toxicity OR: 28.1, 95%CI: 9.391 - 107.627, p<0.001, for autoimmune cirrhosis 25.4 fold) accompanied by a significant increase in mediators of apoptosis (Fas-FasL, TRAIL), compared with normal controls (p<0.01). Furthermore, an increase in the expression of Smad3 (indicator of increased TGF-β signaling) was observed in patients with cirrhosis, compared with normal controls (OR:2.392, 95%CI: 1.604 - 3.575, p=0.012) Conclusions: Our results suggest that acute or chronic tissue damage, irrespective aetiology, results in increased apoptosis, followed by increased phagocytosis and possibly in self-antigen presentation by APCs. Eventually, this could lead in an expansion of natural Tregs that would prevent catastrophic autoimmunity in the damaged tissue. Elucidation of the pathways mediating this potential model could increase our understanding of the role that Tregs play in disease propagation and, for the first time, could have wider implications for the manipulation of Tregs in a therapeutic setting.

EXPRESSION OF NOTCH SIGNALING AND ANTIGEN PROCESSING MOLECULES IN PROGRESSIVE PATHOGENIC BIOPSIES OF CHRONIC HEPATITIS B INFECTION
Nirupma T. Pati, Sujoy Bose, Sukriti Baveja, Hissar Syed, Shiv K. Sarin; Gastroenterology, G B Pant Hospital, New Delhi, India

Background: The Notch signaling plays a key role in cell-fate determination and differentiation, functioning in a cell- and tissue-specific manner. Both upregulated and downregulated Notch1 signalling is seen in carcinogenesis of different tissues. Whereas, in stem cells, notch activity inhibits differentiation and promotes carcinogenesis but in primary epithelial cells high notch activity leads to exit from the cell cycle and commitment to differentiation. Notch1 exerts specific protective effects against HPV-virus and down-modulation of Notch1 was observed in the late stages of HPV-induced carcinogenesis. Aim: To study notch signalling in different stages of HBV induced liver disease and its role in liver disease progression. Patients and Methods: PBMCs of chronic hepatitis B (CHB) (n=10) (age 29.4±13.2 yr., M:F:8:2) patients and healthy controls (n=10) (age 27.9±6.4 yr., M:F:7:3) and liver biopsies from normal liver – 3 (age 49±3.8 yr., M:F:2:1), CHB patients (age 39±12.8, M:F:3:1) HBV cirrhosis –4 (age 36.2±20.0, M:F:3:1) and HBV related HCC –3 (age 55.5±7.2 yr., M:F:3:0) were studied. Total RNA was extracted from PBMCs and biopsies and Notch1, Hes1, Jagged1, and NFKB genes were analyzed by quantitative RT-PCR. Results: Compared to PBMCs of CHB patients, the liver biopsies showed significantly lower expression of Notch1 (p=0.034), Jagged 1 (p=0.021) but not Hes 1 (Table 1). The reduction in expression of these genes was significantly greater in HCC patients compared to CHB and controls. In comparison to control biopsies and PBMCs in CHB, cirrhotic tissue showed significantly lower expression of NFKB (p<0.02). Conclusions: In different stages
of liver disease due to HBV, the PBMCs show higher expression of notch signaling molecules, but in the target liver tissue, the expression of these molecules is significantly inhibited, maximum being in CHB and HCC. This expression pattern of notch1 signaling suggests that this protein may play a permissive or tumor-promoting function in chronic HBV infection.

1043 INTRAHEPATIC STATUS OF REGULATORY T CELLS IN AUTOIMMUNE HEPATITIS, PRIMARY BILIARY CIRRHOSIS, CHRONIC HEPATITIS C, AND CHRONIC HEPATITIS B
Masashi Sakaki, Kazumasa Hiroishi, Toshiyuki Baba, Miki Kushima, Michio Imawari;
1Second Department of Internal Medicine, Showa University School of Medicine, Tokyo, Japan; 2Division of Hospital Pathology, Showa University School of Medicine, Tokyo, Japan

Background/Aims: Regulatory T cells (Tregs) maintain immunological tolerance and suppress autoreactive immune responses. We evaluated the intrahepatic status of Tregs in patients with autoimmune hepatitis (AIH), primary biliary cirrhosis (PBC), chronic hepatitis C (CH-C), or chronic hepatitis B (CH-B).

Methods: We analyzed 85 patients (20 AIH, 22 PBC, 27 CH-C, and 16 CH-B) and 14 controls. Using liver tissue samples obtained by needle biopsy or from marginal parts of resected metastatic liver tumors in controls, immunohistochemical analyses of forkhead box P3+ (Forkhead box P3+), which is a specific marker for Tregs, CD4+, and CD8+ cells were performed. Results: Intrahepatic Tregs were significantly infiltrated in patients with liver diseases than in controls. There were significantly fewer intrahepatic Tregs in AIH patients than in PBC patients (p=0.037). Patients with a low frequency of intrahepatic Tregs were detected significantly less in the AIH and CH-B groups than in the PBC and CH-C groups. We found significantly less infiltration of CD4+ T cells in AIH than in other diseases (p<0.05). Liver-infiltrating CD8+ T cells were detected more frequently in the CH-B group than in other groups (p<0.003). Conclusions: Intrahepatic Tregs were increased in both patients with autoimmune liver diseases and those with viral hepatitis. In autoimmune liver diseases, intrahepatic Tregs in AIH patients were fewer than in PBC patients.

1044 SPECIFIC CONTRIBUTION OF NADPH-OXIDASE IN DISTINCT CELL TYPES DURING HEPATIC FIBROSIS.
Samuele De Minicis, Ekihiro Seki, Christoph Osterreicher, Robert F. Schwabe, David Brenner;
1Department of Medicine, University of California, San Diego, School of Medicine; La Jolla, CA; 2Department of Medicine, Columbia University, New York, NY

Background: NADPH-oxidase is a multi-protein complex that produces differential amount of reactive oxygen species. In addition to its main activity in host defence, NADPH-oxidase plays a central role in the regulation of hepatic fibrosis via induction by angiotensin II, leptin and PDGF. NADPH-oxidase is functionally expressed in several cell types involved in hepatic fibrogenesis, such as hepatic stellate cells (HSC), Kupffer cells (KC) and hepatocytes. However the contribution of this complex in distinct cell types during hepatic fibrosis is unclear. Aims: To determine the role of NADPH-oxidase in different cell populations during hepatic fibrogenesis.

Methods: Hepatic fibrosis was induced by bile duct ligation (BDL) for 21 days or by methionine-choline deficient (MCD) diet for 10 weeks in wild-type (WT) and mice deficient in p47phox, a central component of both phagocytic and non-phagocytic NADPH-oxidase. Hepatic fibrosis was evaluated by Sirius red staining and mRNA expression of collagen α1(I), αSMA, TGFβ and TIMP-1 by quantitative real time PCR. Hepatic steatosis was determined by oil red-O staining. Hepatocellular injury was assessed by serum ALT and AST levels.

Results: Upon BDL, the increase of hepatic collagen and hydroxyproline content was lower in p47phox-/-. mice compared with WT mice. The chimeric mice that contained p47phox-/- BM into WT recipients and vice versa.

Conclusions: The expression pattern of NADPH-oxidase in different cell populations during hepatic fibrosis is consistent with the role of this protein in the development of hepatic fibrosis.

TLR4/MYD88/NF-KB-MEDIATES HEPATIC STELLATE CELLS ACTIVATION BY THE REGULATION OF TGF-B PSEUDORECEPTOR BAMBI IN HEPATIC FIBROSIS

Ekihiro Seki1, Samuele De Minicis1, David A. Brenner1, Robert F. Schwabe2; 1Medicine, University of California, San Diego, School of Medicine, La Jolla, CA; 2Medicine, Columbia University, College of Physicians and Surgeons, New York, NY

Background: The gram-negative bacterial cell wall component lipopolysaccharide (LPS) is elevated in the plasma of patients with liver cirrhosis by increased intestinal permeability. Toll-like receptor (TLR) 4 recognizes LPS and results in NF-kB activation via MyD88-dependent pathway. TLR4 signal also activates IRF-3 via TRIF-dependent pathway. It was assumed that increased LPS level in portal may activate TLR4 on Kupffer cells (KCs), subsequently activating hepatic stellate cells (HSCs) by indirect or direct action of Kcs, resulting in promoting liver fibrosis. Surprisingly, TLR4 on HSCs, but not Kcs, are critical in hepatic fibrosis as we have previously shown using TLR4-chimeric mice. In addition, TLR4 signal activates HSCs by downregulation of Bambi, an inhibitor of TGF-b signal. However, the precise mechanism of Bambi regulation is unknown. Aim: To define the mechanism by which TLR4 signal regulates Bambi expression and HSC activation. Methods: Hepatic fibrosis was induced by bile duct ligation (BDL) on WT, MyD88-/- and TRIF-/- mice. To evaluate liver fibrosis, we measured collagena I (I), aSMA, TGF-b1 and TIMP-1 mRNA expression by real time PCR (qPCR). Collagen promoter activity was assessed in HSCs isolated from collagen-GFP transgenic mice following infection with control or Iksr super-repressor (sr) adenovirus after stimulation with TGF-b plus LPS. Bambi, KC, and IP-10 mRNA expressions in HSCs infected with control or Iksr adenovirus or in HSCs isolated from WT, MyD88-/- and TRIF-/- mice were assessed by qPCR. Results: Upon LPS stimulation, Bambi mRNA expression was downregulated in control virus-infected HSCs, but not in the HSCs infected with Iksr virus. Control, but not Iksr virus infected-HSCs have an increase in collagen promoter activity after TGF-b plus LPS stimulation. In addition, Bambi mRNA expression was downregulated in WT and TRIF-/- HSCs, but not in MyD88-/- HSCs. The MyD88-dependent inducible gene KC was upregulated in WT or TRIF-/- HSCs, but not in MyD88-/- or Iksr-expressing HSCs. In contrast, the MyD88-independent inducible gene, IP-10 was upregulated in WT, MyD88-/- or TRIF-/- HSCs, but not in Iksr-expressing HSCs. Analysis of profibrogenic gene expression showed upregulation of collagen I (I), aSMA, TGF-b1 and TIMP-1 in WT and TRIF-/- BDL liver. In contrast, profibrogenic gene expressions were less increased in MyD88-/- BDL liver. Conclusion: Bambi mRNA expression is controlled in a TLR4/ MyD88/NF-KB-dependent pathway. Consistent with Bambi regulation, the initial event of hepatic fibrogenesis is regulated by the TLR4/MyD88/NF-KB axis. In addition, our results suggested that TLR does not play roles in TLR4 signal in HSCs.

GLYCATED FIBRONECtin STIMULATES HEPATIC STELLATE CELL (HSC) ACTIVATION AND TYPE I COLLAGEN PRODUCTION IN PRIMARY CULTURES

Milan Dodig, Min Li, Srinivasan Dasarathy, Arthur J. McCullough; Department of Gastroenterology and hepatology, Cleveland Clinic Foundation and Lerner College of Medicine, Cleveland, OH

INTRODUCTION: Type II diabetes increases the risk of chronic liver disease and hepatocellular carcinoma. Diabetes has been also found to be an independent predictor of fibrosis in nonalcoholic steatohepatitis (NASH). Metabolic milieu of type II diabetes is characterized by hyperglycemia and high insulin levels due to the insulin resistance. We have previously reported that high insulin levels stimulate type I collagen synthesis by HSC. As this effect was more potent in a high glucose media, in this study we examined the role of nonenzymatic glycation of matrix component fibronectin in HSC activation and fibrogenesis. MATERIAL AND METHODS: HSC were isolated from transgenic mice harboring transgene with Green fluorescent protein fused to COL1A1 gene promoter, using a collagenase pronase digestion followed by density gradient centrifugation. HSC were plated on plastic in low and high glucose media and treated with insulin. Additionally, HSC were initially plated on plastic (to ensure purer population of HSC), than replated at day 3 on plastic, native fibronectin and glycated fibronectin. Fibronectin was glycated for 30 days in 0.5M solution of glucose 6-phosphate at 37°C. HSC were imaged at day 6 and 7 for GFP expression and harvested at day 7 for protein analysis. Type I collagen was detected by Western blot of total cell extract at culture day 7. Adhesion and proliferation assays were performed at day 6 of culture. RESULTS: Insulin treatment of primary HSC cultures stimulated type I collagen expression only in high glucose conditions. HSC plated on glycated fibronectin showed increased proliferation and type I collagen synthesis when compared with cells plated on native fibronectin and plastic. In addition, significantly more HSC plated on glycated fibronectin expressed GFP transgene in culture on both day 6 and 7. Adhesion assay showed significantly more HSCs attached on glycated fibronectin than unaltered fibronectin, indicating possible role of integrins in this effect, a concept supported by our previous studies, demonstrating the importance of fibronectin receptor, alpha5beta1 integrin, in early stages of HSC activation. We detected higher levels of the focal adhesion kinase in HSC plated on glycated fibronectin, suggesting that integrin signaling may be involved in exaggerated HSC activation on glycated matrix. CONCLUSION: Glycated fibronectin stimulates activation and type I collagen synthesis in primary HSC cultures. Glycation of extracellular matrix in the liver of diabetic patients, may be a factor in stimulating fibrogenesis and contributing to a higher rate of fibrosis in these patients.

BENEFICIAL EFFECT OF ANGIOTENSIN-BLOCKING AGENTS ON LIVER FIBROSIS IN PATIENTS WITH HEPATITIS C

Niral Shah1, Hui Zheng2, Joseph Misrahi4, Raymond T. Chung2; 1Departments of Internal Medicine and Pediatrics, Massachusetts General Hospital, Boston, MA; 2Gastroenterology Unit, Department of Medicine, Massachusetts General Hospital, Boston, MA; 3Biostatistics, Department of Medicine, Massachusetts General Hospital, Boston, MA; 4Department of Pathology, Massachusetts General Hospital, Boston, MA

Background: The morbidity and mortality related to chronic Hepatitis C viral (HCV) infection is related to liver fibrosis progression. Current treatments for HCV are limited to interferon and ribavirin, which have unproven effectiveness and limited tolerability as long-term agents in nonresponders. Rational approaches are needed to identify viable antifibrotic agents. Several lines of evidence have implicated angiotensin II as a driver of liver fibrosis. Various animal and clinical studies have
shown that angiotensin-blocking agents attenuate liver fibrosis, but none has evaluated histological data in patients infected with HCV. In this study we evaluated the histological effect of angiotensin-blocking agents in patients with chronic HCV.

Methods: This was a retrospective chart review of 234 patients from our institution during the years 2001-2006 with chronic HCV and concomitant hypertension (HTN), and an available liver biopsy. 143 patients [Group I] received angiotensin-blocking agents (angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blocking agents (ARBs) to treat HTN and 91 patients [Group II] received other anti-hypertensive agents (including beta-adrenergic blocking agents, calcium antagonists, alpha-adrenergic blocking agents and diuretics). All available biopsies were reassessed and restaged by a single, blinded pathologist. Results: The two groups were similar with respect to age, sex, genotype, HCV RNA levels and estimated duration of disease, but the two groups varied significantly with regards to the total proportion of diabetic patients [Group I: 43/143 (30%); Group II: 10/91 (11%), p value 0.0007], a result of the recommended management of hypertension diabetic with ACE inhibitors. There was a significant difference in Ishak fibrosis score [Group I: 3.20; Group II: 3.73, p value 0.04]. Subgroup analysis of non-diabetics demonstrated an even more significant difference between the two groups in Ishak fibrosis score. [Group I: 3.07; Group II 3.69, p value 0.023]. Conclusion: The administration of angiotensin-blocking agents in patients with HCV infection and HTN was associated with histological evidence of decreased fibrosis. In patients without diabetes, this difference was even more pronounced. These data provide support for prospective evaluation of ACE inhibitors or ARBs as possible hepatic fibrosis inhibitors in patients with HCV.

1048 ROLE OF P75 SIGNALLING IN THE PATHOGENESIS OF LIVER FIBROSIS IS CONTEXT AND LIGAND STRUCTURE DEPENDENT

Timothy J. Kendall1, R Christopher Benyon², John Iredale²; ²Liver Group, University of Southampton, Southampton, United Kingdom; ²MRC Centre for Inflammation Research, University of Edinburgh, Edinburgh, United Kingdom

Hepatic myofibroblasts (MFB) express p75, the low-affinity nerve growth factor (NGF) receptor, and sortilin, a putative receptor for proNGF. We propose mature NGF is pro-apoptotic whilst proNGF is both protective from serum-deprivation induced apoptosis and proliferative. During resolution of experimental fibrosis or partially reversible cirrhosis levels of proNGF fall relative to mature NGF. We describe functions of p75 signalling in a murine model of liver fibrosis. Wild-type and p75NTR/exonIII-/- mice that do not express the ligand binding domain but express the intracellular domain were injured with carbon tetrachloride and allowed to recover. At peak fibrosis livers from p75-/- animals contained fewer α-smooth muscle actin (α-sma) positive cells, a marker of MFB, compared with wild-type animals. Wild-type livers had 6.9x more non-parenchymal cells staining positively for a proliferation marker (Ki-67) than p75-/- animals. In recovery there was significantly retarded histological resolution in the livers of p75-/- animals, determined by both semi-quantitative scoring and morphometric image analysis of Sirius red stained sections. There was also a significantly delayed loss of α-sma positive cells. The percentage of MFB undergoing apoptosis, determined by caspase 3 activation, was significantly reduced (day 7, 34% v 75%, p<0.05) in the livers of p75-/- animals relative to wild-type animals indicating that the persistence of MFB is likely to be due to reduced apoptosis. Our findings are broadly supported by the determination of the expression of procollagen-1, TIMP-1 and α-sma mRNA in injured liver by real-time PCR. Deletion of p75NTR/exonIII-/- does not influence the activation of hepatic MFB or the expression of procollagen-1, TIMP-1 and α-sma in vitro, determined by real-time PCR and immunofluorescence. However, MFB isolated from p75-/- mice and activated by culture on plastic significantly fail to respond to mitogens (fetal calf serum and PDGF), consistent with our in vivo findings in livers of p75-/- animals and suggesting a tonic proliferative role for p75 in hepatic MFB. We have demonstrated a dual role for p75 signalling in liver fibrogenesis. During injury p75 has a profibrotic role via proNGF mediation of MFB proliferation, and protection from apoptosis. In contrast, during recovery from liver fibrosis when proNGF levels fall and mature NGF dominates, p75 has anti-fibrotic effects by mediating MFB apoptosis.

red stained sections, examined by morphometry, indicated that portal tract collagen-I remained elevated in neutrophil depleted animals (7.72% area versus 3.52% in saline controls; p<0.05) despite normal reductions in bilirubin and liver enzymes. Quantitative real time PCR results for neutrophil depleted livers demonstrated dramatic increases and a loss of regulation of expression of the neutrophil chemoattractant CINC1, matrix metalloproteinases and tissue inhibitors of metalloproteinases. CONCLUSIONS: We conclude that functioning neutrophils are critical to liver repair following cholestatic injury. Further, neutrophil migration into repairing liver provides inhibitory feedback for normal chemokine and matrix metalloproteinase expression during cholestatic injury and repair.

1050 EVIDENCE OF SNAIL1 TRANSCRIPTION FACTOR INVOLVEMENT IN HEPATIC STELLATE CELLS ACTIVATION PROCESS
Melania Scarpa1,2, Alessia Grillo1,2, Paola Brun1,2, Federica Ditadi1, Giorgio Palù1, Ignazio Castagliuolo1, Diego Martines2; 1Histology, Microbiology and Medical Biotechnologies, University of Padova, Padova, Italy; 2Surgical and Gastroenterological Sciences, University of Padova, Padova, Italy

Background: Following liver injury, hepatic stellate cells (HSC) undergo a process of activation from the quiescent fat-storing phenotype to a highly proliferative myofibroblast-like phenotype. Snail1 is a transcription factor best known for its ability to trigger epithelial-mesenchymal transition (EMT), to influence mesoderm formation during embryonic development and to favour cell survival. Recent studies showed that the aberrant activation of Snail1 is sufficient to trigger renal fibrogenesis and that is expressed in fibroblasts in vivo during the healing process. We therefore hypothesised that Snail1 could be involved in HSC transdifferentiation process. Methods: Primary HSC were isolated from livers of healthy mice and cultured on plastic up to 10 days (in vitro activation model) or from livers of CCl4-treated mice (8 weeks, twice-weekly, i.p.) and cultured 1 day (in vivo activation model). Activation status of HSC was monitored by assessing mRNA level of HSC activation-related genes: α-smooth muscle actin (αSMA), α(1)I collagen (COL1A1), tissue inhibitor of metalloproteinase-1 (TIMP1) and fibronectin (FN). Snail1 expression in HSC and liver was screened by immunostaining and qRT Real Time PCR, whereas Snail1 activity was checked indirectly quantifying mRNA of Snail1-target genes: E-cadherin (E-cad), desmoplakin (DSP) and metalloproteinase-9 (MMP9) by qRT Real Time PCR. Results: We observed a significant increase in Snail1 mRNA level in livers of mice treated with CCl4 for 8 weeks in comparison with livers of healthy mice. These data were confirmed by immunohistochemistry studies which evidenced Snail1 positive cells in fibrotic livers. In vitro studies showed that Snail1 is expressed by HSC and that its transcription is augmented in culture activated (10 days culture) and in vivo activated HSC as compared to quiescent HSC (1 day culture). At protein level we could observe the nuclear localization of Snail1 after the fourth/fifth day of culture. We next analysed the expression of genes which have been shown to be directly (E-cad, DSP) and indirectly (MMP9, FN) regulated by Snail1. Their expression resulted substantially unchanged until the fourth day of culture, afterwards E-cad and DSP expression significantly decreased while FN and MMP9 expression increased. Summary and conclusion: In activated HSC Snail1 is up-regulated and shows a nuclear localization and the expression of some target genes results significantly modified. Our data support a role for Snail1 transcription factor in liver fibrogenesis and its involvement in HSC transdifferentiation process.

1051 INCREASED MORTALITY, ENHANCED LIVER FIBROSIS AND DIMINISHED ACUTE-PHASE RESPONSE AFTER BILE-DUCT LIGATION IN HEPATOCYTE SPECIFIC C-MET/GP130 DEFICIENT MICE
Arne Giebeler1, Nikolaus Gasser2, Małgorzata Borowiak2, Carmen Birchmeier5, Christian Trautwein1, Konrad L. Streitze1; 1Department of Medicine 3, University Hospital Aachen, Aachen, Germany; 2Department of Pathology, University Hospital, Aachen, Germany; 2Developmental Biology/Signal Transduction, Max-Delbrueck-Center, Berlin, Germany; 3Angiogenesis and Cardiovascular Pathology, Max-Delbrueck-Center, Berlin, Germany; 4Department of Molecular and Cellular Biology Howard Hughes Medical Institute, Harvard University, Cambridge, MA

Background: C-Met (HGF receptor) and gp130 (IL6 signal transducer) mediate essential signals known to be involved in proliferation and survival of liver cells. However, a detailed knowledge about their role in hepatocytes during the progression of liver fibrosis is lacking. Material and Methods: Conditional c-Met (Δc-Met) and gp130 (Δgp130) knockout mice (Cre-loxP system) were subjected to bile duct ligation (BDL). Expression of Cre-recombinase was regulated by a hepatocyte-specific pre- and postnatally activated albumin promoter. Results: While generating conditional hepatocyte specific Δc-Met mice using the prenatal (d10.5) active Cre-recombinase resulted in embryonic lethality. In contrast the postnatally activated promoter produced vital offsprings of mice lacking c-Met in hepatocytes. After BDL we observed reduced survival rates in Δc-Met (75%) and Δc-Met/Δgp130 (25%) mice. Both conditional knockout mice had higher transaminases and a significantly enhanced apoptosis rate compared to controls (p<0.05). The knockout mice also displayed more necrotic areas and an enhanced periporal infiltration and proliferation. In contrast, hepatocyte proliferation determined by BrdU uptake was significantly reduced in Δc-Met (p>0.05) and Δc-Met/Δgp130 (p>0.05) compared to wt. Analysis of the Acute-Phase-Response (APR) in Δc-Met/Δgp130 mice revealed a complete lack in SAA, SOCS3 and STAT3 induction. Surprisingly, Δc-Met mice also displayed a significantly reduced induction of APR-gen genes, while preserving the activation of STAT3. In regards to the development of liver fibrosis conditional knockout mice showed a significantly stronger activation of hepatic stellate cells 48h after BDL (control>Δc-Met<Δc-Met/Δgp130). Our results demonstrate the essential protective role of the HGF/IL6 signalling after BDL. Abolished APR, higher apoptosis and reduced hepatocyte proliferation rates together with a stronger activation of hepatic stellate cells ultimately leads to a higher degree of liver fibrosis in mice lacking c-Met and gp130.

AMELIORATION OF BILARY FIBROSIS BY AN ALPHA V-BETA 6 INTEGRIN ANTAGONIST IS MEDIATED BY INHIBITION OF CHOLONGIOTIC ADHESION TO FIBRONECTIN AND CHOLANGIOCYTE TGFBIETA1 ACTIVATION

Eleonora Patsenker1, Yury Popov2, Felix Stickel2, Gerald Niedobitek3, Detlef Schuppkan2; 1Clinical Pharmacology, University of Bern, Bern, Switzerland; 2Gastroenterology, Beth Israel Deaconess, Boston, MA; 3Institute of Pathology, University of Erlangen, Erlangen, Germany

Background and aims: AlphaV beta6 is an epithelial integrin expressed during tissue development, inflammation, wound healing and carcinogenesis. It acts as a receptor for fibronectin and tenascin, and possibly as co-receptor for the activation of latent TGFbeta1. Mice lacking this integrin display resistance to the induction of pulmonary fibrosis and alphaVbeta6 inhibition can ameliorate rat biliary fibrosis (Patsenker et al, AASLD 2006). We therefore examined the molecular mechanisms underlying the antifibrotic effect of alphaVbeta6 inhibition. Methods: Adhesion assays were performed on fibronectin using the human cholangiocyte cell line TFK-1. TGFbeta1 activation was measured by human TGFbeta1 ELISA. Rats subject to bile duct ligation (BDL) for 6 weeks and MDR2-/- mice at age 4 weeks were treated i.p. with the specific alphaVbeta6 antagonist EMDS572040 at 20 or 60 mg/kg/day for 4 and 3 weeks, respectively. Beta6 expression was determined by immunohistology, fibrosis was measured as hepatic hydroxyproline content and fibrosis-related transcripts were determined by quantitative RT-PCR. Bile duct proliferation was quantified by double immunohistochemistry for CK19 and Ki-67 using a point counting technique. Results: AlphaVbeta6 was absent in normal livers, but highly expressed on proliferating bile duct epithelia in fibrosis, with 100-fold increased transcript levels. Its inhibition in vitro reduced cholangiocyte adhesion to fibronectin and endogenous activation of TGFbeta1 by 50%. The alphaVbeta6 antagonist prevented peribiliary collagen accumulation in fibrotic animals by 40-50%. This was paralleled by downregulation of profibrogenic and upregulation of fibrolytic genes, improved liver architecture and function. Conclusions: alphaVbeta6 integrin is strongly upregulated in proliferating bile duct epithelia and drives fibrogenesis via adhesion to fibronectin and auto/paracrine cholangiocyte TGFbeta1 activation. Its pharmacological inhibition blocks the progression of primary and secondary biliary fibrosis.

TOLL-LIKE RECEPTOR-9 ACTIVATION AMELIORATES HEPATIC FIBROSIS ASSOCIATED WITH LYMPHOCYTE INTERACTIONS

Jonathan H. Axelrod2, Elena Khvalevsky2, Sarit Doron1, Jonathan Enk3, Yael Nechemia2, Orit Pappo3, Ethan Galun2, Rifaat Safadi2; 1Liver and Gastroenterology Units; Division of Medicine, Hadassah Medical Center, Jerusalem, Israel; 2Goldyne Savod Institute of Gene Therapy, Hadassah Medical Center, Jerusalem, Israel; 3Pathology Department, Hadassah Medical Center, Jerusalem, Israel

Background: CD8 subsets mediate hepatic fibrosis and NK cells have an anti fibrotic effect. Oligodeoxynucleotides (ODNs) with immunomodulatory motifs (CpG) are acting through TLR9 to stimulate NK cells. We hypothesized that TLR9 would generate an anti fibrotic response. Methods: (I) Hepatic fibrosis was induced by CCl4 administration X2/wk for 6 wks in WT and TLR9-/- mice and was compared to naive. (II) To isolate the effect of TLR9 in lymphocytes, we transferred splenocytes from WT or TLR9-/- donors to irradiated WT recipients. Then fibrosis was induced in recipients by CCl4. (III) CCl4 was induced in WT male mice (groups A to D) for 6 wks. During the last 2 wks of CCl4 administration, mice were weekly treated by hydrodynamic based transfection with either saline (group A), CpG ODN (gr. B), pGEM7 (gr. C) and were compared to control CpG ODN injected mice (gr. D) and naive controls (Group E). Different routes of ODN administrations were also examined. (IV) As TLR9 activation is mediated by IL-6 and to further evaluate if the ODN effect on fibrosis is TLR9-mediated we used the IL-6/- mice. Thus, a similar design in (III) was used in IL-6/- mice and compared to WT response. Results: (I) Compared to WT mice, TLR9-/- mice showed a significant increase of fibrosis. While NK cells were unchanged in TLR9-/- groups compared to the WT, both CD4 and CD8 distributions were reduced in TLR9-/- groups. Post fibrosis; CD4 remains unchanged but CD8 increased. (II) Irradiated WT recipients with TLR9-/- lymphocytes also showed increased fibrosis. While NK cells were unchanged, both CD4 and CD8 distributions were increased in recipients with TLR9-/- lymphocytes and keeping CD8 predominance. (III) Control groups A/D displayed fibrosis levels higher than the ODN treated groups (B/C). Serum ALT levels were elevated in all CCl4 groups but were decreased in the CpG and pGEM7 treated groups. CD8 increased in control groups A/D but was alleviated in treated groups B/C. CD4 cells were decreased and Tregs increased in all fibrotic groups, but without remarkable differences. NK cells decreased following fibrosis in control groups A/D, however, both treated groups B/C showed an increase. Different routes of ODN administration showed similar anti fibrictic effects. (IV) Administration of ODNs to fibrotic IL-6/- mice, did not affect fibrosis or lymphocyte distribution, supporting that ODNs plays a role in fibrosis alleviation via TLR9 activation. Conclusions: TLR9 activation is involved in immune modulation of fibrosis. CpG and pDNA displayed significant anti-fibrotic activity, accompanied by CD8 suppression and increased NK cells.

ANGIOTENSIN 1-7 REDUCES BILE DUCT PROLIFERATION AND HEPATIC FIBROSIS IN THE BILE DUCT LIGATION RAT

John S. Lubel, Chandana B. Herath, Zhiyuan Jia, Louise M. Burrell, Peter W. Angus; Medicine, University of Melbourne, Melbourne, VIC, Australia

Introduction: Angiotensin 1-7 (Ang-(1-7)) is a biologically active peptide of the renin angiotensin system (RAS) which opposes the deleterious actions of angiotensin II. The effects of Ang-(1-7) infusion on the progression of liver disease have never previously been described. We have used the bile duct ligation (BDL) model to determine the impact of Ang-(1-7) on the development of hepatic fibrosis, generation of growth factors and feedback mechanisms within the RAS. Methods: Male Sprague-Dawley rats underwent sham operation (n=11) or BDL (n=22). Animals were studied in three groups. Sham operated rats and 11 BDL rats were implanted with intraperitoneal osmotic minipumps delivering normal saline. A further 11 BDL rats were implanted with pumps delivering Ang-(1-7) (28µg/kg/hr i.p.). Animals were killed after 2 weeks and plasma and liver tissue collected for analyses. Results: Ang-(1-7) significantly improved plasma...
biline and GGT concentrations and reduced hepatic hydroxyproline content and collagen 1A1 gene expression (P<0.05). Alpha smooth muscle actin (α-SMA) immunohistochemistry showed significant attenuation in the Ang-(1-7) treatment group (P<0.05). Similarly, quantitative PCR demonstrated a reduction in α-SMA gene expression (P<0.05). These findings were supported by morphometric analysis of picrosirius staining and bile duct proliferation assessment in liver sections. Bile duct ligation resulted in significant gene up-regulation of key components of the RAS, including ACE, ACE2, AT1 and the putative Ang(1-7) receptor, Mas (P<0.01). However, infusion of Ang-(1-7), resulted in a down regulation of ACE and Mas gene expression (P<0.05). The ACE gene data was further supported by ACE autoradiography of liver tissue which showed a significant suppression of ACE protein in the Ang-(1-7) treated group (P<0.001). The gene expression of growth factors CTGF and VEGF were both attenuated by Ang-(1-7) infusion (P<0.05). Data were analyzed by analysis of variance (ANOVA) with Newman-Keuls Multiple Comparison Test. Conclusions: The RAS is upregulated following bile duct ligation. Ang-(1-7) infusion reduces hepatic fibrosis and bile duct proliferation. This is associated with down-regulation of key components of the RAS (ACE and Mas) as well as critical growth factors (CTGF and VEGF). Reduced gene and protein expression of SMA indicate that Ang-(1-7) may attenuate hepatic stellate cell activation. These novel findings indicate that the ACE2/Ang-(1-7)/Mas axis is activated in chronic liver injury and may represent a potential target for antifibrotic therapy.

ROLE OF C-C CHEMOKINE RECEPTOR 2 (CCR2) DURING CONSTITUTION AND RESOLUTION OF FIBROSIS INDUCED BY CARBON TETRACHLORIDE IN MICE
Claudia Mitchell1, Dominique Couton1, Vincent O. Mallet1, Stanislas Pol2, Laurent Renia2, William A. Kuziel, Helene Gilgenkrantz1; 1genetic and development, Cochin Institute, INSERM U567, CNRS UMR8104, Paris, France; 2Immunology Department, Cochin Institute, INSERM U567, CNRS UMR8104, Paris, France; 3Autoimmune and inflammatory diseases, Protein design labs, Fremont, CA

Inflammatory reaction is part of the fibrogenic process and it is accompanied by an infiltration of leukocytes that is regulated by chemokines. The C-C chemokine receptor, CCR2, has been identified as the primary receptor that mediates monocyte chemoattractant protein-1 (MCP-1) responses. MCP-1 and CCR-2 are up-regulated during the progression of fibrosis in humans. During liver injury, MCP-1 is expressed by hepatocytes, endothelial, Kupffer cells and stellate cells (HSC). In contrast, CCR-2 expression is mainly associated with macrophages and a subpopulation of lymphocytes. These cells have been shown to play a major role in both the constitution and the resolution of liver fibrosis induced by carbon tetrachloride (CCl4) in mice. However, the role of CCR2 in these processes has never been evaluated. We used CCR2 knockout mice (CCR2/-) to determine whether CCR2 is involved both in the establishment and/or the resolution of fibrosis. CCR2/- mutant (n=18) and wild type (n=18) male mice of the same Balb/c Ola background were injected twice weekly during 6 weeks with CCl4. Animals were killed either 48 hours (peak of fibrosis) or 7 days (partial resolution of fibrosis) after the end of the injury. We observed a significant lower level of the fibrotic scar at the peak of fibrosis in mutant animals compared to their control littermates as assessed by red sirius quantification. This effect was correlated with a reduction in the proportion of activated macrophages present in the lesion as defined by quantification of CD68 positive macrophages. In contrast, 7 days after the end of the fibrogenic challenge, whereas fibrosis was diminished in CCR2+/+ mice, CCR2/- mice experienced no regression of their liver injury, and presented marked regions of calcification. This persistence of hepatic injury in mutant animals was correlated with a maintain in TIMP1 mRNA expression. In conclusion, these findings demonstrate that CCR2 stimulates liver fibrogenesis by inducing macrophage infiltration that will subsequently activate HSC and confirm the critical role of macrophages and inflammatory cells for the fibrogenic process. In addition, CCR2 is also involved in the resolution of the fibrotic scar, with an opposite role allowing macrophages to eliminate injured hepatocytes.

INCREASED SUSCEPTIBILITY TO HEPATIC STEATOSIS, INFLAMMATION AND ADVANCED FIBROSIS IN APOLIPROTEIN-E DEFICIENT MICE
Natàlia Ferré1, Marcos Martinez-Clemente1, Marta López-Parrà1, Ana González-Pérez1, Raquel Horrillo1, Anna Planagumà1, Jordi Camps1, Jorge Joven2, Ramón Bataller2, Vicente Arroyo2, Juan Rodes3, Joan Clària1; 1Department of Biochemistry and Molecular Genetics, Hospital Clinic, Centro de Investigación Biomédica Esther Koplowitz (CIBEK), IDIBAPS, University of Barcelona, Barcelona, Spain; 2Liver Unit, Hospital Clinic, Barcelona, Spain; 3Centre de Recerca Biomèdica, Hospital Universitari Sant Joan de Reus, Institut de Recerca en Ciències de la Salut (IRCS), Reus, Spain

The contribution of hyperlipidemia, one of the most important metabolic risk factors, to the progression of liver disease is not established. In this study, we employed apolipoprotein E-deficient (ApoE-) mice, a mouse model of hypercholesterolemia, to assess the relationship between the dysregulation of lipid metabolism and the progression of liperoxidative-induced liver damage. To this end, ApoE-/- and wild-type mice were exposed to carbon tetrachloride for 4, 6 and 8 weeks. Two additional groups received only olive oil. As compared to wild-type, ApoE-/- mice had increased hepatic steatosis as revealed by oil red-O staining. Moreover, the number of F4/80-positive cells, indicative of macrophage infiltration, as well as necroinflammation were increased in liver sections from ApoE-/- mice. At a more advanced stage, ApoE-/- mice exhibited exacerbated fibrosis, assessed by Sirius red staining and α-SMA immunostaining. Interestingly, the number of non-parenchymal cells with a TUNEL-positive nucleus was significantly reduced in ApoE-/- mice. Moreover, liver injury (i.e. ALT and AST) was more severe in ApoE-/- than in wild-type mice. Importantly, significant direct correlations were identified between serum cholesterol and oxysterols and oxidized LDL. Conversely, the contribution of hepatic injury as determined by liver injury parameters (ALT and AST), was more severe in ApoE-/- than in wild-type mice. In addition, ApoE-/- mice exhibited exacerbated hepatic steatosis as assessed by oil red-O staining. Moreover, the number of F4/80-positive cells, indicative of macrophage infiltration, as well as necroinflammation were increased in liver sections from ApoE-/- mice. At a more advanced stage, ApoE-/- mice exhibited exacerbated fibrosis, assessed by Sirius red staining and α-SMA immunostaining. DELETION OF THE THROMBIN RECEPTOR GENE; PAR 1, AMELIORATES LIVER FIBROSIS AND DECREASES TGFβ EXPRESSION BY HEPATIC STELLATE CELLS IN A MURINE MODEL OF CIRRHOSIS

Virginia H. Knight, Jorge Chongue, Peter Tipping, William Sievert;
Centre for Inflammatory Diseases, Monash University, Clayton, VIC, Australia

Thrombin, a pleuripotent serine protease, is principally known for modulating hemostasis but can promote extracellular matrix (ECM) production and has been implicated in liver fibrogenesis. Profibrotic effects of thrombin are thought to occur through protease activated receptor 1 (PAR1) signaling. A previous study has shown that PAR 1 antagonism ameliorates liver fibrosis in a rat bile duct ligation model (Fiorucci 2004). The aim of this study was to investigate whether deletion of the PAR 1 gene protected against liver fibrosis in a model of hepatocyte inflammation and fibrosis and to identify potential mechanisms. Methods: Twice weekly intraperitoneal carbon tetrachloride injections for 5 and 8 weeks were used to induce liver fibrosis in 9 week old wild type and PAR 1 knock-out(-/-) C57/BL6 mice. Liver sections were stained with Sirius red and fibrosis was quantified by computer assisted morphometry. Hepatic collagen content was quantified by hydroxyproline assay. α-SMA Smooth muscle actin(α SMA) expression was detected by Western blot. Hepatic stellate cells (HSC) were isolated from wild type and PAR 1 -/- mice and cultured on plastic in M199 media supplemented with 10% fetal bovine serum. TGF wild type and PAR 1 -/- mice and cultured on plastic in M199 Western blot. Hepatic stellate cells (HSC) were isolated from in a necroinflammatory model of liver fibrosis. The protective effect is magnified with longer duration of liver injury. HSC isolated from PAR1 knockout animals express less TGF β and less α SMA than wildtype animals, suggesting less HSC activation and thus a potential mechanism for the antifibrotic effect. The observation that fibrosis was not completely ameliorated with PAR 1 gene deletion suggests a multifactorial pathway for hepatic fibrogenesis.

HUMAN DISCOIDIN DOMAIN RECEPTOR 1: INTRAHEPATIC FORMS AND IN VITRO FUNCTIONS

Sunmi Song, Nicholas A. Shackel, Xin M. Wang, Katerina Ajami, Geoffrey W. McCaughan, Mark D. Gorrell; Centenary Institute, Royal Prince Alfred Hospital, University of Sydney, Camperdown, NSW, Australia

Discoidin Domain Receptor 1 (DDR1) is a tyrosine kinase receptor that binds and is activated by collagens. Being a receptor of collagen, DDR1 expression needs to be tightly regulated. Transcriptional profiling of human cirrhosis with DNA array and quantitative real-time RT-PCR detected elevated mRNA expression of DDR1 compared to non-diseased liver (Shackel NA, et Am J Pathol. 2002;160:641). The study aims to characterize DDR1 expression in cirrhotic and non-diseased liver and to examine the cellular effects of DDR1 expression. Immunoblots of 10 cirrhotic and 5 non-diseased livers used the anti-DDR1 (C-20 peptide) antibody (Santa Cruz). In situ hybridisation (ISH) used a Digoxigenin (DIG)-labeled (Roche) human DDR1 566 bp riboprobe. Immunostains included cytokeratin 18 (CK18), DDR1 (C-20), CD45, CK19 and CK7. Green fluorescent protein (GFP): DDR1 isoform A fusion protein was transiently expressed in the Huh7 cell line for cell adhesion and transwell migration assays on collagen-I, fibronectin and matrigel. The actin cytoskeleton was stained using phalloidin-594. Two molecular forms of DDR1 protein were differentially expressed in cirrhotic versus non-diseased liver: A 132 kDa form of DDR1 in non-diseased liver but not cirrhotic liver and an 85kDa form present only in cirrhotic liver. As DDR1 is subject to protease-mediated cleavage after collagen-induced activation, this differential expression may indicate more intense activation of DDR1 protein in cirrhotic liver. To determine the cellular localization of DDR1, ISH and immunofluorescence were performed. Intense DDR1 mRNA expression was detected in hepatocytes at the portal/parenchymal interface and the reactive bile duct cells in the septum. DDR1 protein was predominantly in leucocytes, the luminal aspect of biliary epithelium and the bile canalicular domain of hepatocytes, indicating the presence of DDR1 on the apical domain of these epithelial cells. DDR1 overexpression increased Huh7 cell adhesion to collagen-I but decreased adhesion to fibronectin and matrigel. DDR1 overexpressing Huh7 cells showed decreased migration on collagen-I, fibronectin and matrigel. As DDR1 is known to be involved in cellular morphogenesis, the actin cytoskeleton was visualised but was unaltered in DDR1 overexpressing cells. Flow cytometry analysis indicated that DDR1 overexpression did not regulate the expression of matrix metalloproteinase (MMP) 1, 2, 3 or 9. These findings suggest that increased DDR1 expression and activation in cirrhotic liver may have an important role in the pathogenesis of cirrhosis by influencing extracellular matrix – hepatocyte interactions including adhesion and migration.

BXR RECOMBINANT INBRED MOUSE LINES - A GENETIC REFERENCE POPULATION FOR DISSECTION OF THE COMPLEX GENETICS OF LIVER FIBROSIS

Rabea Hall, Sonja Hillebrandt, Katrin Hochrath, Frank Grunenhage, Yildiz Yildiz, Susanne Weber, Stephanie Schwartz, Tilman Sauerbruch, Frank Lammer; Department of Internal Medicine I, University Hospital Bonn, University of Bonn, Bonn, Germany

Background: Previously we have shown that quantitative trait locus (QTL) analysis can detect susceptibility loci for liver fibro-
sis, based on genome-wide linkage analysis in experimental crosses of inbred mouse strains (Hillebrandt et al. Gastroenterology 2002;123:2041-51). In previous studies we identified multiple QTLs and a quantitative trait gene (C5) in a large F2 intercross of fibrosis-susceptible and resistant strains of inbred mice (Hillebrandt et al. Nat Genet 2005;37:835-43). Our aim now was to establish a murine genetic reference population for integrated and replicated analyses of the pathobiology of liver fibrogenesis. Methods: We availed of BXD recombinant inbred lines generated by (i) crossing the two inbred strains C57BL/6J and DBA/2J, and (ii) inbreeding the F2 progeny by brother×sister matings for at least 20 generations. Each of the 80 lines shows a unique mosaic gene set of the two founder strains and has been genotyped for 13377 single nucleotide polymorphisms (SNPs). We conducted whole-genome association scans in the BXD panel for integrated analysis of profibrogenic susceptibility genes. Conclusions: The observed differences in susceptibility to liver fibrosis among the BXD lines demonstrate that this set provides a genetic reference panel for integrated analysis of profibrogenic susceptibility genes. We conclude that the use of such a panel, coupled with transcriptome profiling, will lead to novel insights into the complexity of the genetic control of liver fibrogenesis and allow modeling of gene networks during chronic liver injury. Supported by the German Network for Systems Genetics.

GENETIC ASSOCIATION STUDY OF PROFIBROGENIC GENE VARIANTS USING TRANSIENT ELASTOGRAPHY FOR PHENOTYPIC CHARACTERIZATION OF LIVER FIBROSIS

Frank Grünhage, Stephanie Schwartz, Tilman Sauerbruch, Frank Lammert; Department of Internal Medicine I, University Hospital Bonn, Bonn, Germany

Introduction: Transient elastography (TE) has been employed to determine the stage of liver fibrosis in patients with chronic liver diseases with close correlation to liver histology. Recently based on a genome-wide scan, a novel “gene signature” consisting of 7 single nucleotide polymorphisms (SNPs) has been proposed to identify the risk of progressive fibrosis in patients with chronic hepatitis C virus (HCV) infection (Huang et al. Hepatology 2007; epub). Our aim now was to evaluate this gene signature in a large cohort of patients with chronic liver diseases who underwent TE for assessment of liver fibrosis.

Patients and methods: We enrolled 516 patients with chronic liver diseases, including a subset of 256 patients with chronic HCV infection. Liver stiffness measurements (LSM) were performed by TE; in addition we included patients with unequivocal signs of liver cirrhosis in whom TE failed (e.g. because of ascites). We stratified patients in a severe fibrosis group (LSM >9.5 kPa, or signs of liver cirrhosis) and a no-fibrosis group (LSM <7.5 kPa). Patients were genotyped for the 7 SNPs identified by Huang et al. using PCR-based Taqman assays.

Results: The genetic analyses revealed that carriers of the common allele of a SNP in the ornithine decarboxylase antizyme inhibitor (AZIN1) gene are at increased risk for severe liver fibrosis (OR = 1.75; 95% CI = 1.01 - 3.04; p < 0.05). This association was even more pronounced in the group of patients with chronic HCV infection (OR = 2.89; CI = 1.28 - 6.52; p < 0.01). Overall, there was also a trend (p = 0.069) for an association with the common allele of a SNP in the 5’ region of the adaptor-related protein complex 3 (AP3S2) gene (rs2290351), which showed a significant association in the HCV subgroup (OR = 6.56; p < 0.05). However, inverse risk alleles and no associations between LSM and the other SNPs included in the gene signature in our cohort or in the HCV subgroup indicate that additional studies are needed to validate the predictive value of the profibrogenic gene signature.

Conclusions: Our study demonstrates that TE qualifies for non-invasive phenotyping of fibrosis patients in genetic association studies. Furthermore, some of the recently identified cirrhosis risk variants are also associated with progressive liver fibrosis in our cohorts of patients with chronic HCV infection in particular and chronic fibro-proliferative liver diseases in general.

SYNERGISTIC ANTI-FIBROTIC EFFICACY OF STATIN AND PROTEIN KINASE C INHIBITOR IN HEPATIC FIBROSIS

Jong In Yang1, Jung-Hwan Yoon1, Young-Jue Bang1, Sun Jung Myung1, Bo Hyun Kim1, Jeong-Hoon Lee1, Dong Hee Kim1, Won Kim1, Kyung-Suk Suh2, Hyo-Suk Lee3; 1Department of Internal Medicine, Seoul National University College of Medicine, Seoul, South Korea; 2Department of Surgery, Seoul National University College of Medicine, Seoul, South Korea

Background & Aims: Activated hepatic stellate cells (HSCs) are major participants in hepatic fibrosis, and thus, the suppression of HSC activation or survival has been proposed as anti-fibrotic therapies. Statin has anti-fibrotic efficacy in human fibrosing diseases, such as pulmonary and renal fibrosis, and therefore, is implicated in hepatic fibrosis. However, statin can also activate protein kinase C (PKC), which augments hepatic fibrogenesis, and thereby, is likely to reduce statin’s anti-fibrotic efficacy. Therefore, we hypothesized that the simultaneous treatment of statin and PKC inhibitor may synergistically enhance anti-fibrotic efficacy in hepatic fibrosis. Methods: LX-2 cells (an immortalized human HSC line), pravastatin and enzastaurin (PKC inhibitor) were used in this study. Hepatic fibrosis model was established in BALB/c mouse by injecting carbon tetrachloride intraperitoneally twice per week for 6 weeks. Statin and PKC inhibitor were administered by gavages 5 days per week for 5 weeks. Cellular apoptosis was explored using DAPI or TUNEL staining and immunoblot analysis. Hepatic fibrosis and HSC activation were assessed by morphometric analysis of histological findings and immunohistochemistry for α-smooth muscle actin. Results: Statin induced LX-2 cell apoptosis through activating mitochondrial apoptotic signals. While PKC inhibitor did not induce LX-2 cell apoptosis, the addition of this inhibitor significantly increased statin-induced apoptosis, and this was due to enhanced caspase 9 activation in these cells. The per-
centages of TUNEL-positive HSCs were significantly increased in mice treated with statin+PKC inhibitor as compared to control or single compound-treated mice. The extent of collagen deposition and the percentage of area occupied by activated HSCs were significantly decreased in mice treated with statin+PKC inhibitor as compared to control or single compound-treated mice. Conclusions: These results demonstrate that the simultaneous treatment of statin and PKC inhibitor synergistically enhanced anti-fibrotic efficacy in in vitro and in vivo model of hepatic fibrosis. Therefore, this combination strategy may have therapeutic implication in reducing hepatic fibrosis.

TGFβ1 STIMULATES THE HUMAN α1(I) COLLAGEN PROMOTER BY COOPERATION BETWEEN SMAD2/4 AND SP1 TRANSLATING FACTORS

Polina Sysa, James J. Potter, Xiaopu Liu, Esteban Mezey; Medicine, Johns Hopkins University School of Medicine, Baltimore, MD

Hepatic fibrosis and cirrhosis result from the excessive deposition of predominantly type I collagen, composed of two α1 chains and one α2 chain. TGFβ1, a principal pro-fibrogenic cytokine, activates the human α2(I) collagen promoter via Smads (2, 4). However, the role of Smads in activation of the human α1(I) collagen promoter remains unknown. Sp1, an ubiquitous zinc-finger family transcription factor, binds to numerous sites along the length of the human α1(I) collagen promoter. The enhancement of expression of distinct genes by cooperation of Sp1 and Smad proteins has been described previously. The aim of this study was to determine the roles of Smads and Sp1 in mediating the effect of TGFβ1 signaling on activation of the human α1(I) collagen promoter. The binding of Smads and Sp1 to the proximal collagen promoter was determined by EMSA and their specific sites of binding were determined by sequential 2 bp mutations of the promoter. Transient transfection experiments were performed with cultured human LX-2 stellate cells. Pre-designed shRNA plasmids were used to knockdown Smads and Sp1. Smads and Sp1 separately bound to adjacent sites of the proximal - 174 α1(I) collagen promoter, and expression vectors of Smad2 and Sp1 separately as well as their combination activated the collagen promoter. Smad2 or Sp1 knockdown decreased activation of the promoter with or without the presence of TGFβ1. Smad4 knockdown alone had no effect in either case, but simultaneous knockdown of Smad4 and Sp1 again effectively decreased activation of the promoter in cells not treated with TGFβ1, but not in TGFβ1-treated cells. However, simultaneous knockdown of Smad2 and Sp1 effectively decreased activation of the promoter with or without the presence of TGFβ1. Smad4 knockdown alone had no effect in either case, but simultaneous knockdown of Smad4 and Sp1 again effectively decreased activation of the promoter in either TGFβ1-treated or untreated cells. The knockdowns were confirmed by Western blot and/or mRNA determined by real time PCR. In conclusion, Smad2, Smad4 and Sp1 cooperate in enhancing human α1(I) collagen promoter activity and type I collagen production in human hepatic stellate cells.

shown to reduce fibrosis severity in animal models of disease. Since liver macrophages may be essential for effective fibrosis recovery, a means to specifically target myofibroblasts with a therapeutic that promotes apoptosis has been examined. A human recombinant antibody (termed C1-3) was generated to a peptide sequence present on an extracellular domain of synaptofysin, a plasma membrane protein expressed in activated hepatic stellate cells and myofibroblasts. FITC-labelled C1-3 antibody bound to human and mouse liver myofibroblasts in vitro and was taken up into cells by endocytosis. FITC-labelled C1-3 antibody was then injected i.p. into control mice or mice with liver fibrosis (treatment with CCl4). Antibody appeared in circulating blood within 20 minutes and concentrations peaked at 2 hours. Tissue analysis indicated that the antibody was localised to the fibrotic liver and was not detected in brain, kidney spleen or muscle. Fibrotic liver levels of antibody were maximal after 6 hours and binding was to cells within the scar region as determined by immunohistochemistry or fluorescence microscopy in liver sections. Co-staining for α-smooth muscle actin indicated that the antibody localised specifically only to myofibroblasts. The antibody was not detected in livers from control mice injected with the antibody. In rats, gliotoxin reverses fibrosis through the stimulation of myofibroblast apoptosis, although hepatocyte and Kupffer cell apoptosis also occur. To examine whether targeting gliotoxin to liver myofibroblasts with the C1-3 antibody may be more effective, mice with liver fibrosis were injected with either free gliotoxin; an equivalent dose of gliotoxin conjugated to C1-3 or an equivalent dose of gliotoxin conjugated to an unrelated antibody that does not target any liver cells. Both free gliotoxin and C1-3-gliotoxin stimulated an increase in myofibroblast apoptosis and reduced the numbers of α-smooth muscle actin positive cells in liver sections. However, C1-3-gliotoxin was significantly more effective than free gliotoxin and prevented the increase in hepatocyte and Kupffer cell apoptosis seen with free gliotoxin. The C1-3 antibody is therefore able to selectively target myofibroblasts in a mouse model of liver fibrosis. Antibody conjugation did not prevent antibody targeting or therapeutic activity.

1065 ENHANCED IL-6 PRODUCTION BY HEPATIC STELLATE CELLS IN RESPONSE TO IMATINIB MESYLATED STI571 - (GLEEVEC ®), A NOVEL LINK BETWEEN RECEPTOR TYROSINE KINASE INHIBITION AND HEPATIC REGENERATION

Carlos E. Alvarez1, Youngchul Kim1, Efsevia Albanis1, Maria Isabel Fiel1, Scott L. Friedman1; 1Division of Liver Diseases, Mount Sinai School of Medicine, New York, NY; 2Department of Pathology, Mount Sinai School of Medicine, New York, NY

Background: The hepatic stellate cell (HSC) is a key target of antifibrotic therapies. Gleevec® (imatinib mesylate), is among a new class of small molecule receptor tyrosine kinase (RTK) inhibitors, and is indicated for treatment of CML and GI stromal tumors. Because Gleevec inhibits β-PDGFR signaling, a major pathway of HSC proliferation, we assessed its activity in culture and in vivo, and examined downstream targets of its activity in an immortalized human stellate cell line (LX-2) using cDNA microarray. Methods and Results: Gleevec dose-dependently inhibited LX-2 cell proliferation (0.5 µM – 2.0 µM) with no effect on viability at 12h and 24h. This was associated with progressive inhibition of β-PDGFR phosphorylation as assessed by Western Blot. Mitochondrial activity and superoxide anion production were decreased in response to Gleevec, as assessed by Mito-tracker and FACS. To identify HSC genes altered by Gleevec treatment, cDNA microarray (Affymetrix U133 Chip) was performed on cells with or without Gleevec (2 µM) treated for 12 hours. There was a significant up-regulation of 28 genes involved in cell growth, metabolism or apoptosis, of which 7 were validated by qRT-PCR. This included Interleukin-6 (IL-6), which was elevated 4-fold (P<0.05), and correlated with progressive IL-6 secretion in LX-2 supernatants. Gleevec decreased gene expression in LX-2 of collagen α1(I), α-SMA, β-PDGFR, TGFβ1 receptor type 1, MMP2 and tissue inhibitor of metalloproteinase II (TIMP II). In vivo, Gleevec administered to rats (5 d/wk) beginning 4 weeks after 3d per week IP dosing of thioacetamide, led to reduced lobular inflammation, and collagen content as assessed by pathological scoring and/or morphometry, with significant reductions in portal pressure and downregulation of key fibrogenic genes in whole liver. Importantly, hepatic IL-6 mRNA levels were significantly (1.4 to 2-fold) increased in TAA-treated animals receiving Gleevec compared to animals receiving TAA and vehicle. Conclusions: These findings uncover an unexpected link between inhibition of HSC activation by Gleevec and enhanced secretion of IL-6, a key regenerative cytokine. Impaired IL-6 production during liver injury could be related to up-regulation of one or more RTK targets inhibited by Gleevec. Clarification of specific RTK pathways in HSCs that are linked to IL-6 secretion will broaden our understanding of this agent’s effects and refine anti-fibrotic and regenerative therapies in humans.

1066 CD147 REGULATION OF HEPATOCYTE DERIVED MATRIX METALLOPROTEINASES: A NOVEL PATHWAY INVOLVED IN LIVER FIBROGENESIS

Sarah R. Richardson1, Fiona J. Warner1, Geoff W. Mc Caulaghan1,2, Mark D. Gorrell1,2, Rosa Lam1, Nicholas A. Shackell1,2; 1Liver Immunobiology, Centenary Institute for Cancer Medicine and Cell Biology, Camperdown, NSW, Australia; 2AW Morrow Gastroenterology and Liver Centre, Royal Prince Alfred Hospital, Camperdown, NSW, Australia

Introduction: We have previously shown CD147 is upregulated in the human cirrhotic liver and expressed predominantly on hepatocytes. CD147 is an abundant glycoprotein and a potent inducer of matrix metalloproteases (MMPs-1, 2, 3 & 9) in malignant cells and fibroblasts. The progression of liver fibrosis is characterised by the dysregulation of extracellular matrix turnover, primarily mediated by MMPs. Therefore, we hypothesize that CD147 regulates hepatocyte-derived MMP expression which is capable of matrix remodelling. Methods: Cellular localisation of CD147 and MMPs was determined by immunohistochemistry and immunofluorescence in human cirrhotic liver explants. Progressive changes in CD147 expression were analysed in a rat bile duct ligated model of injury (0, 1, 2, 3 & 4 weeks). MMP and tissue inhibitors of metalloproteinase (TIMP) activity was analysed in primary rat hepatocytes (with and without CD147 blocking antibody) and hepatocelllular hepatic stellate cells (HSCs) by zymography and reverse zymography respectively. In-vivo functional studies of CD147 were performed in mice treated with carbon tetrachloride for 4 weeks using an anti-CD147 blocking antibody (mAb R737.2). Injury was assessed by histological analysis and severity of fibrosis quantitated by hydroxyproline estimation. Results: CD147 mRNA
and protein were increased in progressive injury leading to cirrhosis in humans and in the rat bile duct ligated injury model. Localisation studies showed CD147 and MMPs-1, 2 & 9 are expressed predominantly on hepatocytes. In-vitro studies of MMP from rat primary hepatocytes showed significantly increased MMP-2 & 9 comparable to either rat primary quiescent or in-vivo activated HSCs. Further, significant TIMP-1 & 2 activity was found in media from primary HSCs but not in media from hepatocytes. Importantly, MMP-2 & 9 activity was reduced following administration of a non-CD147 blocking antibody. In-vivo antibody treatment blocking CD147 was associated with a significant reduction in hepatic inflammation, the preservation of hepatic architecture and increased in collagen I deposition (p<0.01). Conclusion: Our studies demonstrate that CD147 regulates hepatocyte derived MMP-2 & 9 production, and that this pathway has a distinct role in remodelling of extracellular matrix in liver injury and fibrogenesis.

1067 DETECTION AND PREVENTION OF HEPATIC FIBROSIS TARGETING TGF-β ACTIVATION REACTION
Soichi Kojima1, Ayako Arai1*, Ryutaro Teraoka1, Shinji Ogawa2, Katsuhiko Shinjo2, 1Med Cell Pathol Res Unit, RIKEN, Wako, Japan; 2Nagoya Lab, Pfizer Japan, Nagoya, Japan

Transforming growth factor (TGF-β), playing a pivotal role in the pathogenesis of liver diseases, is produced as a high molecular weight latent form, and thus must be activated before exerting its biological activities. TGF-β activation is the reaction, by which 25 kD active TGF-β molecule is released from the latent complex. We previously showed that TGF-β is activated by plasmin (PLN) and plasma kallikrein (PLK) during pathogenesis of liver fibrosis and impaired liver regeneration, respectively, and that blockage of these activation reactions with low molecular weight protease inhibitors prevented the development of the diseases in animal models. Now, we determined that PLN and PLK cleaved between K56-L57 and R58-L59 in LAP portion of human latent TGF-β1, respectively, and produced antibodies that specifically recognize the cut ends of each cleavage site. In Western blotting, the antibodies against the PLK-cut ends (anti-R58 and anti-L59 antibodies) recognized the degradation products produced during PLK-mediated activation of latent TGF-β, but did not recognized uncleaved latent TGF-β and only weakly recognized PLN-cleaved latent TGF-β degradates. A similar result was obtained with the antibodies against the PLN-cut ends (anti-K56 and anti-L57 antibodies). The anti-R58 antibodies strongly stained liver sections from patients with fulminant hepatitis compared to normal liver sections from patients that died from pulmonary embolism. On the other hand, the anti-L59 antibodies were successively used to establish ELISA to quantitate LAP degradates released into and circulating in the serum in rat fibrosis models. In bile duct ligation models, we found that serum LAP degradates concentration in fibrotic animals was 7-fold higher compared with those in the control animals (no treatment or sham operation), and showing a good correlation to hepatic contents of hydroxyproline and serum GOT/GPT. Furthermore, we produced the peptide containing these cleavage sites as well as its decoy peptide, in which cleavage site amino acids were all mutated to A. These peptides efficiently suppressed the TGF-β activation reaction, prevented the activation of hepatic stellate cells in culture, and prevented impaired liver regeneration observed in LPS-pre-treated partially hepatectomized mice. These results suggest a key role for PLN/PLK in the generation of active TGF-β, thereby addressing a potential use for PLN/PLK inhibitors and decoy peptides in hepatitis/fibrosis therapy. These results also suggest a potential usage of a LAP degradate as a biomarker for liver fibrosis.

1068 C-REACTIVE PROTEIN AMELIORATES HEPATIC FIBROGENESIS THROUGH INHIBITION OF HEPATIC STELLATE CELL TRANSACTIVATION
Kenichi Ikejima, Kumiko Arai, Kazuyoshi Kon, Tonomori Aoyama, Kyoko Okumura, Reiko Yaginuma, Shunhei Yamashina, Sumio Watanabe; Department of Gastroenterology, Juntendo University, Tokyo, Japan

Recently, minimal increment in serum C-reactive protein (CRP) levels has been recognized as a sensitive marker of micro-inflammation in atherosclerotic lesions and hepatic inflammation in non-alcoholic steatohepatitis (NASH). Although it is well-known that CRP participates in regulation of inflammatory responses involving complement activation, the role of CRP in hepatic fibrogenesis has not been well elucidated. In the present study, therefore, we investigated the effect of CRP on transactivation of isolated hepatic stellate cells (HSCs), and experimental hepatic fibrosis in the rat. Methods: HSCs were isolated from male Wistar rats, and cultured in DMEM supplemented with 10% heat-inactivated FBS up to 7 days prior to experiments. Proliferative responses in cultured HSCs were evaluated by BrdU incorporation, and phosphorylation of ERK1/2 and Akt was detected by Western blotting. For experiments in vivo, hepatic fibrosis was induced in male Wistar rats by repeated intraperitoneal injection of thioacetamide (TAA, 200 mg/kg, 3 times/week) for 6 weeks. Some animals were given rat CRP (1 mg/kg, i.p.) simultaneously starting from the third week for 4 weeks. The degree of hepatic fibrosis was assessed by picro-sirus red staining, and expression of smooth muscle α-actin (αSMA) in the liver was detected by immunohistochemistry. Results: In day-3 cultured HSCs, PDGF-BB (5 ng/ml)-induced increases in BrdU uptake were blunted in the presence of human CRP in a dose-dependent manner, reaching 57% inhibition at a concentration of 1 mg/dl (p<0.05, vs. PDGF alone). The similar tendency was observed in 7 day-cultured, activated HSCs. More importantly, this anti-proliferative effect of CRP was observed not only in human CRP but also in rat CRP, which lacks complementary activation capability. PDGF-induced phosphorylation of ERK1/2 was also inhibited by CRP; however, phosphorylation of Akt was not decreased even in the presence of CRP. On the other hand, TAA-induced hepatic fibrosis was ameliorated markedly when CRP was given simultaneously for 4 weeks. Indeed, induction of αSMA in the liver was prevented remarkably, indicating that CRP also inhibited transactivation of HSCs in vivo. Conclusions: These findings clearly indicated that CRP has an anti-fibrogenic property including direct inhibitory effect on HSC transactivation. The anti-proliferative effect of CRP on HSCs appears to be independent on complement activation, and most likely involves inhibition of the MAP kinase pathway. It is therefore postulated that CRP produced from hepatocytes plays a regulatory role in progression of hepatic fibrosis in NASH.

THE FUNCTIONAL CONTRIBUTION OF BONE MARROW- Derived CELLS TO LIVER FIBROSIS IN A MOUSE MODEL OF CHRONIC LIVER INJURY

Yiannis N. Kallis1, Rob Goldin2, John Iredale3, Stuart Forbes2; 1Dept. of Medicine, Imperial College London, London, United Kingdom; 2Dept. of Histopathology, Imperial College London, London, United Kingdom; 3MRC Centre for Inflammation Research, University of Edinburgh, Edinburgh, United Kingdom

Aims: A significant proportion of the hepatic fibrogenic cell population in chronic liver disease in humans and animal models is of bone marrow (BM) origin. The purpose of this study was to 1) evaluate the relative contribution of the BM-derived (exogeneous) and intra-hepatic (endogeneous) fibrogenic cell compartments to hepatic fibrosis in a carbon tetrachloride (CCL4) model of injury; 2) to determine whether the BM can influence the liver’s fibrotic response to injury by manipulation of BM genotype. Methods: r/r collagen transgenic mice (r/r) have an exaggerated fibrotic response to liver injury compared to C57B6 wild-type (Wt) equivalents due to constitutive resistance of collagen I to degradation. Recipient female mice were myelo-ablated and received BM transplantation from male donors according to the following four experimental groups: 1) Wt BM into Wt recipient, 2) r/r BM into Wt recipient, 3) Wt BM into r/r recipient, 4) r/r BM into r/r recipient. Liver fibrosis was induced by 8 weeks of intraperitoneal CCL4. Liver tissue was harvested immediately post injury (day 1) and into recovery (day 9) and fibrosis quantified by digital image analysis of histological sections. (groups of n=6) Results: r/r collagen mice display increased hepatic fibrosis to CCL4 injury over controls, a phenotype enhanced into recovery after liver injury (4.63% vs 3.22% p=0.038, and 4.06% vs 2.40% p=0.004, respectively). Wt mice receiving BM transplantation from r/r donors have an increased hepatic fibrotic response and r/r transgenic mice receiving BM transplantation from Wt donors have a diminished fibrotic response to injury compared to controls, particularly into the recovery phase (2.80% vs 2.40% p=0.013, and 2.78% vs 4.06% p=0.008, respectively at day 9). The degree of liver fibrosis in the two mismatch BM transplanted groups was approximately equivalent (3.70% & 3.63% at day 1, 2.80% & 2.78% at day 9, in the r/r BM into Wt recipient and Wt BM into r/r recipient groups respectively) and levels of fibrosis were intermediate between wholly wild-type or r/r mice indicating that BM-derived cells and endogeneous intra-hepatic fibrogenic cell populations contribute equally to the pathogenesis of liver fibrosis. [results expressed as mean % surface area collagen] Conclusions: In this in vivo functional assay of liver fibrosis, both circulating BM-derived cells and intra-hepatic derived fibrogenic cell populations contribute equally to the development of liver fibrosis. Moreover, manipulation of the fibrogenic propensity of the BM can influence the ensuing fibrotic response of the liver to a chronic injurious stimulus.

ACCELERATED ORTHOTOPIC HCC GROWTH IS LINKED WITH INCREASED PRO-ANGIOGENIC AND PRO-METASTATIC FACTORS IN MURINE LIVER FIBROSIS

Miroslaw Kornek1, Esther Raskopf2, Rene Tolba3, Tilman Sauverbruch3, Volker Schmitz3; 1Dept of Medicine, Imperial College London, London, United Kingdom; 2Department of Surgery, University Hospital Bonn, Bonn, Germany; 3Internal Medicine I, University Hospital Bonn, Bonn, Germany

Background & Aims: Most experimental therapy studies are performed in mice that bear subcutaneous or orthotopic hepatomas but are otherwise healthy and non-fibrotic. However, the majority of hepatocellular carcinoma develops in patients suffering from pre-existing liver fibrosis. Therefore, we wanted to investigate tumor establishment and development after tumor cell implantation into mice with pre-existing liver fibrosis. Methods: Liver fibrosis was induced by thioacetamide and ethanol co-administration in female C3H/He mice. Orthotopic HCC was established by subcapsular intrahepatic injection of 105 HCC cells (Hepa129) into the left liver lobe. Fibrosis induction was verified by measuring hepatic microcirculation (HM) using laser doppler flowmetry one week before implantation and collagen staining. Ten day post implantation tissue samples were harvested for mRNA/cDNA preparation. Transcript levels of VEGF-A, -C, -D and their receptors VEGFR-1/2 and -3 were determined besides MMP-2 and MMP-9 by semiquantitative real time PCR (LightCycler, Roche Diagnostics, Mannheim, Germany). Results: The combination of TAA/EtOH induced liver damage resulting in 64% fibrosis as demonstrated by collagen staining. Accordingly, functional relevance was demonstrated by a relative decline (about 50%) in HM in fibrotic mice liver. Tumor growth was considerably accelerated in fibrotic mice compared to the non-treated controls ten days after tumor cell implantation. Mean tumor volume in fibrotic and non-fibrotic mice reached 956 [mm3] and 260 [mm3] (p=0.0073), respectively. Additionally, metastatic spots were mainly observed in fibrotic but not in non-fibrotic mice (27 vs. 3.1, p<0.0001). Advanced tumor stage was associated with elevated transcription levels VEGFR-1, -2 and high VEGFR-3 values were observed in tumors from fibrotic mice. VEGF-C/D levels were even higher elevated by pre-existing fibrosis. Furthermore, intratumoral MMP-2 and MMP-9 transcription was also increased in liver fibrotic mice. In contrast to VEGF-C and VEGF-D, VEGF-A transcription itself was not affected by pre-existing fibrosis at the time point of examination. Conclusion: Our data show, that tumor growth and metastasis were considerably accelerated in fibrotic livers in mice and that advanced tumor stage was associated with elevated intratumoral Flk-1 and Flt-1 and increased hepatic MMP-2 and MMP-9 transcription levels. Elevated intratumoral VEGFR-3 receptor status and increased intratumoral VEGF-C/D transcription levels had been linked with advanced metastasis. This work was supported by a Deutsche Krebshilfee grant.

CONCORDANCE BETWEEN FIBROTEST® (FT) AND FIBROSCAN® (FS): A NEW NON-INVASIVE METHODOLoGY FOR IMPROVING ACCURACY IN A WORLD WITHOUT A GOLD STANDARD

Thierry Poynard1, Patrick Ingiliz2, Mona Munteanu2, Pascal Lebray1, Rachel Morra1, Djamilia Messous1, Françoise Imbert-Bismut1, Yves Benhamou2, Vlad Ratzou2, 1Hepato Gastro Groupe Hospital, Pitie Salpetriere, Paris, France; 2Biopredictive, Paris, France

Background. Liver stiffness measurements (LSM) using FS, and FT, are widely used as non invasive fibrosis markers. The aim was to identify factors associated with FS accuracy using FT as a non-invasive endpoint and vice versa. Methods. The proof of concordance between FT and FS was established in patients suffering from pre-existing liver fibrosis. Therefore, we wanted to investigate tumor establishment and development after tumor cell implantation into mice with pre-existing liver fibrosis. Methods: Liver fibrosis was induced by thioacetamide and ethanol co-administration in female C3H/He mice. Ortho-
Background / Aim: The role of nitric oxide (NO) on liver injury and fibrosis is unclear. The purpose of this study was to determine the effects of inducible NO synthase deficiency (iNOS-/-) on liver injury and fibrosis produced in mice by chronic CCl4 administration. METHODS: Wild type (wt) or mice with iNOS deficiency were subjected to biweekly CCl4 injections over 8 weeks, while controls were given isovolumetric injections of olive oil. RESULTS: Serum AST and ALT levels were lower after CCl4 in the iNOS-/− than in the wt animals, which correlated with decreased necrosis on liver histology. Also, there were a lower number of stellate cells (α-SMA immunostaining), a lesser degree of fibrosis (morphometric determination of sirius stained slides), and twice as many apoptotic cells (TUNEL assay) after CCl4 in the iNOS-/− as compared to wt animals. In addition, immunostaining for ssDNA, another measure of apoptosis, was significantly higher in the iNOS-/− animals. α1(I) collagen mRNA, determined by real time PCR, was markedly increased after CCl4 in the wt and to a significantly lesser extent in the iNOS-/− mice. Tissue inhibitor metalloproteinase 1 (TIMP-1) mRNA, matrix metalloproteinase 2 (MMP-2) mRNA and MMP-9 mRNA were increased after CCl4 in the wt but not in the iNOS-/− mice. Conclusion: NO protects against CCl4 induced apoptosis. In the absence of iNOS, there is decreased necrosis, increased apoptosis, and reduced liver fibrosis.

1074 TREATMENT OF ESTABLISHED CIRRHOSIS WITH SV40 VECTORS ENCODING INSULIN-LIKE GROWTH FACTOR 1
Luciano Sobrevals, Nerea Razquin, Gloria Gonzalez-Aseguinolaza, Carlos Rodriguez, Puri Fortes, Jesus Prieto; Gene therapy and hepatology, CIMA/UNAV, Pamplona, Spain
Liver transplantation is the only curative treatment for advanced liver cirrhosis. Therapies aimed at halting the progression of the disease are urgently needed. Previous studies have shown that the administration of recombinant insulin like growth factor-1 (IGF-I) induces hepatoprotective effects in experimental cirrhosis. However, the necessity of using high daily doses of the protein for a long period of time makes this therapy very costly hampering their clinical application. As an alternative therapeutic approach, we have evaluated whether sustained IGF-I expression within the liver from viral vectors based on the Simian Virus 40 (rSVIGF-I) could exert therapeutic effects in liver cirrhosis. We have previously shown that intraportal injection of rSVIGF-I in rats prior to the development of liver cirrhosis induces the expression of hepatocyte growth factor (HGF) in the liver and delays the progression of the disease. In the present study we have tested the effect of the vector in rats that had already developed advanced liver cirrhosis. Liver cirrhosis was induced in Sprague-Dawley male rats by intragastric administration of CCl4 for 12 weeks and then a single dose of rSVIGF-I (1011 vp/rat) was administered by different routes. The following administration routes were tested: intraportal (IP), intrahepatic (IH), intraarterial (IA) and intrabiliar (IB). At the end of the study, cirrhotic rats treated with rSVIGF-I showed reduced serum bilirubin, transaminases and liver fibrosis scores as well as increased expression of serum albumin as compared to mock-infected cirrhotic animals. The effects were more prominent in rats treated by IP or IA injection, suggesting that these routes could allow better access of the vector to hepatocytes in fibrotic livers. IGF-I expression correlated with the increase of mRNA levels of IGF-I binding protein 3 (whose synthesis is induced by IGF-I) and with upregulation of HGF, a factor that seems to mediate hepatoprotective effects of IGF-I. These results indicate that established cirrhosis can be reverted by IGF-I and also, that rSVIGF-I are promising vectors for the treatment of this disease.

1075 MULTIPLE GENETIC MARKERS IN TLR4 REGION ARE ASSOCIATED WITH CIRRHOSIS RISK IN CHC PATIENTS
Hongjin Huang1, Olivia Abar1; Charley Rowland1; Ramasubbu Venkatesh1, Mitchell L. Shiffman2, Ramsey Chi-Man Cheung3, Teresa L. Wright4, Thomas J. Layden5, Nathalie H. Bzowej, Thomas White, Scott L. Friedman1; 1Celerion, Alameda, CA; 2Virginia Commonwealth University, Richmond, VA; 3Stanford University, Stanford, CA; 4University of California San Francisco, San Francisco, CA; 5University of Illinois, Chicago, IL; 6California Pacific Medical Center, San Francisco, CA; 7Washington School of Medicine, New York, CA

BACKGROUND: We have recently developed a 7 gene Cirrhosis Risk Score (CRS) signature that can predict the risk of developing cirrhosis in patients with chronic hepatitis C (CHC) (Hepatology, 2007, in press, E-pub April 26). Among them T399I is located in the Toll like receptor 4 (TLR4) gene, which has an identified role in hepatic fibrosis. AIM: To determine the role of other genetic markers in or near TLR4 in cirrhosis risk.

METHODS: We developed assays for an additional 157 single nucleotide polymorphisms (SNPs), covering the region from 98 kb upstream to 161 kb downstream from the original T399I SNP. These 157 SNPs were genotyped in 1,020 CHC patients (708 Caucasians) enrolled from 2 US centers. All patients had liver biopsy prior to treatment and clinical data. In all statistical analyses, Cases were defined as subjects with Bridging fibrosis/Cirrhosis (F3-4) while Controls were No-fibrosis (F0) on liver biopsy. We first performed univariate analysis to identify individual markers significantly associated with cirrhosis risk. We then used the Haplo.Score program to determine significant haplotypes in this region. Last, logistic regression was used to determine the relative importance of each SNP conditional on the effect of other SNPs for all possible pairs in the region.

RESULTS: Of 157 SNPs in the TLR4 region, nine were significantly associated with cirrhosis risk with p<0.005. Their odds ratios (OR=1.68-2.96) were comparable to that of the original T399I SNP. The frequency of the risk alleles is 23.8-94.3%. Among the nine SNPs, one missense (D299G), three intronic and four intergenic SNPs were located in or near the TLR gene; one intronic SNP was in an uncharacterized gene (47kb from TLR4). The two missense TLR4 SNPs T399I and D299G are in nearly complete linkage disequilibrium (R²=0.934). In addition, a 2-SNP haplotype containing the risk allele of the original T399I SNP showed a 24-fold stronger association with cirrhosis risk than T399I by itself (p value 1.37E-05 vs. 3.34E-04). Analysis of the relative importance of the SNPs in the entire region identified one intronic SNP in TLR4 and one intronic SNP in the nearby uncharacterized gene that were associated with cirrhosis risk independent of T399I, suggesting these 3 SNPs may be responsible for the cirrhosis risk in this region.

CONCLUSIONS: We found additional SNPs and haplotypes associated with cirrhosis risk at an equivalent or more significant level than the original T399I. Identification of additional markers in the remaining six gene regions of CRS is ongoing. These findings could lead to a more predictive signature for cirrhosis risk and improve the management of CHC patients.

Disclosures: The following people have nothing to disclose: Hongjin Huang, Olivia Abar, Charley Rowland, Ramasubbu Venkatesh, Joseph Catanese, Mitchell L. Shiffman, Ramsey Chi-Man Cheung, Teresa L. Wright, Thomas J. Layden, Nathalie H. Bzowej, Thomas White, Scott L. Friedman

1076 BMP-7: THE KEY ANTAGONIST OF TGF-β1 IN LIVER FIBROSIS?
Olaf Scherner, Wanda N. Vreden, Steffen K. Meurer, Ralf Weiskirchen, Axel M. Gressner; Inst of Clinical Chemistry and Pathobiochemistry - Central Laboratory, RWTH University Hospital, Aachen, Germany

Background: Transforming growth factor-β1 (TGF-β1) has been accepted as the master cytokine not only in the fibrotic response in the liver. Bone morphogenetic protein-7 (BMP-7), a member of the same superfamility of cytokines, antagonizes profibrogenic functions of TGF-β1 in diverse cellular systems. In the liver a regenerative function of BMP-7 was described but the expression of BMP-7 in isolated liver cells as well as its antifibrotic potential is controversially discussed. Results: First of all we could detect BMP-7 in isolated liver cells. Although hepatic stellate cells (HSC) and hepatocytes express all necessary BMP-7 receptors, only hepatocytes express BMP-7 while HSC do not. This was shown by RT-PCR and immunohistochemistry. In vitro we could show that HSC are responsive to BMP-7 by western blot analysis of phosphorylated Smad1/5 and an increased luciferase activity when using the artificial BMP-reporter (BRE)2-
luciferase. When applied in parallel we could clearly demonstrate that BMP-7 antagonizes the profibrogenic actions of TGF-β1, in that the TGF-β1-induced collagen I and PAI-1 synthesis was completely blocked. Furthermore, we could show by using the (CAGA)12-MLP luc reporter that the basis for this antagonism is most likely a reduced activation of Smad3. Although hepatocytes show a similar sensitivity towards BMP-7 compared to HSC, TGF-β1 induced (CAGA)12-MLP luc activity was not influenced by BMP-7. Nevertheless BMP-7 was able to reduce the LDH concentration in TGF-β1 treated hepatocytes, implying an anti-apoptotic effect. Finally we could demonstrate, in a model of liver fibrosis induced by bile duct ligation (BDL), an increase in BMP-7 expression confirmed by an adenoviral (BRE)2-luc reporter activated in vivo and RT-PCR. Conclusion: We conclude that BMP-7 is a cytokine which is involved in the maintenance of normal liver function. We figured out two different aspects of BMP-7 function: 1) The upregulation of BMP-7 during liver injury protects hepatocytes from TGF-β-mediated apoptosis. 2) BMP-7 directly antagonizes TGF-β-induced extracellular matrix synthesis regulated by Smad3.

KUPFFER CELL-DERIVED CONNECTIVE TISSUE GROWTH FACTOR (CTGF) AND TRANSFORMING GROWTH FACTOR ALPHA (TGFα) MEDIATE THE PROFIBROGENIC EFFECTS OF LEPTIN IN VITRO

Jianhua Wang, Isabelle Leclercq, Joanne Brymora, Mehdi Ramezani-Moghadam, Roslyn M. London, Kumar Subramaniam, Jacob George; Storr Liver Unit, Westmead Millennium Institute, Westmead, NSW, Australia

Introduction The mechanism[s] by which leptin exerts its profibrogenic effects are currently unclear. Some data suggest that leptin acts directly on hepatic stellate cells (HSCs) to trigger fibrogenic gene expression. We hypothesized that in vitro cell culture models will help elucidate the mechanisms whereby leptin activates profibrogenic gene expression in HSCs. Methods Non-parenchymal liver cells (HSCs, KCs and SECs) were isolated from wt or leptin-resistant fatty (fa/fa) Zucker rat and cultured for various times from 2 to 6 days. Recombinant rat leptin (10 nM, 100 nM) was subsequently added. Gene expression of Type I collagen, TIMP1, TGFβ1 and CTGF were assessed by real time PCR. HSC α-smooth muscle actin (α-SMA) and JAK/STAT3, MAPK and PI-3K signalling pathways were assessed by immunoblot. The WST-1 assay was used for HSC proliferation. Immunocytochemistry was performed to assess CTGF protein expression. Electrophoretic mobility shift assays (EMSA) were performed for AP-1 and NF-kB DNA binding ability. Results Leptin treatment of HSCs in culture failed to potentiate profibrogenic effects. In KCs treated with leptin, TGFβ1-induced collagen I and CTGF were in part responsible for mediating these effects. In KCs treated with leptin compared to controls. We were unable to demonstrate any increase in TGFβ1 protein in KC lysates or in KC-conditioned medium by ELISA or immunoblotting. Since CTGF expression is stimulated by TGFβ, we next inhibited TGFβ production in KCs treated with or without leptin using a soluble TGFβ type II receptor. Kupffer cells treated with the soluble receptor but not a control immunoglobulin demonstrated down regulation of CTGF protein. Finally, leptin potentiated pSTAT3, pAKT and pERK1/2 in KCs as well as enhanced AP-1 and NF-kB DNA binding activities in KCs. Conclusion: Leptin and its functional receptors play a crucial role in HSC activation and liver fibrosis principally through indirect effects via soluble mediators released from KC. Increased expression of CTGF and TGFβ are in part responsible for mediating these effects.

LOSARTAN REDUCES THE EXPRESSION OF PROFIBROGENIC GENES AND INFLAMMATION IN PATIENTS WITH CHRONIC HEPATITIS C

Jordi Colmenero1, Ramón Bataller1, Pau Sancho-Bru1, Xavier Forns1, Miquel Bruguera1, Marlene Dominguez1, Montserrat Moreno1, Vicente Arroyo1, David Brenner2, Pere Ginès1; 1Liver Unit, Hospital Clinic de Barcelona, IDIBAPS, Barcelona, Spain; 2San Diego School of Medicine, University of California, San Diego, CA

Background & Aims: There are no antibiotic therapies for patients with chronic hepatitis C in whom viral infection cannot be cured. Angiotensin II type 1 receptor (AT1) blockers have been shown to reduce liver fibrogenesis in experimental models of liver disease, but their effects on liver fibrogenesis in humans is unknown. We investigated the effect of losartan, an AT1 blocker, on liver fibrogenesis in patients with chronic hepatitis C who did not respond to antiviral therapy. Methods: Forty patients with chronic hepatitis C and significant liver fibrosis (F2-F4) received oral losartan (50 mg/day) for 18 months. Two paired liver biopsies were performed before and after treatment. The degree of fibrosis and inflammation were evaluated by histological analysis (METAVIR). Collagen content, the amount of myofibroblasts and inflammatory cells were estimated by measuring the percentage of the whole biopsy area stained with Sirius Red, anti-α-SMA and anti-CD43, respectively. Liver fibrogenesis was assessed by quantifying mRNA expression of key genes encoding extracellular matrix proteins, fibrogenic mediators, inflammatory cytokines, pro-oxidant proteins and components of the renin-angiotensin system through real-time PCR. Results: Oral losartan was well tolerated in all patients. Treatment with losartan was associated with a decrease in inflammatory activity in 8 patients (57%) and a decrease in the fibrosis stage decreased in 7 patients (50%). Treatment with losartan was associated with a significant reduction in the expression of key genes involved in liver fibrogenesis. The mean reduction in the expression of procollagen α1(I), procollagen α2(I), utPA, MMP2 and Rac1 was 30%, 23%, 40%, 27% and 21%, respectively. Patients with reduced inflammatory activity showed a pronounced down-regulation of procollagen α1(I) (44%) and additional down-regulation of TIMP-1 and inflammatory cytokines (MCP-1 and Gro-α). Patients with improved fibrosis showed a reduction in collagen content and in the amount of myofibroblasts compared to patients without fibrosis improvement. Patients with improved inflammation showed a significant decrease in the CD43-positive area compared to patients in whom inflammation did not improve. Losartan treatment did not affect renal function, serum liver tests or viral load. Conclusions: Oral losartan for 18 months decreases the expression of genes involved in liver fibrogenesis and
reduces the inflammatory activity in patients with chronic hepatitis C. The effects of AT1 blockers in chronic hepatitis C should be further investigated in randomized controlled studies.

Background & Aims: Statins, besides their lipid lowering properties, exert beneficial effects in chronically damaged tissues. Angiotensin II (Ang II) plays an important role in liver fibrogenesis by inducing oxidative stress, promoting hepatic inflammation and stimulating TGFβ1 and collagen gene expression. We investigate whether atorvastatin modulates Ang II-induced pathogenic effects in the liver. Methods: Male Wistar rats were infused with saline or Ang II (50 ng/kg/min) for 4 weeks through a subcutaneous osmotic pump. Rats received either vehicle or atorvastatin (40 mg/kg/day) by gavage. H&E liver specimens were blindly scored by an expert pathologist. The degree of hepatic inflammation, oxidative stress as well as the expression of genes involved in the hepatic wound healing response to injury were assessed by CD43 immunostaining, 4-HNE immunostaining and quantitative PCR, respectively. The effect of atorvastatin on Ang II-pathogenic effects were also assessed in cultured hepatic stellate cells (HSC), a major fibrogenic cell type. Cell proliferation (3H-thymidine incorporation), secretion of interleukin-8 (ELISA) and gene expression of procollagen a1(I) were studied cultured primary HSC. Ang II (10-8M) stimulated cell proliferation (3H-thymidine incorporation), secretion of interleukin-8 (ELISA) and gene expression of procollagen a1(I) and TGFβ1. All these effects were reduced in the presence of atorvastatin. In addition, atorvastatin reduced Ang II–induced procollagen a1(I) and TGFβ1 gene expression in the rat livers. These results were markedly blunted by atorvastatin attenuates the inflammatory and fibrogenic effects of Ang II in the liver. Therefore, statins could have beneficial effects in conditions characterized by hepatic inflammation and fibrogenesis.

T CELL DERIVED MEMBRANE MICROPARTICLES CONTAINING EMMPRIN INDUCE PROFIBROLYTIC ACTIVATION IN HEPATIC STELLATE CELLS
Yury Popov 1, Jessica Zaks 1, Franck Grall 2, Tawia Liebermann 2, Nezam H. Afdhal 1, Detlef Schuppan 1; 1Gastroenterology, Beth Israel Deaconess Medical Center, Boston, MA; 2Proteomics&Genomics, Beth Israel Deaconess Medical Center, Boston, MA

BACKGROUND: T cell interactions with hepatic stellate cells (HSC) may be a determinant of liver fibrosis progression. Microparticles (MP) are small membrane vesicles shed from various cell types during activation and apoptosis. In most chronic liver diseases, such as viral and autoimmune hepatitis, activated T cells are driving force of disease progression and their turnover is greatly increased at the sites of active tissue remodeling. Here we studied and analyzed the effect of T-cell derived MP on the profibrogenic activation of HSC. METHODS: MP were generated from Jurkat T cells subjected to apoptosis induction with staurosporine, and purified from cell-free supernatant by differential ultracentrifugation. Characterization and quantification of MP was done by electron microscopy FACS. MP proteins were analyzed by MALDI-TOF mass spectrometry. Human LX-2 HSC (gift of Dr. S.L. Friedman) were incubated with increasing numbers of MP for up to 36h. Profibrogenic and fibrolytic transcripts were quantified by quantitative RT-PCR. To study membrane interaction of MP with HSC, tracking experiments were performed using PKH26 fluorescent-labeled MP. RESULTS: Apoptosis induction in Jurkat cells lead to 7-9 fold increase of MP production compared to untreated cells. Electron microscopy revealed that preparations of MP contained round empty vesicles with a lipid bilayer and sizes between 50 and 700 nm. Incubation of freshly isolated MP with HSC greatly induced fibrolytic MMP-1 and 3 mRNA transcripts (3- and 30-fold, respectively), while profibrogenic TIMP-1 mRNA, was unchaged and procollagen a1(I) was moderately downregulated. Tracking experiments revealed rapid transfer of fluorescent label from MP to HSC membranes already after 30 min, being retained for at least 12h. MALDI-TOF mass spectrometry of purified MP revealed high levels of CD147/Emmprin/Basigin, an MMP inducer that is putatively responsible for the observed effects. CONCLUSIONS: 1. T cell derived MP potently induce fibrolytic activation of HSC; 2. This suggest a novel cytokine-independent mechanism of fibrogenesis modulation by activated/apoptotic T cells in chronic liver diseases. 3. EMMPRIN is a prime candidate to mediate the fibrolytic switch.

Background/Aim: We previously reported that celecoxib potentiates hepatic fibrosis in CCl4-treated rat. However, Hui et al. reported that celecoxib potentiates hepatic fibrosis in bile duct ligation (BDL)- and thioacetamide (TAA)-induced hepatic fibrosis models in rat. Methods: We used immortal human HSC established by functional expression of the telomerase catalytic subunit. We treated HSC with celecoxib (50 µg/ml) after infection of adenovirus expressing constitutively active Akt (Ad5myrAkt) or adenovirus expressing GFP (Ad5GFP). Hepatic fibrosis was induced in Wistar rats by BDL for 4 weeks or by peritoneal TAA injection for 5 weeks. Celecoxib (20mg/kg/day) was orally administered from the beginning of liver injuries. Untreated BDL- and TAA-rats served as controls. Extracellular matrix (ECM) was Trichrome stained and quantified by morphometry. Hydroxyproline content in liver tissue was measured. Expression of α-SMA was assessed by immunohistochemistry. Hepatic mRNA levels of COX2, α-SMA, TGF-β1, collagen α1(I) was quantified by real-time RT-PCR. Results: Celecoxib induces HSC apoptosis and inhibits Akt phosphorylation in HSC. Celecoxib-induced HSC apoptosis is significantly attenuated in HSC infected with Ad5myrAkt but not in those infected with Ad5GFP. AST, ALT, and alkaline phosphatase levels are decreased in celecoxib treated group in TAA-rats (p<0.01) but not in BDL-rats. Liver tissue morphometry after Trichrome staining shows that celecoxib decreases hepatic ECM deposition in both BDL-rats (BDL only vs. BDL-celecoxib 52.8% vs. 37.9%, p=0.035) and TAA-rats (TAA only vs. TAA-celecoxib 17.9% vs. 10.8%, p<0.001). Hepatic hydroxyproline content and α-SMA expression are significantly decreased by celecoxib in both BDL- and TAA-rats. In both BDL-rats and TAA-rats, COX2, α-SMA, TGF-β1, and collagen α1(I) mRNA is upregulated. Celecoxib treated rats shows significantly decreased mRNA expression of COX2, α-SMA, TGF-β1, and collagen α1(I) compared with untreated rats in both BDL- and TAA-induced hepatic fibrosis models. Conclusions: Celecoxib shows anti-fibrogenic effects in both BDL- and TAA-rats suggesting celecoxib as a potential anti-fibrotic agent for hepatic fibrosis. Celecoxib-induced inhibition of Akt activation in hepatic stellate cells at least partially contributes to the anti-fibrotic effect of celecoxib.

1081 CELECOXIB SHOWS ANTI-FIBROTIC EFFECT IN HEPATIC FIBROSIS MODELS IN RAT AND INDUCES APOPTOSIS OF HEPATIC STELLATE CELLS THROUGH INHIBITION OF AKT ACTIVATION

Yong-Han Paik1, KwanSik Lee1, SoHee Kang1, MoonYoung Kim1, JungIl Lee2, DaYoung Kim1, Sang Hoon Ahn1, KwangHyub Han1, ChaeYoon Chan1, YoungMyoung Moon2, David Brenner3; 1Internal Medicine, Yonsei University College of Medicine, Seoul, South Korea; 2Department of Gastroenterology and Hepatology, Yamaguchi University Graduate School of Medicine, Ube, Japan; 3Department of Gastroenterology and Hepatology, Yanbian University Hospital, Yanji, China

Objective: Nonalcoholic steatohepatitis (NASH) may develop into fibrosis, cirrhosis and hepatocellular carcinoma. The rennin-angiotensin system is related to liver fibrosis and hepatic stellate cells (HSCs) play an important role in the liver fibrogenesis. Telmisartan, an angiotensin II type 1 receptor (AT1) antagonist, can function as an agonist of peroxisome proliferator-activated receptor γ. So we hypothesized that telmisartan could improve NASH-related fibrosis. Materials and Methods: The effect of telmisartan was studied by in vivo and in vitro. In vivo, HSCs were isolated from rat liver, and the cells were treated with telmisartan at the dose of 0 to 25µM. Using Western blotting, we checked HSC activation marker of α-SMA and how HSCs express AT1 and ANG II. Using real-time PCR, we determined fibrotic gene expression. In vitro, we used choline-deficient L-amino acid–defined diet induced rat liver fibrotic model, which is an established model of NASH. The total study periods were 10 weeks. The rats were treated with telmisartan at the dose of 0, 0.5, 1.0 and 2.5mg/kg body weight/day. The liver fibrosis index was measured by Azan and Sirius red stain and immunohistochemistry of α-SMA. The liver tissue expression of fibrotic gene and the serum biochemical marker were also determined. Furthermore, the preneoplastic lesion of placental glutathione S-transferase (GST-P) positive lesions was analyzed. Results: In vitro, telmisartan inhibited HSCs expression of α-SMA and decreased the mRNA expression of type 1 procollagen and TIMP-1, 2 in a dose-dependent manner. HSCs expressed AT1 and ANG II and the expression increased as the cells undergoing activation. In BrdU incorporation assay, we found telmisartan blocked ANG II induced HSCs proliferation. In vivo, telmisartan (0.5, 1.0 and 2.5mg/kg) treated rats showed decreased extracellular matrix accumulation by 25%, 41% and 65% of control (p<0.01 respectively); simultaneously, telmisartan reduced the area of α-SMA positive cells by 27%, 35% and 49% of the control (p<0.01 respectively). The development of GST-P-positive preneoplastic lesions in each group revealed in area as (125.1±42.9, 87.0±21.3, 58.8±20.4, 45.9±17.4 µm²/section) and the number as (4±3.0, 2±1.8, 2±1±1.4, 0.8±0.6/section), which were showed significant reduced by telmisartan (p<0.01 respectively). The mRNA expression of type 1 procollagen and the serum hyaluronic acid, total bile acid were significantly decreased by telmisartan. Conclusions: Telmisartan prevented liver fibrosis and attenuated enzyme-altered preneoplastic lesions in NASH related liver fibrosis via inhibition of HSCs activation. Telmisartan will be a candidate drug for NASH patients.

1083 Natriuretic peptide improved liver fibrosis in rat model using new treatment system

Naoki Yamamoto, Noriko Ishigaki, Haiyan Jin, Kouchi Uchida, Shuji Terai, Isao Sakaida; Department of Gastroenterology and Hepatology, Yamaguchi University Graduate School of Medicine, Ube, Japan

[Aim/Background]: The natriuretic peptide (NP) are used as the acute heart failure treatment in clinical and it is reported that the suppression of fibrosis in the heart and the lung recently. In this study, we made the in vivo model that can estimate the effect of new drugs on liver fibrosis by new injection system using 24 hour continuous infusion pump system. Using the in vivo model, we checked the effect of atrial natriuretic peptide (ANP) or C-type natriuretic peptide (CNP) on liver fibrosis. [Methods]: Wistar rats were injected with dimethyltinrosamine (DMN) twice a week via interperitoneal (i.p.) for 4 weeks to make the liver fibrosis. Fibrotic rats were assigned to three groups (each group n=6): DMN only, DMN+ANP (1.0 µg/kg/min), DMN+CNP (1.0 µg/kg/min). Each group was given by continuous intravenous dosage system used 24 hour infusion pump for 3 weeks after 1 week of DMN administration. The liver fibrosis index was measured by H-E, Azan, Sirius Red staining. The state of hepatic stellate cell was analyzed by α-SMA staining. Laboratory data was also analyzed. Collagen type 1, TIMP-1, TIMP-2 and MMP2 mRNA expression was analyzed by real time RT-PCR system. [Results]: The NP treated groups showed decrease of serum AST (mean value: ANP 81.8 vs CNP 95.4 vs Control 2000 IU/l P<0.01) ALT (mean value: ANP 63.8 vs CNP 44.8 vs Control 2000 IU/l P<0.01). Liver fibrosis was suppressed by ANP group or CNP group more than control group in both Azan and Sirius Red Stain (P<0.01). In Western blot analysis, ANP or CNP group inhibited α-SMA expression (P<0.01). ANP or CNP also significantly inhibited Type 1 procollagen, TIMP-1, TIMP-2, MMP9 and MMP2 mRNA expression (all of P<0.01). [Conclusion]: The natriuretic peptide (NP) inhibited liver fibrosis in our in vivo model. The NP will be a candidate drug for liver cirrhosis patients.

1084 Transient elastography (FibroScan®) in patients with chronic hepatitis C virus infection and haemophilia A

Frank Grünhage1, Johannes Oldenburg2, Georg Goldmann2, Natasha Vidovic1, Jan-Christian Wasmuth1, Tilman Sauerbruch1, Frank Lammert1; 1Department of Internal Medicine I, University Hospital Bonn, Bonn, Germany; 2Institute of Pathology, University of Erlangen, Erlangen, Germany

Introduction: In patients with bleeding disorders and chronic hepatitis C virus (HCV) infection liver biopsy for assessment of fibrosis stage is generally avoided because of potential hazardous complications, high costs, and low patients' acceptance. Thus, non-invasive methods for fibrosis staging are warranted. Methods and patients: We recruited 83 patients with chronic HCV infection and haemophilia A (HCV-A) and 297 HCV patients without haemophilia A (HCV-wo); a significant proportion of patients was co-infected with HIV (40% and 12%, respectively). In addition, we included 29 HCV patients and sustained virological response to interferon therapy (HCV-SVR). We determined serum surrogate markers for fibrosis (AST/platelets ratio index [APRI], Forns index) and performed transient elastography (FibroScan®) in all patients, and recorded histological stages of liver fibrosis if available. Correlation of serum markers and liver stiffness was tested using Pearson’s correlation coefficient and linear regression analysis. Results: In the HCV-wo group, histological stages of liver fibrosis show a highly significant linear correlation with all non-invasive fibrosis tests (transient elastography, APRI and Forns index (n=88; p<0.001). HCV-A patients display more advanced liver fibrosis, as indicated by differences in liver stiffness (15.4 vs. 11.4 kPa; p=0.011) and Forns index (8.98 vs. 8.27; p<0.05), albeit there are younger than HCV-wo patients (42 vs. 55 yrs; p<0.001). In HCV-A patients, elastography results correlate with serum markers tests (p<0.001), but this correlation is not present in HCV-A patients with pronounced fibrosis in elastography (> 12.5 kPa). Of note, responders to interferon therapy display lower liver stiffness than non-responders or naive patients (7.2 vs. 14.0 kPa; p<0.001; 7.2 vs. 10.9 kPa; p<0.01), whereas Forns index and APRI show no differences. Conclusions: Despite younger age, haemophilic patients present with more advanced fibrosis, most likely due to coinfection with HIV. Responders to interferon therapy show lower liver stiffness than patients with ongoing HCV infection. We conclude that transient elastography and serum surrogate markers help to identify haemophilic patients at risk for rapid progression of fibrosis. Moreover, transient elastography might be useful for monitoring regression of fibrosis after resolution of HCV infection.

1085 Inhibition of angiogenesis by a vitronectin receptor antagonist worsens liver fibrosis

Eleonora Patsenker1, Yury Popov2, Felix Stickel1, Gerald Niedobitek2, Detlef Schuppan2; 1Clinical Pharmacology, University of Bern, Bern, Switzerland; 2Gastroenterology, Beth Israel Deaconess Medical Center, Boston, MA; 3Institute of Pathology, University of Erlangen, Erlangen, Germany

Background and aims: Hepatic fibrogenesis is dependent on neoangiogenesis. However, the impact and role of angiogenesis in liver fibrosis progression are ill defined. The vitronectin receptor (integrin alpha V beta 3) is central to angiogenesis by mediating migration, proliferation and tubulogenesis of endothelial cells, but also drives fibrogenic activation of hepatic stellate cells (Xu et al, JBC 2004; Patsenker et al, J Hepatol 2007). We therefore studied the effect of alphaVbeta3 inhibition in models of liver fibrosis in vivo. Methods: Liver fibrosis in rats was induced by bile duct ligation (BDL) for 6 weeks or by i.p. thioacetamide (TAA) for 12 weeks. The alphaVbeta3 inhibitor EMD121974 (cilengitide) was given i.p. twice daily at 15 mg/kg from week 2-6 after BDL and for 8 weeks after discontinuation of TAA. Liver collagen was determined as hydroxyproline content, and fibrosis related gene expression was measured by quantitative RT-PCR. Angiogenesis was assessed by immunostaining with CD31 antibody and vessel counting using a point counting technique. Results: Treatment of both BDL and TAA fibrotic rats with cilengitide resulted in a further significant increase of hepatic collagen accumulation by 30%, upregulation of profibrogenic gene expression, and was accompanied by an increase of GGT and bilirubin (4.7- and 1.3-fold vs. untreated fibrotic controls, respectively) in rats with BDL, while liver enzymes and bilirubin remained unchanged in TAA-treated rats that received cilengitide. In both fibrosis mod-
HYPERDYNAMIC CIRCULATION IN INFANTS WITH BILARY ATRESIA AND PORTAL HYPERTENSION

Ronen Arnon1,2, Shubhika Srivastava1, Michael Fahey1, Nanda Kerkar1,2, Benjamin L. Shneider1; 1Pediatrics, Mount Sinai, New York, NY; 2RMTI, Mount Sinai, New York, NY; 3Division of Gastroenterology, Children’s Hospital Pittsburgh, Pittsburgh, PA

The hyperdynamic circulation (HC) is a well described phenomenon in adults with cirrhosis, yet it has not been carefully examined in children. Infants with biliary atresia (BA) often develop cirrhosis and prominent portal hypertension (PH) with its complications, ascites and variceal bleeding. Goal: To evaluate the presence of HC in infants with BA and PH. Methods: Chart review of patients < 1 year with BA and PH that underwent pretransplant cardiac evaluation between 1/1994 to 12/2006. PH was defined by: 1. presence of endoscopic evidence of esophageal / gastric varices, or 2. Splenomegaly or ascites by clinical examination and/or imaging, and radiologic evidence of esophageal /gastric varices or hypersplenism. Evaluation included vital signs and echocardiographic assessment including measurement of left ventricular systolic and diastolic dimensions, septal and posterior wall thickness, quantification of shortening fraction, detailed diastolic function assessment (mitral valve inflow Doppler) and assessment of longitudinal function (Doppler Tissue, DTI), derived indices of both systolic and diastolic function. Patients with congenital heart disease or receiving medications that can affect HR or BP were excluded. Twice as many healthy aged matched infants that underwent cardiac evaluation served as controls. Results: 9 patients (5M) mean age 7±1.8 months and 18 controls (12M) mean age 6.52±2.2 months (p=0.76) were included. 8/9 patients underwent prior portoenterostomy; 7/9 had one or more episodes of variceal bleeding. Mean Hb level at echocardiography was 10 ±1.5 gr/dl. There was no statistical difference in the HR, Pulse Pressure (Table 1) and DTI parameters between the groups. Shortening fraction, systolic and diastolic BP were significantly higher in infants with BA.

Conclusion: Circulatory differences were observed in infants with biliary atresia and PH. Resting heart rate is relatively unchanged and blood pressure is increased. The hyperdynamic circulation is instead manifest by evidence of increased contractility. These novel findings have important implications for the management of portal hypertension in young children.

ADAPTIVE CHANGES OF HEPATOCYTE TRANSPORTERS AND NUCLEAR RECEPTORS IN PEDIATRIC PATIENTS WITH EARLY AND LATE-STAGE CHOLESTASIS

Huey-Ling Chen1, Yu-Jung Liu1, Hui-Ling Chen2, Yan-Hsuan Ni1, Shan-Shin Wu1, Ming-Chih Ho1, Hong-Yuan Hsu1, Mei-Hwei Chang1; 1Pediatrics, National Taiwan University Hospital, Taipei, Taiwan; 2Hepatitis Research Center, National Taiwan University Hospital, Taipei, Taiwan; 3Surgery, National Taiwan University Hospital, Taipei, Taiwan

The adaptive changes of hepatocyte transport proteins and nuclear receptors during obstructive cholestasis in humans are important yet remain unclear. To investigate the early-stage and late-stage adaptive responses, we investigated liver samples from children with chronic obstructive liver disease, including patients with biliary atresia during Kasai operation (n=8, 64+/−17 days), and patients who progressed to late-stage cholestasis underwent orthotopic liver transplantation (n=8, 10.50+/−3.12 months). Expression levels of the sinusoidal and canalicular transporters, nuclear receptors, and CYP enzymes were analyzed by real-time RT-PCR and immunofluorescent staining in comparison to age-matched pediatric controls and neonatal intrahepatic cholestasis. At early-stage cholestasis, most canalicular transporters and sinusoidal uptake transporters were down-regulated, including BSEP, MDR3, MR2P, NTCP, and OATPβ; except that OStα/β were up-regulated. At late-stage obstructive cholestasis, BSEP returned to normal, MDR3 and MDR1 were up-regulated, and sinusoidal exporter OStα/β and MRP4 were up-regulated. FXR was down-regulated at early-stage cholestasis, returned toward normal levels at late-stage cholestasis, and the expression level of PXR was decreased profoundly in late-stage obstructive cholestasis, while SHP and CAR were unchanged. Immunofluorescent staining showed unchanged BSEP, increased MDR3, MDR1, and decreased MR2P signals well-targeted to the canalicular membrane at late-stage obstructive cholestasis, with higher expressions in zone 1 and 2 than zone 3. The expression levels of multiple genes were directly related to FXR levels, confirming FXR as the main regulator of bile acid transport. In conclusion, different adaptive changes occurred in early-stage and late-stage cholestasis in human. FXR-BSEP remained unchanged at late-stage cholestasis to maintain bile acid homeostasis. PXR was markedly down-regulated at the progress of late-stage obstructive cholestasis, and could be a potential target for therapy.

THE ROLE OF ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY IN DIAGNOSIS OF BILIARY ATRESIA IN INFANTS
Naresh P. Shanmugam, P. Harrison, J. Devlin, N. Kumaran, Mark Davenport, Dino Hadzic; Paediatric Liver Unit, King's College Hospital, London, United Kingdom

Aim: To investigate role and safety of endoscopic retrograde cholangiopancreatography (ERCP) in diagnosing biliary atresia (BA) in infants with prolonged conjugated jaundice, where standard clinical work up including laboratory tests, ultrasound and liver biopsy have failed to produce a definite diagnosis. Patients and Methods: We retrospectively analysed our database for infants younger than 100 days who underwent ERCP for diagnosis of BA from June 1997 to May 2007. Results: Amongst 2079 infants investigated for prolonged jaundice, 224 (10.7%) was diagnosed with BA over the observation period. ERCP was performed in 48 (2.3%) infants (24 male; median age: 58.5 days, range 19 – 98 days; median weight: 4 kg, range, 2.07- 5.3 kg). All infants had acholic stools, including 3 with associated alpha-1-antitrypsin PiZZ deficiency and 2 with bile salt export pump deficiency (PFC-2). Forty-seven infants had liver biopsy, while the remaining one had haemophilia C. Liver histology showed non-specific cholestasis (n=18, 38%), giant cell hepatitis (n=12, 26%), large bile duct obstruction (n=10, 21%) and mixed cholestatic and hepatic features (n=7, 15%). Cannulation of papilla was unsuccessful in 3 (6.25%) infants. These three infants were eventually diagnosed with BA on laparotomy. Of the remaining 45 children, ERCP demonstrated intrahepatic biliary tree in 20 (42%), while 25 (52%) proceeded to laparotomy. Of those, BA was confirmed macroscopically and histologically in 22 (46%). Three remaining infants who underwent explorative laparotomy, but not Kasai portoenterostomy had CMV hepatitis, neonatal sclerosing cholangitis, 1 (5%) Caroli disease and 9 (45%) normal biliary tree. After ERCP 3 infants (6.25%) had obstruction (n=10, 21%) and mixed cholestatic and hepatic features (n=7, 15%). Cannulation of papilla was unsuccessful in 3 (6.25%) infants. These three infants were eventually diagnosed with BA on laparotomy. Of the remaining 45 children, ERCP demonstrated intrahepatic biliary tree in 20 (42%), while 25 (52%) proceeded to laparotomy. Of those, BA was confirmed macroscopically and histologically in 22 (46%). Three remaining infants who underwent explorative laparotomy, but not Kasai portoenterostomy had CMV hepatitis, neonatal cholestasis and right and left hepatic duct hypoplasia. Amongst the 20 children in whom ERCP ruled out BA, 10 (50%) had neonatal sclerosing cholangitis, 1 (5%) Caroli disease and 9 (45%) normal biliary tree. After ERCP 3 infants (6.25%) had slight intraabdominal extravasation of the contrast, but none had clinical pancreatitis or perforation. Conclusion: ERCP is a safe procedure for diagnosing BA even in small infants with the positive predictive value of 88% and negative predictive value of 100%. In specialized centres this procedure could prevent unnecessary laparotomy in majority of infants with ambiguous clinical findings.

parison. Using phylogenetic tree construction and direct sequence comparison, we analyzed the distinct features of HBV genomes from children with HCC. [Results]: Phylogenetic analysis indicated that the majority (71.4%) of HB from children with HCC contained recombinant sequences of both genotypes B and C and clustered in two very closely related clades that were clearly distinguishable from HBV genomes of patients (children and adults) with chronic HBV infection and adults with HCC. Sequence analysis identified a consensus 12-bp pre-S2 deletion in 57.1% of HBV genomes of children with HCC. Other characteristic mutations were also found throughout HBV genome. [Conclusion]: The majority of full-length sequences of HBV isolated from children with HCC belonged to recombinant strains of genotype B and C, which are clearly distinguishable from HBV genomes of patients with chronic HBV infection and adults with HCC. Those HBV strains from HCC children contained unique mutations, particularly a short pre-S2 deletion, which may be associated with early HCC development.

INTRAFAMILIAL TRANSMISSION OF HEPATITIS C VIRUS IN CHILDREN: CORRELATION WITH ViroLOGICAL AND IMMUNOLOGICAL PARAMETERS
Sanan M. Kamal1,2, Samer El Kamary3,4, Michelle Shardell3, Mohamed Hashem3,4, Iman Fathy2,3, Gihan Galal3, Maha Sobhi5,2, Amany Ibrahim2, Ahmed Ismail2, Ahmed Hassan3,4, Amal Abdel Baky6, Hoda Mansour4,5,6,7, Liver Disease Center, Ain Shams University, Cairo, Egypt; 2Liver Disease Center, Harvard Institutes of Medicine, Boston, MA; 3Liver Disease Center, Ain Shams University, Cairo, Egypt; 4Pediatrics, University of Maryland, Baltimore, MD; 5Liver Diseases, DIAGSERA, Cairo, Egypt; 6Preventive and International Medicine, University of Maryland, Baltimore, MD; 7Liver Diseases, DIAGSERA, Cairo, Egypt

Background: Intrafamilial transmission of hepatitis C virus (HCV) infection has been reported, however the extent of its role and the factors associated with it are poorly understood. Objectives: To determine risk factors of transmission in children potentially exposed to HCV when one or both parents are infected. Patients and Methods: We examined 20 families (total of 93 subjects: 40 adults, 53 children) where one or both parents were HCV infected. Children living with infected parent/s were enrolled, a questionnaire inquiring about HCV risk factors was completed, and serum was screened for HCV antibodies (ELISA). Positive samples were confirmed by polymerase chain reaction and tested for genotype, HCV RNA viral load, HVR1 sequence analysis (nucleotide positions 1156 to 1234), HCV-specific CD4+ and cytotoxic CD8+ T cell responses (ELSpot), natural killer cells, and cytokines. Generalized linear mixed effects models were used to analyze the data to account for correlation between children from the same family. Results: Fifteen children (28%) were HCV infected and none had risk factors other than contact with the infected parent/s. Boys were more likely to be infected than girls (Odds Ratio (OR)=2.3; 95% confidence interval (CI): 0.6, 8.3; p = 0.23). Genotype and nucleotide sequencing of the HVR1 region of HCV isolates infecting parents and children had > 95% homology. When both parents were HCV infected, 43% of children were infected compared to 9% when one parent was infected (OR = 8.0; 95% CI: 1.6, 40.6; p = 0.012). Among families with only one infected parent, children of infected mothers had 9.5 times greater odds of being infected than children of infected fathers (95% CI: 0.4, 217, p = 0.16). Although older parental age and higher maternal HCV viral load were associated with higher odds of child infection, only higher paternal viral load was significant (OR=1.02 per 10,000 copies, 95%CI:1.001, 1.04, p = 0.039). Those delivered vaginally had 2.5 higher odds of infection than those delivered via Cesarean section (95% CI: 0.3, 23.1, p = 0.41). Interestingly, 74% of children with no detectable viremia had HCV-specific CD4 + or CD8+ T cell responses of > 30 SFC x 106 (95% CI: 49%, 90%). Conclusion: Our data show that biparental HCV infection and high paternal HCV RNA levels were significantly associated with intrafamilial pediatric HCV infection. The observation that HCV-specific CD4+ and CD8+T-cell responses exist in HCV negative children may imply a protective potential for these responses and might have important implications for vaccine development and epidemiologic studies.

Schwarz13; 1Gastroenterology, Hepatology, & Nutrition, CHOP, Philadelphia, PA; 2Gastroenterology, Cincinnati Children’s Hospital Medical Center, Cincinnati, OH; 3Gastroenterology, Maryland Medical Research Institute, Baltimore, MD; 4Gastroenterology, University of Florida, Gainesville, FL; 5Gastroenterology, Children’s Hospital Boston, Boston, MA; 6Surgery, New York Presbyterian-New York Hospital/Columbia, New York, NY; 7Gastroenterology & Nutrition, George Washington University, Washington D.C., DC; 8Gastroenterology, Indiana University Medical School, Indianapolis, IN; 9Gastroenterology, Children’s Hospital & Regional Medical Center, Seattle, WA; 10Gastroenterology, Hepatology, & Nutrition, The Children’s Hospital Denver, Denver, CO; 11NIDDK, NIH, Bethesda, MD; 12Gastroenterology, UCSF Children’s Hospital, San Francisco, CA; 13Gastroenterology, Johns Hopkins University School of Medicine, Baltimore, MD; 14Pathology, Armed Forces Institute of Pathology, Washington D.C., DC

Background: Auto-antibodies are described frequently in adults with chronic HCV, with thyroid antibodies present in 14% and autoimmune hepatitis antibodies in up to 90%. These antibodies have prevented some adults from undergoing or successfully completing treatment with interferon. Although children with HCV generally tolerate treatment better than adults and have a higher response rate, little is known about the frequency with which autoantibodies are present. Understanding this baseline feature may be important in developing recommendations for treatment of pediatric patients with chronic HCV. Aim: Our aim was to assess the incidence and describe the correlates of positive antibodies, thyroid peroxidase (TPO), anti-nuclear antibody (ANA), anti-smooth muscle antibody (ASMA) and anti-Liver Kidney Microsomal antibody (LKM) in treatment naive children (ages 5 to 18 years) with chronic HCV. Methods: From 12/2004 to 6/2006, 128 children were screened at entry to the multi-center, NIH funded Peds-C Network clinical trial. Labs were determined centrally and a single pathologist scored all biopsy slides. Assays for ANA, ASMA, ALKM, and TPO were measured at baseline. Results: Subjects had a mean age of 11.2 years (56% male), 77% had vertically acquired HCV, 15% unknown, 7% transfusion, less than 1% drug or sex. 82% were Caucasian, 6% African American, 9% Hispanic,
4% Asian. Genotype 1a was present in 60%, 1a/1b in 1%, 1b in 22%. Genotype 2a in 5%, 2b in 1%, Genotype 3b in 10%, Genotype 6a in 1%. Mean ALT was 60.2 U/L. Liver histology demonstrated moderate inflammation in 38%/severe in 3%. Moderate fibrosis 5% / cirrhosis 2%. Of the 128 children screened, 18 (14%) had measurable auto-antibodies - 44% were ASMA positive (range 1:80-1:160), 33% ANA positive (range 1:80-1:320), 17% LKM positive (range 33.9-65.2 units, ULN20.1), and 6% TPO positive (108.8 IU/ml ULN2.1 IU/ml). Using Chi square and Fisher’s, no significant correlates of antibody positivity were found with age, gender, race/ethnicity, ALT, mode of acquisition, genotype, degree of liver fibrosis or inflammation scores. A trend toward older age was found for ANA positivity, with the three oldest patients having the highest titer (ages 15, 16 and 17 yr. ANA 1:320). Conclusion: This study demonstrates less frequent TPO, LKM, ASMA and ANA positivity in children with Chronic HCV compared to adults. We speculate that these autoantibodies may be of importance in the side-effect profile and treatment response in children treated with antivirals.

1093 TREATMENT OF HEPATITIS B USING INTRON A VS PEGINTERFERON IN COMBINATION WITH LAMIVUDINE IN CHILDREN

Patricia A. Harren, Kara Ventura, Mercedes Martinez, Dominique Jan, Robert S. Brown, Steven J. Labritto; The Center for Liver Disease and Transplantation, New York Presbyterian Medical Center, New York, NY

Aim: To assess the safety, tolerability and efficacy of 2 combination therapy regimens using interferon (IFN) and lamivudine (LAM) to treat E antigen (Ag) positive pediatric hepatitis B (HBV) infected patients. Methods: 34 patients (age 2-16 years) at a single center were assessed over a 5 years. Baseline labs included liver profile (LFT), complete blood count (CBC), thyroid function test (TFT), HBV E Ag, HBV E antibody (Ab) and HBV DNA quantitative PCR. All patients had a liver biopsy with the intent to treat to grade and stage disease. Exclusion criteria included HIV co-infection, stage 4 disease, severe thrombocytopenia, thyroid disease, uncontrolled depression and history of non-compliance. Two treatment regimens were used. Group A: 16/34 patients received Intron A, 5 million unit/m2 SQ daily (max dose 10 million units) for 5 months with LAM (staggered by one month) 4mg/kg/day orally (max dose 100mg) until E Ag seroconversion or resistance. Group B: 6/34 patients received Peginterferon Alfa 2b (Peg-IFN), 1.5mcg/kg/week for 24 weeks with LAM as above. Monthly assessments included vital signs, weights, LFT, CBC, TFT, HBV DNA, HBV E Ag, and HBV E Ab. Results: Twenty-four males and 10 females were assessed. Liver biopsies demonstrated Stage 0-3, Grade 0-3 disease. Group A demographics: 4 Asian, 2 Hispanic, 6 African American, 4 Caucasian with vertically transmitted disease in 13/16. At screening all had HBV DNA > 200 million copies, 6/16 had normal LFT. On therapy 15/16 had undetectable HBV DNA with 8/16 achieving E Ag seroconversion at mean of 44 weeks (range 22-69). Safety data: none developed thyroid dysfunction, 2/16 patients had neutropenia (1 treated with IFN dose reduction, 1 treated with Neupogen), 1 patient required an antidepressant, 1 patient stopped IFN due to seizure, and 2/16 required nutritional supplements for weight loss. One subject developed LAM resistance. Group B demographics: 3 Asian, 2 Hispanic, 1 African American all with vertical transmission. At screening all had HBV DNA > 200 million copies and normal LFT. No patient cleared DNA on therapy and no patient achieved E Ag seroconversion. Two of 6 required nutritional supplements for weight loss and no other adverse effects occurred. Conclusions: Combination therapy with IFN and LAM in a staggered manner is safe and effective in pediatric patients with chronic HBV infection. Combination therapy with Peg-IFN and LAM at the dosing assessed is not equally efficacious and should not be used in pediatric patients until further clarification of dosage and frequency.

1094 HBEAG SEROCONVERSION CORRELATES WITH A HIGH NUMBER OF CORE GENE MUTATIONS AND WITH GENOTYPES B AND D IN PAEDIATRIC PATIENTS

Ivana Carey, Maria Mytilinaiou, Antonietta Giannattasio, Sanjay Bansal, Paul Cheeseman, Dita Cebecauerova, Giorgina Mieli-Vergani, Diego Vergani; Institute of Liver Studies, King’s College London School of Medicine at King’s College Hospital, London, United Kingdom

Background: The outcome of hepatitis B virus (HBV) infection results from the interaction between virus and host immune response. While effective immune recognition usually controls viral replication, escape mutations may arise from the immune system selective pressure, with consequent persistent infection. Aim: To investigate whether there is a relationship between presence of mutations within HBV core gene, HBV genotypes, HBV DNA viral load and HBeAg seroconversion in five different HBV infection settings. Patients: One hundred paediatric patients (median age 13.1 years, 54 males) were divided into 5 groups according to their HBeAg/HBsAg status and amino-transferases activity (Table 1). Methods: HBV DNA was isolated from serum samples. The presence of point mutations within HBV pre-core and core promoter regions and amino acid substitutions within immunodominant epitopes of HBV core gene was analysed by direct sequencing (mutations/patient). HBV genotypes were determined by direct sequencing. HBV DNA viral load was quantified by real-time PCR (log10 copies/ml). Results: A higher number of mutations within the HBV pre-core region and HBV core gene was detected in HBeAg negative patients than in those HBeAg positive (pre-core: 4.5 ± 0.2 vs. 2.6 ± 0.2, p = 0.001 and core: 5.5 ± 0.4 vs. 4.1 ± 0.3, p = 0.04). Genotypes B and D were more prevalent in HBeAg negative children than in those HBeAg positive (80% vs. 58%, p < 0.001). HBV-DNA viral load was significantly higher in groups A (mean ± SEM, 7.9 ± 0.2), B (6.8 ± 0.3), and D (7.5 ± 1.2) compared to C (3.4 ± 0.3) and E (1.0 ± 0.4) (p = 0.001). Among HBeAg negative children, those with genotypes B and D had a higher number of pre-core mutations and tended to have a lower number of core mutations than those with genotypes A, C and E (pre-core: 5.5 ± 0.4 vs. 4.1 ± 0.2, p = 0.04; 4.7 ± 0.3 vs. 5.7 ± 0.3, p = 0.1, respectively). Conclusions: Irrespective of genotype, emergence of HBV core gene mutations is associated with HBeAg seroconversion. In patients with genotypes B and D, that more frequently lose HBeAg, seroconversion is associated also to a high number of pre-core mutations. To what extent these mutations result from the selective pressure of the immune system or are virally determined remains to be clarified.
1095 GRAFT HISTOLOGY UP TO 10 YEARS AFTER PEDIATRIC LIVER TRANSPLANTATION: HIGH INCIDENCE OF SEVERE FIBROSIS, CORRELATED WITH TRANSPLANT RELATED FACTORS

Rene Scheenstra1, Paul M. Peeters2, Henkjan J. Verkade1, Anette S. Gouw2; 1Pediatrie Gastroenterology, University Medical Center Groningen, Groningen, Netherlands; 2Hepatobiliary Surgery, University Medical Center Groningen, Groningen, Netherlands; 3Pathology, University Medical Center Groningen, Groningen, Netherlands

Introduction: Previously we showed that 31% of liver grafts have portal fibrosis at 1 year after pediatric liver transplantation (LTx; Transplantation 2000; 6:236). The presence of fibrosis correlated positively with transplant related factors, including cold ischemia time (CIT) and biliary complications. Aim of the study: To assess progress and development of fibrosis in liver grafts in the long term after pediatric LTx and to identify possible risk factors. Methods: We reviewed protocol biopsies obtained at 5 and 10 yrs after LTx from the originally included 77 patients/grafts. We analyzed the relationships between histology and parameters of transplantation and follow up. Severity of fibrosis was evaluated using a three point scale: 0 = no fibrosis, 1 = portal fibrosis without bridging (mild fibrosis), 2 = portal fibrosis with occasional bridging (moderate fibrosis), 3 = diffuse portal bridging (severe fibrosis/cirrhosis). Results: At 5 and 10 yrs after LTx, 66/77 (85%) and 55/77 (71%) biopsies were available, resp. Missing biopsies at 10 yrs included 77 deaths and 6 retransplants. Between 1 yr and 5 yrs after LTx, the prevalence of fibrosis increased from 31% to 67%, but remained stable thereafter (10 yrs: 65%). However, the percentage of patients with severe fibrosis continued to increase, from 10% (5 yrs) to 27% (10 yrs). The presence of fibrosis at 1 yr tended to correlate with re-transplantation (p=0.054). The incidence of severe fibrosis after 10 yrs was significantly higher in patients who had fibrosis at 1 yr after LTx, compared with those without fibrosis at 1 yr (p= 0.004). At 5 years, ASAT and yGT values were significantly higher in patients with fibrosis than in those without fibrosis (ALAT 23 ± 13 vs. 36 ± 28 U/l; GGT 30 ± 52 vs. 112 ± 149 U/l; resp., each p<0.05). At 10 yrs after LTx, corresponding values were not significantly different. Sixty four percent (64%) of patients without fibrosis at 1 yr after LTx had developed some degree of fibrosis at 10 yrs (25/39). The development of fibrosis starting after 1 yr was strongly related to CIT, donor/recipient ratio and type of preservation fluid (these factors were also strongly interrelated). The CIT of the grafts that developed late fibrosis was longer than that of grafts without fibrosis at 10 yr (11.4 ± 3.9 h vs. 7.2 ± 3.8 h; p = 0.004). Conclusion: At 5 and 10 yrs after pediatric LTx, the majority of grafts have fibrosis in protocol biopsies. At least 25% of the grafts, fibrosis progresses to cirrhosis in 10 yrs after pediatric LTx. Even fibrosis that only develops after the first year post LTx is strongly correlated with transplant related factors.

1096 IMPROVED PREDICTIVE VALUE OF PELD WITH THE ADDITION OF SERUM SODIUM AND PLATELET COUNT

Tassos Grammatikopoulos1, Rachel M. Taylor1, Juan Gonzalez2, Nora Donaldson2, Anil Dhawan1; 1Paediatric Liver Centre, King’s College London School of Medicine at King’s College Hospital NHS Foundation Trust, London, United Kingdom; 2Biostatistics Unit, King’s College London Dental Institute, London, United Kingdom

Aim: To re-evaluate the prognostic value of the Paediatric End-stage Liver Disease (PELD) score with the inclusion of parameters that indicate portal hypertension reflecting on platelet count (Plt), aspartate aminotransferase (AST) to Platelet Ratio Index (APRI), spleen size and haemodynamic decompensation [serum sodium (Na)] at listing and at time of transplantation (LT). Methods: Medical records of 85 patients (38 male) with biliary atresia waiting for liver transplantation from 2001-2006, were reviewed retrospectively. 3 patients died and 5 patients were admitted in PICU requiring ventilation prior to transplantation. Median age at transplantation was 1 year [range, 0.39-13]. PELD score and above mentioned parameters were recorded at the time of listing and at the time immediately before liver transplantation. A multivariate and a univariate Cox regression analysis were performed for the endpoints death/PICU admission whilst on the list. Three models were evaluated for their predictive power for both endpoints. The area under the receiver operating characteristic curve (AUC ROC) was used to compare models. Results: The median time between listing and LT was 84 [range, 13-682] days. The median PELD score at the time of listing was 15 [range, –10 to 36], which significantly increased to 17 [range, –5 to 42] just before LT (p<0.001). At the time of listing the median values were for sodium 136mmol/L [range, 128-144], for platelet count 16×10^12/L [range, 29-577], and for APRI 2.7 [range, 0-27.84]. Paired statistics between existing PELD and our variables did not improve its prediction of endpoints. In a multivariate Cox regression models PELD+Plt, PELD+Na and PELD+Plt+Na (King’s PELD) all variables had a significant association (P<0.7). The regression coefficients of predictors were used as multiplicative factors to calculate the new severity scores. A univariate logistic regression analysis for death was performed (King’s PELD: odds ratio 2.72, 95% CI 1.01-7.32; p 0.05). The ROC analysis that was done to the King’s PELD showed that the best cut-off point to dichotomise was 48.84 to predict death (odds ratio 6.73, 95%CI 1.63-27.84; p 0.01). The new scoring system is: -0.42*Age(<1yr)-0.55*Sbili+2.34*INR-1.78*Alb+0.46*Growth+0.47*Plt+11.09*Na The median King’s PELD at the time of listing was 48 [range, 46-50] and prior to transplantation was 46 [range, 44-48]. Conclusions: The PELD does not reflect the severity of disease in our cohort. The new King’s PELD is a better predictor of endpoints on the waiting list. Further prospective analysis is in progress.

PEDIATRIC LIVER RETRANSPRANTATION: OUTCOMES AND A PROGNOSTIC SCORING TOOL

Adam R. Davis1, Philip Rosenthal1, David Glidden2; 1Pediatrics, UCSF, San Francisco, CA; 2Epidemiology and Biostatistics, UCSF, San Francisco, CA

Approximately 15% of all pediatric transplant recipients require retransplantation. No multi-centered study has evaluated the outcome of retransplantation or the predictors of transplant-free survival in children. Aim: To evaluate the outcome of liver retransplantation in children at multiple centers and develop a simple prognostic scoring system. Methods: Retrospective cohort study using the United Network for Organ Sharing (UNOS) transplantation database of patients who were ≤20 years of age when they received their primary transplant and who underwent at least one retransplantation (N=1,408). Using a random 2/3 of the subjects, we developed a prognostic scoring system by performing a multivariate Cox analysis using primary diagnostic category, reason for graft failure, age and whether the patient was on life support at the time of transplant as predictors. The scoring system was verified in the remaining 1/3 of the subjects. Results: Stratifying the verification group into terciles by prognostic score demonstrated its predictive value. Those in the low-risk category had similar survival to primary transplant recipients. Those in the high-risk category had 5.7 (95% CI: 4.0 – 8.0) times the risk of death or retransplantation as those in the low risk category (Figure 1). Discussion: This scoring system could assist practitioners in providing anticipatory guidance to families on expectations after retransplantation. Current donor allotment in pediatrics functions on an urgency basis, however directing liver donations towards those with better expected outcomes may bring higher utility from a limited resource. This tool could assist in developing an outcomes based allotment system.

LIPID-ENRICHED DIET INDUCES GROWTH RETARDATION AND LIVER STEATOSIS IN CYSTIC FIBROSIS MICE

Charles-Henry Cottart1, Elise Bonvin2, Colette Rey1, Dominique Wendam3, Jean-François Bernaudin4, Sylvie Dumont2, E. Lasnier3, Dominique Debray1, Annick Clément3, Chantal Housset1, Monique Bonora2; 1UMR_S 680, Inserm, Université Pierre et Marie Curie - Paris 6, Paris, France; 2UMR_S 719, Inserm, Université Pierre et Marie Curie - Paris 6, Paris, France; 3Anatomie Pathologique, AP-HP Hôpital Saint-Antoine, Paris, France; 4EA3499, Université Pierre et Marie Curie - Paris 6, Faculté de Médecine, Paris, France; 5Biochimie, AP-HP Hôpital Saint-Antoine, Paris, France

Background: There is evidence to indicate that, in cystic fibrosis (CF), the nutritional status influences lung and liver injury, which currently represent the two main causes of death in this disease. To better define the impact of nutrition in CF disease, we herein compared the phenotypic traits of CF mice fed either a liquid diet (Peptamen) or a standard chow together with a PolyEthylenGlycol (PEG) osmotic laxative, two strategies commonly used to prevent intestinal obstruction in CF mice. Peptamen, a diet designed to feed infants or young children who suffer malnutrition, contains more lipids than standard chow (3.7 vs 1.6 g/100 Kcal) and mostly medium-chain fatty acids (more than 95%), whereas standard chow contains predominantly long-chain fatty acids (70%). Methods: Male CF mice with a complete exon-10 knockout of the CFTR gene (CFtrtm1Unc) (n = 56) and their normal littermates (n = 35) were randomly assigned at weaning, to standard chow, standard chow with PEG or Peptamen. Survival, growth, liver and ventilatory status assessed by whole-body plethysmography, were determined in these animals, followed-up until 120 days. Results: The survival rate of CFtr-/- mice was similar in the groups under Peptamen feeding and PEG treatment (77% and 73%, respectively, after 60 days). At weaning, CFtr-/- mice were significantly smaller than normal littermates. While PEG did not affect growth in CFtr+/+ mice, Peptamen regimen caused growth delay in both CFtr-/- and CFtr+/+ mice during the pre-adult period (30-60 days). Growth catch-up occurred thereafter, but CFtr-/- mice remained smaller than CFtr+/+ mice, whatever the diet. Hepatomegaly was observed at 120 days in Peptamen fed CFtr-/- mice, liver/body weight ratio being significantly higher in this group than in all other groups. Liver steatosis was detected in all animals of this group and exceeded 10% in half of them. By comparison, steatosis exceeding 10% was detected in 1 out of 5 Peptamen fed CFtr+/+ animals and in no PEG-treated CFtr-/- animals. No bile duct lesion was observed. Minute ventilation was significantly lower in CFtr-/- mice than in CFtr+/+ mice, without any difference between Peptamen-fed and PEG-treated animals. Conclusions: These results provide evidence that CFTR genetic defect may cause growth retardation, hypoventilation, and predisposition to liver steatosis, the most common hepatic lesion in CF patients. They indicate that growth delay and steatosis in this setting, are influenced by regimen and are paradoxically aggravated by a lipid-enriched diet, designed for malnutrition (whereas bile duct lesions are likely to be influenced by genetic factors).

1099
CAN INSULIN-LIKE GROWTH FACTOR BINDING PROTEIN-1 (IGFBP-1) IDENTIFY OVERWEIGHT CHILDREN AT RISK OF DEVELOPING STEATOHEPATITIS?
Carlos E. Martinelli1, Alexandra C. Moura-Ribeiro1, Paula C. Bezzan1, Jorge Elias2, Ana L. Martinelli2; 1Pediatrics, School of Medicine of Ribeirão Preto, University of São Paulo, Ribeirão Preto, Brazil; 2Medicine, School of Medicine of Ribeirão Preto, University of São Paulo, Ribeirão Preto, Brazil

The prevalence of obesity in children and the high morbidity associated with metabolic syndrome emphasizes the importance of the early diagnosis of insulin resistance (IR). IR has been considered the main derangement in nonalcoholic fatty liver disease and steatohepatitis (NASH). NASH can progress to severe liver fibrosis. Recent data implicate hepatic IR as a culprit in accumulation of free fatty acids as triglycerides in hepatocytes. Markers of hepatic IR in children are lacking. Insulin is the main inhibitor of the hepatic production of IGFBP-1; this prompted us to study IGFBP-1 as an early marker of hepatic IR in overweight children. Oral glucose tolerance test was performed in 34 children and adolescents with BMI≥85th percentile and the insulin sensitivity index (ISI) was calculated. Glucose (G), insulin (I) and IGFBP-1 were measured in fasting serum samples. In order to characterize children at risk for IR a clinical-laboratory index (CLI) was calculated considering the following risk factors: BMI≥3 SDS, acanthosis nigricans, positive family history of IR, insulin levels≥20 μU/l, HOMA-R≥2 and G:I ratio<7. Considering CLI≥3 (3 or more risk factors) as a criterion to define IR, ISI<4.6 showed 87.5% of sensitivity and 94.5% of specificity in diagnosing IR. Based on this ISI value, patients were further classified as IR (ISI<4.6, n=15) and non-IR (ISI≥4.6, n=19). Fasting IGFBP-1 was lower in IR (median: 17 μg/l) than in non-IR (43 μg/l) group (P<0.01) and IGFBP-1<26 μg/l was observed in 11/15 (73%) IR but in only 5/19 (26%) non-IR patients (P<0.01). Four patients with IR had IGFBP-1>26 μg/l suggesting impairment of insulin action at hepatic level. In conclusion, ISI<4.6 seems to be a good indicator of peripheral IR in overweight children and adolescents, while IGFBP-1 determination may contribute to diagnose hepatic-IR among children and adolescents with peripheral IR and in this way identify those patients with higher risk of developing more severe liver injury.

PREDICTORS FOR SEVERE COURSE OF CYSTIC FIBROSIS-RELATED LIVER DISEASE IN CHILDREN
Nynke Doornebal, Frank Bodewes, HenkJan J. Verkade; Pediatrics, University Medical Centre Groningen, Groningen, Netherlands

Cystic Fibrosis (CF) is associated with a specific form of liver disease in some patients. Cystic fibrosis-related liver disease (CFLD) is usually characterized by a relatively benign clinical course. A minority of CF patients, however, develop cirrhosis and portal hypertension. Currently, we cannot predict which CF patients develop a severe form of CFLD. We set out to determine which clinical, biochemical and ultrasound parameters were associated with the development of a severe course of CFLD in a cohort of CF patients. METHODS: We reviewed the clinical charts, including ultrasound and biochemical results, of all pediatric CF patients born between 1988 and 2006 seen in our institution. Severe CFLD was defined as multilobular cirrhosis on ultrasound and/or signs of portal hypertension (splenomegaly, varices). Patient characteristics, clinical details and ultrasound findings were recorded. RESULTS: Sixty-three children with CF were included. Multilobular cirrhosis and/or portal hypertension were found in 8 children (12.7%). The mean age at which severe CFLD was diagnosed was 7.8 years (range 3-12 years). No apparent biochemical or ultrasound abnormality was present one year before severe CFLD was diagnosed in 4 of the 8 children (50%). At 1 year before diagnosis, growth retardation (height < -2SD) and elevated γ-glutamyltransferase (γ-GT two times or more > 50 U/l in successive controls) were significantly associated with severe CFLD (p=0.045 and 0.011 respectively). No other biochemical serum parameters [alkaline phosphatase, ASAT, ALAT, bilirubin, bile acids], nor gender, history of meconium ileus, distal intestinal obstruction syndrome or neonatal cholestasis, were associated with the development of severe CFLD. Similarly, hepatomegaly, diffuse inhomogeneous parenchyma or increased hepatic echogenicity on ultrasound were not associated with a severe course of CFLD. CONCLUSIONS: In our retrospective cohort of 63 pediatric CF patients, 13% developed CFLD with multilobular cirrhosis and/or portal hypertension. At 1 year before the diagnosis of severe CFLD, growth retardation and elevated γ-GT levels were associated with subsequent development of severe CFLD. Ultrasound findings or biochemical parameters did not predict the development of severe CFLD. Half of the patients did not have any biochemical or liver ultrasound abnormality at 1 year before the diagnosis of severe CFLD.

PATTERN OF DIAGNOSTIC EVALUATION FOR THE CAUSES OF PEDIATRIC ACUTE LIVER FAILURE (PALF): OPPORTUNITIES FOR QUALITY IMPROVEMENT
Michael Narkewicz1, Dominic Dell Olio2, Saul J. Karpen3, Susan Krug5, Karen F. Murray4, Kathleen B. Schwarz5, Nada Yazigi6, Song Zhang2, Steven H. Belle2, For the Pediatric Acute Liver Failure Study Group2; 1Pediatrics, University of Colorado at Denver Health Sciences Center, Denver, CO; 2Pediatrics, University of Pittsburgh, Pittsburgh, PA; 3Biostatistics, University of Pittsburgh, Pittsburgh, PA; 4Pediatrics, University of Washington, Seattle, WA; 5Pediatrics, Baylor College of Medicine, Houston, TX; 6University of Birmingham, Birmingham, United Kingdom; 7Pediatrics, Cincinnati Children's Hospital, Cincinnati, OH; 8Pediatrics, Johns Hopkins University, Baltimore, MD

PALF is a rare disease that leads to liver transplantation or death in up to 50% of affected children. We hypothesized that there would be variability in the diagnostic evaluation of PALF that might suggest opportunities for improved diagnosis of causes of PALF. Thus, the goal of this study is to describe the frequency of specific diagnostic evaluations for the common causes of PALF in the PALF Study Group Database of 611 patients to clarify current practice. Methods: PALF was defined as severe liver dysfunction occurring within 8 weeks of onset of illness, with no known underlying chronic liver disease in patients from birth through 17 years of age. Patients with coagulopathy corrected with Vitamin K are not included in the study. The database was queried for the diagnostic evaluation for the most common causes of PALF which, outside of indeterminates (48.4% of the cohort) were drug exposure including acetaminophen (16.2% of the cohort), metabolic disease (12.3% of the cohort), autoimmune hepatitis (5.9% of the cohort), infections (5.2% of the cohort). We examined the frequency of screening for these etiologies in patients labeled as indeterminate as final diagnosis by the investigator and clinical team. Of the 296 subjects cate-
orized as indeterminate, 48 were less than 6 months old. The number screened for the four most common etiologies are shown in the table. Of the 296 subjects categorized as indeterminate, only 2% had a complete evaluation for the most common etiologies. Conclusions: Current practice indicates that screening methods are not standardized for drug, metabolic and autoimmune causes of PALF and hence are inconsistent in patients ultimately given a diagnosis of indeterminate ALF. This offers an opportunity to improve the diagnosis and potential treatment options in children with PALF.

1012 CLINICAL SIGNIFICANCE OF THE ABERNETHY MALFORMATIONS (CONGENITAL ABSENCE OR HYPOPLASIA OF THE PORTAL VEIN)

Matthew Y. Suh1, Humberto Azpurua2, Yoshihiro Kitano3, Heung B. Kim1, 1Surgery, Children's Hospital Boston, Boston, MA; 2Obstetrics and Gynecology, Yale New Haven Hospital, New Haven, CT; 3Surgery, Saitama Children's Medical Center, Saitama, Japan

PURPOSE/METHODS: Congenital absence of the portal vein (Abernethy I) and congenital hypoplasia of the portal vein (Abernethy II) have been collectively classified as one clinical entity, congenital extrahepatic portosystemic shunt (CEPS). Anecdotal differences between Abernethy I and Abernethy II malformations have been noted. However, aggregate data do not exist as these rare malformations have been reportedly sporadically in case reports or small series. We performed a systematic literature review to elucidate the difference between the two types of Abernethy malformations. RESULTS: 109 CEPS cases were identified (70 Abernethy I and 39 Abernethy II). There was a significant predisposition for developing hepatic tumors among Abernethy I cases (50% Abernethy I vs. 10% Abernethy II, p<0.0001). Malignant tumors were more common among Abernethy I cases (11% Abernethy I vs. 2.5% Abernethy II, p=0.15). Hepatic encephalopathy (HE) was less frequent in Abernethy I cases (14% Abernethy I vs. 36% Abernethy II, p=0.017); however, an additional 14% of Abernethy I cases reported subtle neurologic and developmental findings without HE (i.e. mild mental retardation, developmental delays and radiologically evident lesions in the brain). When hyperammonemia was present, 26% of Abernethy I cases reported HE, with an additional 26% reporting subtle neurologic and developmental findings. In contrast, 70% of Abernethy II cases with hyperammonemia reported HE (p=0.006). Four of 10 Abernethy I cases with HE (40%) reported treatment via liver transplantation with a success rate of 100%. Thirteen of 14 Abernethy II cases with HE (93%) reported treatment via shunt ligation or banding with a success rate of 92%. Hepatopulmonary syndrome (HPS), an uncommon complication of end stage liver disease, occurred in both types of Abernethy malformations without hepatic dysfunction (5.7% Abernethy I vs. 2.5% Abernethy II). Successful liver transplantation was reported in a single Abernethy I case. Shunt ligation was successful in another Abernethy II case. CONCLUSION: Abernethy I patients should be screened for development of hepatic tumors, given 11% prevalence of hepatic malignancy. Hyperammonemia was a stronger predictor of HE among Abernethy II cases than among Abernethy I cases. However, rigorous neurologic testing for Abernethy I patients with hyperammonemia may be warranted, given 26% prevalence of subtle neurologic and developmental findings without HE. In Abernethy I cases with refractory HE, liver transplantation may be considered. Shunt ligation or banding is recommended for such Abernethy I cases.

1103 SCLEROSING CHOLANGITIS IN CHILDREN-RETROSPECTIVE SINGLE CENTER REVIEW

Tamir Miloh1,2, Ronen Arnon1,2, Benjamin L. Schneider3, Frederick Suchy1, Nanda Kerkar1,2, 1Pediatrics, Mount Sinai Hospital, New York, NY; 2RMT, Mount Sinai Hospital, New York, NY; 3Division of Gastroenterology, Children's Hospital Pittsburgh, Pittsburgh, PA

Sclerosing Cholangitis (SC) is a rare progressive cholestatic disease in children with limited data on presentation and management in childhood. Charts of 47 patients younger than 21 years with cholangiography or histology proven SC, seen at Mount Sinai Hospital within the last 20 years were reviewed. 29 patients had both liver biopsy (Bx) and magnetic resonance cholangiopancreatography (MRCP), 8 also had endoscopic retrograde cholangiopancreatography (ERCP). 4 ERCP and Bx, 4 had only Bx and 2 patients only MRCP or ERCP. The mean age at diagnosis was 11 +/- 4.9 years (range 2-20 years), 62% were male. Signs and symptoms occurred in 91% with hepatomegaly, abdominal pain, diarrhea, fatigue and splenomegaly in decreasing prevalence. Inflammatory Bowel Disease (IBD) was found in 65% [Ulcerative Colitis, UC, 49% and Crohn's 16%], concurrent with SC in 59%, IBD first in 26% and SC first in the rest. Autoimmune hepatitis (overlap) occurred in 32% (16% with concurrent IBD). Peripheral anti-neutrophil cytoplasmic antibody was positive in 42% (50% of patients had IBD), anti smooth muscle antibody in 42%, anti-neutrophil cytoplasmic antibody was positive in 42% (50% of patients had IBD), anti smooth muscle antibody in 42%, anti-nuclear antibody in 26% and liver kidney microsomal antibody in none. Family history for autoimmune disease was found in 15%. In patients studied with MRCP, both extra and intrahepatic biliary disease were found in 40%, intrahepatic only in 14%, extrahepatic only in 10% and normal in 36%. Cholelithiasis was diagnosed in 12% and ERCP intervention (papillotomy, stent placement or balloon dilatation) was performed in 15%. Colonoscopy was performed in 60% of patients revealing pancolitis in 29%, rectal sparing in 29% and was normal in 18%. All patients were treated with ursodeoxycholic acid (UDCA), 9 patients with autoimmune overlap were treated with additional steroids and/or azathioprine, 2 patients were treated with methotrexate. Median pre/post-therapy laboratory values were gamma-glutamyl transpeptidase 317/42 U/L, alkaline phosphatase 566/193 U/L and alanine aminotransferase 143/41 U/L. Liver transplantation was performed in 8

ROLE OF LIVER HISTOLOGY IN THE MANAGEMENT OF ACUTE LIVER FAILURE IN CHILDREN
Jonathan M. Hind, Alberto Quaglia, Rachel Taylor, Anil Dhawan; Paediatric Liver Centre, King’s College Hospital, London, United Kingdom

Aim: The aetiology of acute liver failure (ALF) remains unknown in many children (46% in this series). Liver biopsy may be perceived to be a useful tool in diagnosis and management of ALF, though risks increase with multisystem disease and coagulopathy leading to the transjugular approach in some centres. The aim of this study was to evaluate the role of liver histology in the diagnosis and management of paediatric ALF. Methods: 211 children presented to a single paediatric hepatology centre from 1989-2004 with ALF (INR>2 unresponsive to vitamin K with abnormal liver enzymes). History slides were available in 111 children (57 male, median age 5.15 years, range 0-17.4). These were examined by a single histopathologist, blinded to clinical details. 53 samples were from biopsies (50 percutaneous, 2 open, 1 transjugular) taken during the course of ALF with blood product support (8), immediately after death (19), or at recovery (26). 58 samples were slides from explanted livers taken at transplantation. The histology findings were compared with the final clinical diagnosis. Results: The median interval between admission and biopsy was 15 days (range 1-298). History did not contribute to diagnosis in 46/53 (87%). 6 samples showed massive hepatic necrosis, 3 severe acute hepatitis, 16 non-specific. In 11, histological diagnoses were suggested but these differed from the final clinical diagnosis. In 7, histology confirmed the clinical diagnosis. In all of these cases the clinical diagnosis was made and management decided before biopsy was performed. In 3, histology findings were suggestive of chronic liver disease, possibly autoimmune hepatitis, but the clinical diagnosis was indeterminate. In 2 of these autoantibodies were negative, immunoglobulins normal, and they remain without treatment and with normal blood test results after 2 years follow-up. In the 3rd case the child died on day 1 of admission. In 7, histology performed median 32 (range 5-298) days from admission showed normal liver. In the explant group, histology did not contribute to diagnosis in 44/58 (76%). 39 samples showed massive hepatic necrosis, 2 non-specific. In 3, histological diagnoses were suggested but these differed from the final clinical diagnosis. In all of these cases the clinical diagnosis was made and treatment instituted before transplantation. Conclusion: In our experience, histopathology from liver biopsy in children with ALF did not add to management, nor did explant histology further identify any diagnoses.

1105
BUDD CHIARI SYNDROME IN CHILDREN: A SINGLE CENTRE EXPERIENCE IN THE UNITED KINGDOM
Roshni Vara1, Natalie J. Bab1, John Karani2, Gholam J. Mutti2, Nigel Heaton3, Giorgia Mieli-Vergani1, Anil Dhawan1; 1Paediatric Liver Centre, King’s College Hospital NHS Foundation Trust, London, United Kingdom; 2Haematology Department, King’s College Hospital NHS Foundation Trust, London, United Kingdom; 3Liver Transplantation, King’s College Hospital NHS Foundation Trust, London, United Kingdom; 4Radiology Department, King’s College Hospital NHS Foundation Trust, London, United Kingdom

Methods A retrospective review of 13 children diagnosed with Budd Chiari Syndrome (BCS) between 1982-2006. Data was collected to study the clinical presentation, aetiology, management and outcome. Results 13 children (6 male), median age (range) at presentation was 10.68 years (1.62-16.31 years). Presenting features included hepatosplenomegaly in 13, ascites in 11, jaundice in 7, lethargy in 7 and gastrointestinal bleeding in 2. Laboratory investigations showed median (range) INR 1.44 (1.03-6.00), bilirubin 25umol/L (5.185-158 umol/L), aspartate transaminase 53 iu/L (8-510 iu/L), albumin 40 (25-51), serum sodium 138mmol/L (121-146mmol/L), haemoglobin 11.0g/dl (7.2-13.8) and platelet count 242x109/L (29-373). Investigations included ultrason, CT and angiography, in addition detailed procoagulant studies were carried out as and when they became available. Procoagulant states were identified in 9; paroxysmal nocturnal haemoglobinuria (PNH) in 3, antiphospholipid syndrome in 2 and factor V Leiden heterozygosity and protein C deficiency (40 u/dl) in each. Ultrasound was diagnostic of BCS in 12 (92%) whilst CT identified the abnormality in 1 and liver biopsy and angiography in 1. Sites of occlusion were main hepatic veins in 5 (38%), main hepatic veins with partial inferior vena cava (IVC) occlusion in 3 (23%), small hepatic venules in 3 (23%) and IVC thrombosis in 2 (15%), co-existing portal vein thrombosis in 2. Liver biopsy showed features of venous outflow obstruction in 9, cirrhosis in 2 and fibrosis in 2. Acute management included diuretics, anti-coagulation, paracentesis and endoscopy. Definitive management included liver transplantation (LT) in 4; indications being acute liver failure in 2 and decompensated cirrhosis in 2. Surgical shunts in 4, percutaneous venous dilatation in 2 and transjugular intrahepatic portosystemic shunt in 1 of the patients with PNH, followed by matched unrelated bone marrow transplantation. 5 (36%) died, median age 9.85 years (range 6.09-14.98 years), causes of death were; multisystemic complications of PNH in 1, hepatopulmonary syndrome in 1. 3 patients died after LT (1 of septicemia 3 months after LT, 1 of multiorgan failure in the immediate post operative period and the other died of an unexplained neurologic event 3 years after LT). 8 patients are alive and well at their last follow up, median 2.53 years (range 0.66-6.57 years). Conclusions Procoagulant states are the commonest cause of BCS in children. The management and outcome of this rare condition continues to be heterogeneous and carries a high mortality.

Non-alcoholic Fatty Liver Disease (NAFLD) is known to be related to predictors of coronary heart disease (CHD) such as insulin resistance, dyslipidemia, central obesity, and metabolic syndrome (MS). Recently, several reports suggested a possible role of NAFLD in the development of CHD. However, correlation between NAFLD and CHD in the general population is not well established. The aim of this study was to determine whether subjects with NAFLD in a general large population have an elevated 10yr risk of CHD, as estimated using the Framingham risk score (FRS). 21130 subjects enrolled in general health examination were recruited. NAFLD was diagnosed by typical sonographic findings and < 20 gram/day alcohol consumption, based on questionnaire. The risk of cardiac events in 10 yrs was estimated using Framingham equation: the score was computed based on age, total cholesterol, HDL-cholesterol, blood pressure, diabetes status and smoking status. Class of FRS was defined: low risk ≤5%, mild risk >6<10%, intermediate risk 10<20%, high risk: ≥20%. 3289 out of 21130 (15%) subjects were excluded because they had known causes of liver disease (1690 alcoholic, 975 HBV, 242 HCV, 193 other hepatitis history) and history of heart disease (189). NAFLD was diagnosed in 5888 (27.9%) subjects. Other normal 11953 subjects were enrolled in control group. The severity of NAFLD was graded into three group by ultrasonographic findings; 0 normal [n=11953], grade [gr] 1 mild fatty liver [n=3356], grade 2 moderate-severe fatty liver [n=2532]. Univariate analyses revealed that severity of NAFLD related to age, BMI, waist circumference, HT, AST, ALT, Total cholesterol, triglyceride (TG), HDL-cholesterol, LDL-cholesterol, glucose, HbA1c, uric acid, and FRS class (p<0.05). Multivariate regression analyses with confounding factors showed strong association of higher FRS with the severity of NAFLD, both among men (age<50: gr 1 OR 1.35 95% CI 1.13-1.62, gr2 OR 1.66 95% CI 1.36-2.02; age>50 gr1 OR 1.19 95% CI 1.03-1.38, gr2 OR 1.48 95% CI 1.25-1.74, p<0.01) and women (age<50: gr1 OR 3.18 95% CI 1.23-8.21, gr2 6.14 95% CI 2.11-17.89; age>50: gr1 1.84 95% CI 1.53-2.22, gr2 2.38 95% CI 1.89-2.99, p<0.01). ALT threshold for increased risk of CHD (FRS >10%) was lower in women (>18.5 IU/L) than in men (>24.5 IU/L). NAFLD itself represents an important risk factor of CHD regardless of other metabolic syndrome components. Also, we found that ALT level for increased risk of CHD was much lower than normal range. These associations are more prominent in women

1108 INHERITED VARIANTS OF GENES INVOLVED IN INSULIN SIGNALING AFFECT THE RISK OF HEPATIC FIBROSIS IN NAFLD
Paola Dongiovanni, Luca Valenti, Raffaela Rametta, Anna Ludovica Fracanzani, Silvia Fargion; Internal Medicine, University of Milan, Ospedale Policlinico IRCCS, Milano, Italy

Background & Aims: Inherited factors play a major role in the pathogenesis of type 2 diabetes and the metabolic syndrome, whose hepatic expression is NAFLD, a leading cause of liver disease. Aim was to assess the role of well-characterized functional polymorphisms of genes involved in insulin signaling and lipogenesis on the risk of NAFLD progression to fibrosis. Patients and Methods: 235 pts with NAFLD, 150 with liver biopsy (57 with and 93 without fibrosis), and 135 controls. The Leu162Val PPARalpha, Pro12Ala PPARgamma2, Lys121Gln PC-1, Gly972Arg IRS-1, and Glu84Arg TRB3 polymorphisms were determined by restriction analysis. Data were compared by chi-square and t-Test, when appropriate. The risk of fibrosis was adjusted by logistic regression analysis considering as independent variables genetic polymorphisms, age, ALT, and ferritin levels. Results: By univariate analysis, the IRS-1 972Arg and the PPARalpha 162Val alleles, previously linked to insulin resistance, were associated with higher prevalence of diabetes/impaired glucose tolerance and higher HOMA insulin resistance index (p<0.05). The IRS-1 972Arg allele (prevalence 13% in NAFLD) was associated with higher prevalence of fibrosis in biopsied patients (55% in positive patients vs. 36% in negative ones; OR 2.5, 95% CI 0.99-7; p=0.06), whereas the gain of function 84Arg allele (prevalence 23% in NAFLD) of TRB3, which inhibits lipogenesis, was associated with lower fibrosis (28% in positive patients vs. 43% in negative ones; OR 0.39, 95% CI 0.15-0.95; p=0.04). Conclusions: Genetic factors affecting insulin signaling, which regulates metabolism and survival of hepatocytes, are associated with liver damage in NAFLD, thus supporting therapy with insulin sensitizing drugs. However, insulin resistance is not always associated with fibrosis, but the molecular mechanism and the genetic background may play a role.

1109 DAILY CANNABIS USE, A NOVEL RISK FACTOR OF STEATOSIS SEVERITY IN PATIENTS WITH CHRONIC HEPATITIS C
Christophe Hezode1,2, Elie-Serge Zafra2,3, Françoise Roudot-Thoraval1,2, Charlotte Costentin1, Ali Hessami1, Fatima Medkour1, Magali Bouvier-Alias4, Jean-Michel Pawlotsky4, Sophie Lotersztajn2, Ariane Mallat1,2; 1Hepatology, Hopital Henri Mondor, Paris XII University, Creteil, France; 2INSERM U841, Hopital Henri Mondor, Paris XII University, Creteil, France; 3Pathology, Hopital Henri Mondor, Paris XII University, Creteil, France; 4Virology, Hopital Henri Mondor, Creteil, France; 5Public Health, Hopital Henri Mondor, Paris XII University, Creteil, France

Cannabis Sativa binds two receptors CB1 and CB2. We recently reported a profibrogenic effect of CB1 receptors (Teixeira-Clerc, Nature Med 2006) and found a significant relationship between daily cannabis use and fibrosis severity in patients with chronic hepatitis C (CHC). Recent experimental evidence from others and our group indicates that both CB1 (Osei Hyaiman et al, J Clin Invest 2005) and CB2 receptors (Deveaux et al. AASLD 2007) promote liver steatogenesis. Therefore, the aim of this study was to evaluate the impact of cannabis use on steatosis severity in patients with CHC. 315 consecutive naïve patients were included. Several parameters were recorded at liver biopsy, including epidemiological data, intake of cannabis, alcohol, and maintenance treatment over the preceding semester, BMI, diabetes, serum fasting glucose, triglycerides and cholesterol levels, HCV genotype and viral load. Histology was assessed, without knowledge of clinical data, by two pathologists according to METAVIR (activity grade and fibrosis stage), and marked steatosis was defined as ≥30%. Patients (M/F: 223/92, mean age 45±11 yrs, 60 patients with steatosis ≥30%) were grouped according to cannabis smoking as none (200, 63.5%), occasional (<1 daily joint: 39, 12.4%, median/month =4) or daily users (≥1 daily joint: 76, 24.1%, median/month = 75). In unadjusted analysis, intake of cannabis, alcohol, and maintenance treatment significantly more frequent in daily cannabis users, compared to occasional and non users (p=0.03 and p=0.02, respectively). By logistic regression analysis, independent predictors of steatosis severity included daily cannabis use [OR: 2.1, [95%CI: 1.0-4.5], p=0.03], activity ≥A2 [OR: 2.1, [95%CI: 1.0-4.3], p=0.04], genotype 3 [OR: 5.4, [95%CI: 2.6-11.3], p=0.0001], hyperglycemia or diabetes [OR: 5.1, [95%CI: 1.8-15.0], p=0.003], BMI ≥27 [OR: 2.1, [95%CI: 1.0-4.3], p=0.05] and high viral load [OR: 1.7, [95%CI: 1.0-2.9], p=0.05]. Upon adjustment on viral genotype (3 vs non 3) or alcohol intake (< vs ≥30g/d), marked steatosis was significantly more frequent in daily cannabis users, compared to occasional and non users (p=0.03 and p=0.02, respectively). In summary, our study discloses a strong link between daily cannabis use and steatosis severity in patients with CHC, in keeping with the known steatogenic effect of CB1 receptors and with our recent experimental data indicating that CB2 also promotes steatogenesis. Our findings further indicate that patients with untreated CHC should be advised to refrain from daily cannabis use.

PIGMENT EPITHELIUM-DERIVED FACTOR (PEDF) REGULATES HEPATOCYTE LIPID CONTENT THROUGH ITS INTERACTION WITH ADIPOSE TRIGLYCERIDE LIPASE (ATGL)

Arijeet Gattu1, Christine Shugrue1,2, Susan Crawford3, Chuanhun Chung1,2, 1VA CT Medical Center, West Haven, CT; 2Yale University, New Haven, CT; 3Pathology, Northwestern University, Chicago, IL

Background: PEDF is a multifunctional protein with neurotrophic, antiangiogenic and anti-tumor activity. A recent report indicated that the receptor for PEDF is ATGL, a newly discovered lipase that mediates the first step in triglyceride (TG) breakdown. Our studies identify PEDF—ATGL binding in murine hepatocytes and HCC cell lines, and demonstrate that loss of PEDF leads to fat accumulation in the liver. Methods: Wildtype (WT) and PEDF null hepatocytes were isolated and used 24-48h after isolation. Immunoprecipitation (IP) of ATGL with recombinant PEDF (rPEDF) was done using WT and PEDF null hepatocytes, and HCC cell lines. Immunofluorescent colocalization of PEDF and ATGL was characterized. Qualitative and quantitative TG content was assessed with Oil Red O staining and enzymatic determination of lipid content. TG content was normalized per µg protein or body weight. A liver/body weight ratio was calculated for WT and PEDF null animals.

Results: ATGL from PEDF null hepatocyte lysates was preferentially bound by rPEDF compared to WT lysates suggesting tight native binding interactions. Immunoblotting of the post-IP supernatant showed that rPEDF binds the majority of ATGL in HCC lysates. Immunofluorescence showed PEDF and ATGL localization around adiposomes. TG content was significantly greater in PEDF null hepatocytes than WT, 141.3 ± 16.1 vs 74.7 ± 12.1 mg/dl/µg, (p<0.05). Restoration of rPEDF to PEDF null hepatocytes showed a trend toward decreased TG content from 141.3 ± 16.1 to 110.2 ± 5.7 mg/dl/µg (p=0.06) but not in WT hepatocytes, 74.7 ± 12.1 vs 61.4 ± 4.3 mg/dl/µg (p=NS). The TG content was similarly increased in PEDF null livers compared to WT. The liver/body weight ratio in PEDF null livers was significantly greater than WT livers (4.62 ± 0.11 vs 4.09 ± 0.08, p<0.001). Sections of PEDF null livers showed increased cell proliferation compared to WT.

Conclusion: PEDF regulates hepatocyte lipid content through its interaction with ATGL.

ALCOHOL CONSUMPTION IN SEVERELY OBESE PATIENTS WITH NONALCOHOLIC FATTY LIVER DISEASE: RELATIONSHIP WITH HEPATIC FIBROSIS

Helma P. Cotrim1, Alessandro Almeida1, Erivaldo Alves1, Daniel May1, Antonio Ricardo Ferraz2, Stephen H. Caldwell3, Luiz Antonio Freitas1, 1Medicine, Universidade Federal da Bahia, Salvador, Brazil; 2CPqGM - FIOCRUZ - BAHIA, Salvador, Brazil; 3Virginia University, Charlottesville, VA

Background: Moderate alcohol consumption has been associated with improved insulin activity, a lower prevalence of type II diabetes and a favorable vascular risk in severely obese. This study aimed to examine the association between light-to-moderate alcohol consumption and severity of nonalcoholic fatty liver disease (NAFLD) in the obese patient. Method: A cross-sectional study was performed in severely obese subjects, who underwent liver biopsy during bariatric surgery from October 2004 to April 2005. The patients were classified into 3 groups according to alcohol consumption: G1: alcohol intake > 20g/day and < 40g/day; G2: alcohol intake= 20g/day; G3: no alcohol intake. Alcohol consumption was determined by clinical interviews and questionnaire. Insulin resistance (IR) was calculated by homeostasis model assessment (HOMA). IR was considered when HOMA was > 3. Biopsies were scored and classified as isolated steatosis (Type I); steatosis + inflammation (Type II); steatohepatitis (steatosis, ballooning of hepatocytes and inflammation) (Type III); and steatohepatitis with fibrosis and cirrhosis (Type IV). The study was approved by the Ethics Committee for Medical Research (CPqGM - FIOCRUZ, Bahia).

Results: There were 132 subjects (83 female and 49 male) mean age 37.27 +/- 11.06 (18 to 65) years with a body mass index of 43.9 +/- 5.6 kg/m². G1, G2 and G3 included 19, 56 and 57 patients respectively. Histological diagnoses by levels of alcohol consumption were: G1 (moderate alcohol): 2 (10.5%) had normal liver and 89.5% (17) had NAFLD, Type III or IV, G2 (light alcohol): 6 (10.7%) had normal liver and 1.8% (1) had Type 1 or 2 and 87.5% (49) had Type III or IV of NAFLD, and G3 (no alcohol intake): 6 (10.5%) had normal liver, 3.5% (2) had Type 1 or 2 and 86% (49) had Type III or IV. One of these had cirrhosis. IR was evaluated in 102 patients. It was correlated with moderate and no alcohol intake in 81.3% and 78.7% cases respectively (p<0.05). In patients with light alcohol intake 54.8% did not present IR. Conclusions: Light-to-moderate alcohol consumption was not associated with the severity of NAFLD in obese patients. Steatohepatitis with fibrosis had a similar prevalence in patients with or without history of alcohol intake. However, light alcohol intake may protect the severely obese patients from insulin resistance. Dissociation of the effect on IR versus liver histology is consistent with a complex and as yet incompletely understood interaction between alcohol and obesity-related liver disease.

ARTERIALIZATION OF CENTRAL ZONES IN NONALCOHOLIC STEATOHEPATITIS (NASH)

Linda D. Ferrell1, Patricia Belt2, Nathan M. Bass3, Clinical Research Network for the Nash1; 1Pathology, Univ of California San Francisco, San Francisco, CA; 2NASH Clinical Research Network, Johns Hopkins Center for Clinical Trials, Baltimore, MD; 3Medicine, Univ of California San Francisco, San Francisco, CA

Background. Injury with fibrosis in the central zone (CZ) is a typical diagnostic feature of NASH. We have reported small arteries within CZ scars in alcoholic steatohepatitis, and noted in this setting that the arteries appear to extend from portal areas to CZ in serial sections. Since that study, we have anecdotally also noted arterial ingrowth into the CZ in NASH, a finding that in either entity can lead to mistaken identification of a scarred CZ as a portal tract (and in particular, a portal tract with ductopenia), and so results in errors in the pathologic diagnosis. This study examines for the presence of these arteries in NASH and at what stage they are noted. Methods. 100 biopsies (BX) of NASH with fibrosis stage > 1a from the NASH Clinical Research Network participants from Feb 2005 through Aug 2006 were randomly selected for evaluation of H&E and trichrome stains. Parameters examined included: prevalence of arteries graded as 0 (none), 1 (1-2/BX), 2 (<50% of CZs), 3 (>50% of CZs) and ductular metaplasia in CZ as + or -. The NASH activity score (NAS), stage of fibrosis, and size of liver needle BX determined by central review were obtained from the database. All BXs reviewed had at least 5 CZ and were deemed adequate by central review. Results. Arteries were present in 40/100 (40% of cases), determined as rare in 18%, and common (grade 2-3) in 22% (See Table). The arterIALIZATION of CZs was increased in the higher stage lesions (68%, or 29/47 cases in stage 3-4) as compared to stage 1-2 (21%, or 11/53 cases), with increased prevalence correlating directly with higher stage. Ductular metaplasia was a common associated finding (53%, or 22/40 cases with arteries). Conclusions. Arteries in the scarred CZ of NASH are a common finding in late stage disease, but can rarely be seen in this location as early as stage 1b. Such arteries are likely due to the remodeling of the vascular architecture as scarring progresses in NASH. The presence of this aberrant artery, particularly in samples with ductular metaplasia in the same scarred CZ, can lead to the erroneous determination of the CZ as a portal tract, and thus result in failure to diagnose NASH by a pathologist who may not be aware of this finding. (Supported by Research-Grant DK61738 from the NIDDK.)

MODERATE LIQUOR CONSUMPTION IS ASSOCIATED WITH A DECREASED PREVALENCE OF SUSPECTED NONALCOHOLIC FATTY LIVER DISEASE

Winston Dunn1, Ronghui Xu2, Jeffrey Schwimmer3; 1Medicine, UCSD, San Diego, CA; 2Pediatrics, UCSD, San Diego, CA; 3Mathematics, UCSD, San Diego, CA

Background: Moderate liquor consumption has been shown to protect against coronary heart disease (CHD). Subjects at risk for coronary heart disease (CHD) are often at risk for nonalcoholic fatty liver disease (NAFLD). The effect of modest wine consumption on NAFLD has not been studied and the recommendation of wine for patients at risk for both diseases is controversial. Despite the potential for liver injury, wine has been shown to ameliorate metabolic risk factors common to NAFLD and CHD. Therefore the aim of this study is to test the hypothesis that modest wine consumption is associated with decreased prevalence of NAFLD. Methods: We included subjects in the Third National Health and Nutrition Examination Survey who either reported no alcohol consumption or preferentially drinking wine with total alcohol consumption up to 10g per day. Suspected NAFLD was based on unexplained ALT elevation over two sets of cut points: the cut point of the reference laboratory (ALT > 43) and the cut point based on the 95th percentile of healthy subjects (ALT > 30 for men, ALT > 19 for women). Alternate explanations of abnormal ALT were excluded (excessive alcohol, viral hepatitis, iron overload, and medications). Multivariate analysis adjusted for age, gender, race, neighborhood population density, income, education, caffeine intake and physical activity level. Result: 7211 non-drinkers and 945 modest wine drinkers comprised the study sample. Based on the reference laboratory cut point, suspected NAFLD was observed in 3.2% of nondrinkers and 0.4% of modest wine drinkers. The adjusted odds ratio was 0.13 (95% CI 0.05 – 0.37). Using the healthy subject cut point, suspected NAFLD was observed in 14.3% of nondrinkers and 8.6% of wine drinkers. The adjusted odds ratio was 0.48 (95% CI 0.31 – 0.74). Conclusion: Modest wine consumption is associated with reduced prevalence of abnormal ALT from sus-

1115 ANALYSIS OF HEPATIC EXPRESSION OF GENES INVOLVED IN LIPID AND IRON METABOLISM IN NON-ALCOHOLIC FATTY LIVER DISEASE

Hironori Mitsuyoshi, Kohichirou Yasui, Yuiichi Harano, Yoshito Itoh, Takeshi Okanoue
Kyoto Prefectural University of Medicine, Kyoto, Japan; Akashi City Hospital, Akashi, Japan; Sai-seikai Suisa Hospital, Suisa, Japan

Aims: Oxidative stress is considered critical in the development of nonalcoholic fatty liver disease (NAFLD). Hepatic steatosis results in reactive oxygen species (ROS) generation through oxidation of fatty acid and/or iron overload, thereby progressing to steatohepatitis. Although the important molecules involved in these metabolisms are well defined, their roles in the natural course of disease remain unknown. Therefore, we investigated hepatic genes involved in oxidation and synthesis of fatty acid and iron accumulation in patients with NAFLD. Methods: Liver biopsies were undertaken in 74 consecutive patients with NAFLD (simple steatosis / steatohepatitis: 33 / 41). Histological staging followed that of Brunt. Hepatic levels of thioredoxin (Trx), a ROS-inducible antioxidant, were used as markers of oxidative stress. The following genes were quantified from biopsy specimens using real-time PCR and normalized by β-actin: Trx, peroxisome proliferators-activated receptor-α (PPARα), acyl-CoA dehydrogenase C4-12 (ACADM), cytochrome P450 2E1 (CYP2E1), acyl-CoA oxidase (ACOX), sterol regulatory element binding proteins-1c (SREBP1c), fatty acid synthase (FASN), transferrin receptors 1 and 2 (TFR1 and TFR2), and hepcidin (HAMP). Twelve normal livers were used as controls. Results: Hepatic levels of Trx were significantly higher in livers of patients with NAFLD than in normal livers (p < 0.0001). The level of Trx increased as the stage progressed (p = 0.074) and significantly correlated with that of PPARα, ACADM, CYP2E1, and ACOX (p < 0.0001, each). However, the levels of fatty acid-oxidizing genes significantly decreased at the later stage of NAFLD (p < 0.05, each). In parallel with these findings, the levels of SREBP1c (p < 0.05), FASN, and steatosis similarly decreased. On the other hand, hepatic iron score (HIS) tended to correlate with stage (p = 0.095). The levels of TFR1, TFR2, and HAMP were significantly higher in NAFLD patients than in normal livers, and they significantly correlated with those of Trx (p < 0.0001, each). The level of TFR1 significantly correlated with stage (p = 0.05), whereas the level of TFR2 significantly correlated with that of PPARα (p < 0.0001). The level of HAMP significantly correlated with HIS (0.01) as well as serum levels of ferritin (p < 0.001). Conclusion: Our results indicated that 1) although oxidation of fatty acid exacerbates oxidative stress in NAFLD, these effects attenuate as the disease progresses, 2) TFR1 and TFR2 may continue hepatic accumulation of iron, despite hepatic synthesis of HAMP in response to iron load, 3) upregulation of TFR2 may possibly be associated with PPARα.

1116 NON-INVASIVE DIAGNOSTIC BIOMARKERS FOR NON-ALCOHOLIC STEATOHEPATITIS (NASH)

Ancha Baranova, Mohammed Jarrar, Clare Nugent, Arian Afendy, Caitlin Quigley, Maria Stepanova, Hazem Elariny, Zachary Goodman, Vikas Chandhoke, Zobair M. Younossi

From the spectrum of non-alcoholic fatty liver disease (NAFLD), only patients with NASH have been shown to progress to cirrhosis. To date, liver biopsy remains the gold standard for diagnosis of NASH. Liver biopsy is expensive and is associated with a small but definite risk. There is an urgent need for the development of non-invasive diagnostic biomarkers for NASH. Recent data suggest the role of apoptosis, hepatocyte necrosis as well as adipocytokines in the pathogenesis of NASH. AIM: To develop a non-invasive diagnostic biomarker panel which could reliably distinguish NASH from simple steatosis (SS). METHODS: 69 patients with a liver biopsy were included (22 patients with NASH, 15 with SS and 32 weight-matched controls with normal liver biopsies). Liver biopsies were interpreted by a single hepatopathologist. NASH was defined as steatosis, lobular inflammation, ballooning degeneration with or without Mallory bodies and/or fibrosis. Clinical data and serum samples were collected at the time of biopsy. Serum was assayed for adiponectin, resistin, insulin, glucose, TNF-alpha, IL-6, IL-8, total CK18 (M65, a measurement of overall cell death due to both apoptosis and necrosis) and caspase cleaved CK18 (M30, a specific measurement of apoptosis). RESULTS: In the entire cohort, M30 apoptosis measurements correlated with levels of TNF-alpha (R = 0.4986, p < 0.0001) and IL-8 (R = 0.3052, p = 0.0108), but not with IL-6, visfatin, resistin, adiponectin, or HOMA. An indirect measurement of necrosis, M65-M30, did not correlate with any of the parameters measured. In NASH patients (N = 37), M30 apoptosis measurements correlated with the Homeostasis Model Assessment (HOMA) (R = 0.5106, p = 0.0013), TNF-alpha (R = 0.4816, p = 0.003), and IL-8 (R = 0.3052, p = 0.015). These findings further support the role of insulin resistance and pro-inflammatory cytokines in NASH. In the entire cohort, histologic NASH could be reliably predicted by a combination of M30 (apoptosis), M65-M30 (necrosis), serum adiponectin and serum resistin (Model p-value = 0.0001; AUC = 0.908, Sensitivity = 0.773, Specificity = 0.872). Use of M30 (apoptosis) as a sole predictor of NASH was a less reliable diagnostic biomarker (Model p-value = 0.000089; AUC = 0.710, Sensitivity = 0.636, Specificity = 0.872). CONCLUSIONS: A combination of ELISA-based measurements of apoptosis and necrosis markers as well as adipocytokines could be used to develop a simple diagnostic biomarker panel for NASH. If validated, this biomarker could become very useful in the clinical management of patients with NAFLD.

Effect of Pentoxifylline on Clinical, Biochemical, and Metabolic Parameters, Hepatic Necroinflammation, Fibrosis and Stellate Cell Activation in Patients with Nonalcoholic Steatohepatitis

Deepak K. Singh1, Puja Sakhija1, Archana Rastogi1, Ajay Kumar2, Ranjana Gondal1, Shiv K. Sarin2

Pentoxifylline inhibits proinflammatory cytokines including TNF-α and may be antifibrogenic. TNF-α may cause hepatic necroinflammation, fibrosis and impaired insulin sensitivity in patients with nonalcoholic steatohepatitis (NASH). Inhibition of TNF-α by Pentoxifylline may be an important therapeutic strategy in NASH. AIM: To study the effect of Pentoxifylline on clinical, biochemical and metabolic parameters, hepatic necroinflammation, fibrosis and stellate cell activation in patients with NASH. METHODS: Nineteen patients included in the study were given Pentoxifylline 1200mg/day. All baseline clinical and lab data was recorded. A pre-therapy liver biopsy was done in all cases. Histologic features, necroinflammatory grade and fibrosis stage on liver biopsy were scored as per Brunt et al (1999). All the patients tolerated the drug well. After one year, a repeat liver biopsy was done. All the pre and post therapy clinical and lab data was compared. To accurately assess changes in hepatic fibrosis, immunostaining with anti-α-SMA was done in paired liver biopsies and hepatic stellate cell index (HSCI) was calculated. RESULTS: Mean age of patients was 35±8.8 yrs. After 12 mo. of therapy there was a significant reduction in BMI (25.3±1.9 vs 23.1±2.2, p=0.000), AST (70.3±25.5 IU/mL vs 27.9±6.3 IU/mL, p=0.000), ALT (108.6±50.3 IU/mL vs 35.8±14.5 IU/mL, p=0.000), serum insulin levels (13.5±7.4 IU/mL vs 7.9±2.9 IU/mL, p=0.000) and insulin resistance (HOMA-IR) (3.6±1.9 vs 1.9±0.9, p=0.000) levels. No significant change was observed in bilirubin (p=0.105), albumin (p=0.517), blood sugar (p=0.461), HDL cholesterol (p=0.224). Though TNF-α levels reduced the difference was not significant (p=0.075). On histologic examination of liver biopsies, a significant decrease was observed in steatosis (p=0.008), lobular inflammation (p=0.042) and necroinflammatory grade (p=0.014). No decrease was observed in ballooning degeneration (0.155), portal inflammation (0.527) and fibrosis stage (0.298). HSCI increased significantly in zone 1, 2 and 3 of hepatic lobule (1.6±0.8 vs 5.3±2.4, p=0.013). The increased HSCI was seen even in cases which had decreased fibrosis stage or similar stage in pre and post therapy biopsies. CONCLUSION: Pentoxiphylline therapy significantly improves clinical, biochemical and metabolic parameters in patients with NASH. It also leads to reduction in steatosis, necroinflammation and lobular inflammation. TNF-α level are also reduced after therapy, but not statistically significant. The limited effects of Pentoxiphylline on hepatic fibrosis and HSCI could be due to need for a higher dose of the drug requiring greater suppression of TNF levels.

Adipose Tissue of Insulin Resistance in NASH Patients

Masahiko Shimada1,2, Hiromu Kawahara1, Masayoshi Yamada1, Masayuki Fukura1, Mutsumi Tsuchishima1, Shuhei Yoshida2, Yoshiaki Kitamura2, Morihiko Yoshino2, Shujiro Takase1

Background/Aims: Insulin has the function of controlling the breakdown of fatty acids in adipocytes and reducing the level of free fatty acid (FFA) in the blood. However, if insulin resistance develops, then the effectiveness of controlling the breakdown of fatty acids is reduced, and FFA will also reach high levels, even while insulin is at a high level. For non-alcoholic steatohepatitis (NASH) patients, insulin resistance is often detected in the liver, but it remains to be elucidated whether insulin resistance can be detected in adipose tissue. Methods: The subjects consisted of 30 simple steatosis (SS) persons who were matched by BMI, age, and sex (BMI 26.4, age 51.3, 14 females) and 30 NASH persons (BMI 26.7, age 52.2, 15 females). Among these patients, the fasting blood sugar level (FBS), fasting immunoreactive insulin (IRI), HOMA-IR, serum adiponectin level, FFA, Tcho, HDL-cho, TG, and ALT were measured, after which it was determined whether the level of FFA in the blood is higher among NASH patients than among SS patients. In addition, in order to detect the presence or absence of insulin resistant adipose tissue in NASH patients, we investigated whether the effectiveness of insulin in controlling the breakdown of fatty acids had decreased and whether the FFA in the blood were at a high level (>800 μEq/l), even while IRI was at a high level (>10.0 ng/ml), in comparison with SS. Results: The hematological findings showed the following findings, with SS values preceding those of NASH—FBS: 91.8, 104 mg/dl; IRI: 6.2, 13.6 μg/ml; HOMA-IR: 1.3, 4.1; serum adiponectin: 8.4, 5.0 μg/ml; FFA: 431, 698 μEq/l; Tcho: 221, 212 mg/dl; HDL-cho: 54, 47 mg/dl; TG: 93, 126 mg/dl; and ALT: 70, 78 IU/l. FFA (P=0.0024) was at a significantly higher level in NASH patients. In addition, a significant difference in FBS, IRI, HOMA-IR, and serum adiponectin was detected between SS and NASH. Regarding the presence or absence of insulin resistant adipose tissue in NASH patients, the number of cases of high-level IRI was 22 for NASH, and the number of cases of high-level FFA was 9 (30%) of these cases. Conversely, 6 cases with high-level insulin were detected in SS, but there was only 1 case of high-level FFA (3%), and insulin resistance was significantly detected (P=0.0013) in the adipose tissue of NASH patients. Conclusions: Although no difference in the BMI was detected, the FFA showed a higher level in NASH than in SS. In addition, the effectiveness of insulin was also found to decrease in the adipose tissue of 30% of the NASH patients, thus indicating that this may be one possible cause for the development of NASH.

1119 HIGH SENSITIVITY C-REACTIVE PROTEIN IS AN INDEPENDENT CLINICAL FEATURE OF NONALCOHOLIC STEATOHEPATITIS (NASH) AND ALSO OF THE SEVERITY OF FIBROSIS IN NASH

Yuichi Nozaki, Masato Yoned, Takuma Higurashi, Hiroshi Iida, Hironori Mawatari, Hiroki Endo, Ayako Tomimoto, Kyoko Yone-mitsu, Tomoyuki Akiyama, Koji Fujita, Hirokazu Takahashi, Masahiko Inamori, Noritsahi Kobayashi, Yasunobu Abe, Kenseke Kubota, Hiroyuki Kikikoshi, Satoru Saito, Atsushi Nakajima; Division of Gastroenterology, Yokohama City University, Yokohama, Japan

[Background and aims] The changes in nonalcoholic fatty liver disease (NAFLD) range over a wide spectrum, extending from steatosis to steatohepatitis (NASH). However, it has remained difficult to differentiate between NASH and non-progressive NAFLD by clinical examination. We investigated the interrelationships between serum high-sensitivity CRP (hs-CRP) and the presence of obstructive sleep apnea (OSA) in patients with NAFLD.

[Methods] hs-CRP were measured in 101 patients with histologically verified NAFLD (29 with steatosis and 71 with NASH) and a total of 200 patients with OSA. The results of the multiple regression analysis revealed that as compared to that in cases with steato-sis, hs-CRP was significantly elevated (p = 0.0048) in cases of NASH. Furthermore, among the patients with NASH, hs-CRP was significantly elevated in cases with advanced fibrosis as compared with that in cases with mild fibrosis (p = 0.0384), even after adjustment for age, gender, existence of diabetes, BMI, visceral fat area, subcutaneous fat area, HOMA-IR, HDL-cholesterol, triglyceride, and LDL-cholesterol. In regard to the results of the RT-PCR study, the intrahepatic mRNA expression of CRP, but not IL-6, was increased in patients with NASH as compared with steatosis (p = 0.0228).

[Conclusions] This is the first report to demonstrate consistent and profound elevation of hs-CRP in cases of NASH as compared with simple non-progressive steatosis, but also a clinical feature of the severity of hepatic fibrosis in cases of NASH.

1120 PRESENCE OF OBSTRUCTIVE SLEEP APNEA IS ASSOCIATED WITH FIBROSIS IN PATIENTS WITH NONALCOHOLIC FATTY LIVER DISEASE

Poonam Mishra, Clare Nugent, Chunhong Bai, Mariam Afendy, Theresa Egasani-Elises, Hazem Elariny, Zobair M. Younossi; Center for Liver Diseases, Inova Health System - Inova Fairfax Hospital, Annandale, VA

[Background] Nonalcoholic fatty liver disease (NAFLD) is a common cause of chronic liver disease which is associated with obesity and insulin resistance. Obstructive sleep apnea (OSA) is also independently associated with insulin resistance and is a common disorder in obese patients. AIM: To determine the polysomnographic predictors of fibrosis in patients with nonalcoholic steatohepatitis (NASH). METHODS: 101 patients who underwent bariatric surgery were selected from our database. Pre-operative demographic, anthropometric, clinical, laboratory, liver histology and full overnight polysomnographic data were available. Excess alcohol intake (defined as ≥20gm/day for males and ≥10gm/day for females) and other causes of chronic liver disease were excluded. NASH was defined as steatosis, hepatocyte ballooning degeneration and lobular inflammation with or without fibrosis or Mallory bodies. Apnea was defined as the complete cessation of airflow ≥10 seconds and hypopnea was defined as a ≥50% or greater reduction in airflow or respiratory effort ≥10 seconds accompanied by a ≥4% or greater desaturation. The average number of episodes of apnea and hypopnea per hour of sleep (apnea-hypopnea index, AHI) was calculated. AHI > 5 is considered abnormal according to the American Academy of Sleep Medicine (AASM) consensus. RESULTS: Out of 101 patients, 79 had NASH and 22 had Non-NASH. Out of 79 NASH patients, 66 had mild fibrosis, 7 with advanced fibrosis and 6 had no fibrosis. Presence of metabolic risk factors such as diabetes, hyperlipidemia and hypertension were similar in all three groups. Presence of sleep apnea was similar in fibrosis vs. non fibrosis group (84% vs. 75%, p=0.32). Lowest desaturation (nadir oxygen saturation) was significantly lower in patients with fibrosis vs. non-fibrosis (76% vs 85%, p=0.004). Mean nocturnal oxygen saturation in patients with fibrosis was 90.4 vs. 93.0 in non-fibrosis group (p=0.02). Although patients with fibrosis had a trend towards increasing AHI, it did not reach statistical significance (p=0.08).

[Conclusions] Presence of sleep apnea is associated with significant fibrosis in patients with NAFLD. Further studies are warranted to study the effect of optimizing sleep apnea management on liver outcome.

1121 PROTEOMIC ANALYSIS OF SERUM BIOMARKERS IN PATIENTS WITH NONALCOHOLIC STEATOHEPATITIS USING SELDI-TOF/MS OR MALDI-TOF/MS

Hirofumi Uto1, Yoko Sato2, Yaichi Ishida2, Yaichiro Takami2, Shuji Kamura1, Akihiro Moriiuchi1, Susumu Hasegawa1, Makoto Oketani1, Akio Id1, Tomoaki Nakajima1, Takeshi Okanoue3, Hirohito Tsobuch1,1Department of Digestive and Life-style related Disease, Kagoshima University Graduate School of Medical and Dental Sciences, Kagoshima, Japan;2Miyazaki Prefectural Industrial Support Foundation, Miyazaki, Japan;3Molecular Gastroenterology and Hepatology, Kyoto Prefectural University of Medicine Graduate School of Medical Science, Kyoto, Japan;4Liver Diseases Section, Akashi Municipal Hospital, Akashi, Japan

[Background and Aims] Nonalcoholic fatty liver disease (NAFLD) is a common chronic liver disease. Among NAFLD patients, only those with nonalcoholic steatohepatitis (NASH) are at increased risk for progression to cirrhosis and hepatocellular carcinoma compared to patients with simple steatosis. However, there is no serum biomarker for NAFLD or NASH, and identifying high-risk patients is extremely difficult. This study illustrates how surface-enhanced laser desorption and ionization (SELDI)- or matrix-assisted laser desorption/ionization (MALDI)-time of flight mass spectrometry (TOF/MS) is a valuable method to profile and identify serum proteins in patients with different NAFLD subtypes in order to discover a novel serum marker for NASH.

[Methods] NAFLD patients were classified as simple steatosis or NASH by liver biopsy. A total of 71 serum samples, including serum from 25 NASH patients, 20 patients with simple steatosis, and 26 healthy controls were examined by SELDI-TOF/MS using the IMAC 30 chip. Serum
protein profiles were analyzed with the accompanying software to screen for potential NASH markers. For protein identification, an affinity-bead-purified serum protein was subjected to MALDI-TOF/MS analysis, followed by Mascot identification of the peptide sequences and a search of the National Center for Biotechnology Information protein database. RESULTS: Three serum protein peaks with mass-to-charge ratios (m/z) ranging from 3000 to 5000 were significantly upregulated in NAFLD samples compared to healthy control samples. One protein peak was also significantly downregulated in NASH patients compared to simple steatosis patients by SELDI-TOF/MS. However, these 4 serum proteins were not identified by high-performance liquid chromatography. To optimize MALDI-TOF/MS analysis based on the best markers distinguishing NASH and control spectra, cation-exchange beads were used for serum protein profiling. Three markers between 1000 and 3000 m/z were upregulated in NAFLD sera compared to healthy control sera. These three protein peaks were detected in 44 NAFLD samples and were not detected in any healthy control samples. These three peaks were identified as different isoforms of the same protein with some portions deleted. CONCLUSIONS: Proteomics approaches such as SELDI-TOF/MS and MALDI-TOF/MS could greatly facilitate the discovery of serum biomarkers in NAFLD patients. Identifying these proteins will help clarify NASH pathogenesis and identify potential markers for NASH.

1122 PIOGLITAZONE ENHANCES HEPATIC, MUSCLE AND ADIPOSE TISSUE INSULIN SENSITIVITY AND AMELIORATES SYSTEMIC INFLAMMATION IN PATIENTS WITH IGT OR T2DM AND NASH

Kenneth Cusi1, Renata Belfort4, Steve Harrison2, Bogdan Balas1, Stephen Schenker1, Celia Darland1, Amalia Gastaldelli1, Kenneth Brown1, Jean Hardies1; 1The University of Texas Health Science Center at San Antonio, San Antonio, TX; 2Brooke Army Medical Center, San Antonio, TX

Background: We reported that pioglitazone (PIO) improves glucose metabolism and histology (steatosis/necro-inflammation) in pts (pts) with IGT or type 2 diabetes (T2DM) and non-alcoholic steatohepatitis (NASH) (Belfort, NEJM 2006). Because insulin resistance (IR) and systemic inflammation are involved in the pathogenesis of NASH, we further examined the effect of PIO on both variables. Methods. Pts (n=55) received a hypocaloric diet (-500 kcal/d) and were randomized (double-blind) to PIO (45mg/d) or placebo (Pbo) for 6 months. Pts had the following studies before and after treatment: 1) liver biopsy; 2) liver fat by magnetic resonance spectroscopy (LMRs); 3) plasma levels of inflammatory markers; 4) double-tracer OGTT to assess glucose tolerance, endogenous (liver) glucose production (EGP) and glucose clearance. We calculated indexes of hepatic (Hep-IS = 1/[EGP x fasting insulin]), muscle (Muscle-IS= Rd/insulin during OGTT) and adipose tissue (Adipo-IS= 1/[FFA x fasting insulin]) insulin sensitivity. We also studied 15 controls (CON) without T2DM or NASH (no biopsy). Results. NASH pts (vs. CON) had higher fasting/OGTT plasma glucose, A1C, insulin and FFA levels, LMRs, and lower adiponectin and glucose clearance (all p<0.001) – each defect being reversed by PIO [all p<0.001; Belfort, NEJM 2006]. In NASH pts, Hep-IS, Muscle-IS and Adipo-IS were all reduced (~75%, ~43% and ~50%, respectively, p<0.01) and associated with reduced fasting/OGTT glucose clearance (r= 0.37 to 0.44, p<0.01). Pbo did not change glycemic control/insulin sensitivity, but PIO markedly increased Hep-IS, Adipo-IS and Muscle-IS from 1.2- to 1.8-fold (p<0.001 vs. pre-T and Pbo). Adiponectin increased ~3-fold (p<0.001) and correlated strongly with improved Hep-IS (r=0.37), Adip-IS (r=0.54), OGTT glucose clearance (r=0.44), steatosis (r=0.49) and necroinflammation (r=0.51, all p<0.01). NASH pts had an increase in markers of systemic inflammation: hsCRP x ~3-fold and IL-6, TNF-α, VCAM and ICAM by 40-50% (all p<0.01 vs. CON). PIO significantly reduced hsCRP (6.1±1.0 to 3.1±0.8 mg/L, p<0.04), TNF-α (2.2±0.1 vs. 2.0±0.1 pg/ml, p<0.01), TGF-β (31±2 vs. 26±2 ng/ml, p<0.05), VCAM (323±32 vs. 480±32 ng/ml, p<0.01) and ICAM (315±17 vs. 268±10 ng/ml, p<0.01). Conclusion: pts with IGT/T2DM and NASH have severe hepatic/muscle/adipose tissue insulin resistance and systemic inflammation. Amelioration of insulin resistance by PIO reduces hepatic lipogenesis and fat accumulation by acting at multiple levels, including substrate supply (glucose, FFA), hormonal control (lowering plasma insulin and increasing adiponectin) and lipid-associated inflammation, which helps explain its clinical efficacy.

1123 OXIDATIVE STRESS PROFILES IN PEDIATRIC NON ALCOHOLIC FATTY LIVER DISEASE

Richard Rosencrantz1, Hong Lin2, Yin Yan Xu2, Susanna Cunningham-Rundles3; 1Pediatric Gastroenterology and Nutrition, New York Presbyterian Hospital-Weill Cornell Medical Center, New York, NY; 2Pediatric Hematology/Oncology, New York Presbyterian Hospital-Weill Cornell Medical Center, New York, NY; 3Host Defense Program, New York Presbyterian Hospital-Weill Cornell Medical Center, New York, NY

Background: Non Alcoholic Fatty Liver Disease (NAFLD) in the pediatric population is an under recognized pathologic entity since most patients are clinically asymptomatic until a late stage of disease. There is limited knowledge about oxidative stress variability in the pediatric literature. Oxidative stress may be related to alterations in immune response that preferentially enhance hepatic inflammation and NAFLD progression. Identifiable biomarker patterns that accurately represent oxidative stress would be an important advance in NAFLD recognition and therapeutic intervention. Aim: To explore oxidative stress biomarker models and lymphocyte immunophenotype profiles in pediatric patients within the clinical spectrum of NAFLD. Patients and Methods: Sixteen obese patients (BMI>95th percentile, mean age 11.5 years, range 3-17 years, 5 females) were included in the study. Standard liver function tests, creatinine-adjusted urinary F2-isoprostane, lymphocyte immunophenotype subsets and a liver sonogram were obtained. Other causes of liver disease were excluded. Three groups were compared: steatohepatitis group; hepatic steatosis group; an obesity only group without liver abnormalities was used as a control. Results: The steatohepatitis group had approximately 2-fold higher average creatinine-adjusted urinary isoprostane excretion compared to the hepatic steatosis and obese groups. Higher serum ALT values correlated with increased average F2-isoprostane; however, a linear relationship was not seen with or without NAFLD. In addition, there was a decreased percentage of CD3+CD4+ T-cells compared with the obese group (p<0.05) and normal controls (p<0.01) and an increased percentage of...
CD19(+) B-cell lymphocyte subsets in the steatohepatitis group compared with normal controls (p=0.06) studied in parallel. Conclusion: Higher levels of oxidative stress as measured by urinary F2-isoprostane and altered percentages of T- and B-cell lymphocyte subsets are associated with steatohepatitis as reflected in both liver function test and NAFLD-specific sonographic abnormalities compared to obese controls. The use of these modalities in identifying pediatric patients with NAFLD warrants further investigation.

1124 SHORT-TERM VARIABILITY IN COMMONLY USED LIVER TESTS: IMPLICATIONS FOR CLINICAL PRACTICE

Mariana Lazo1, Elizabeth Selvin2, Jeanne M. Clark1,2; 1School of Medicine, Johns Hopkins Medicine, Baltimore, MD; 2Welch Center for Prevention, Epidemiology, and Clinical Research, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD

Objectives: Although liver tests are routinely used in clinical settings to screen and monitor hepatic diseases, the short-term within-person variability of serum aminotransferases (AST, ALT), alkaline phosphatase (AP), gamma glutamyl-transferase (GGT) and total bilirubin is largely unknown. The magnitude of within-person variability has important implications for the use and interpretation of these tests. Methods: We analyzed repeated measurements (17 days apart on average) on 1,864 adults from the National Health and Nutrition Examination Survey III (NHANESIII) Second Examination. We describe the intra-individual variability in liver tests, as measured by the within-person coefficient of variability (CVw). We also assessed the proportion of subjects with persistently elevated levels as defined by NHANES III as follows: two measurements of AST >31 U/L for women and >40 U/L for men; ALT >31 U/L for women and >37 U/L for men; GGT >55 U/L; AP >117 U/L and total bilirubin >1 mg/dl. Results: There was significantly higher variability (p <0.05) within-person variability in the measurements of total bilirubin (CVw = 23.4%, 95% CI: 22.4%-24.3%) and ALT (CVw = 20.4%, 95% CI: 19.5%-21.2%) compared to AST (CVw, 13.9%; 95% CI: 13.2%-14.5%), and GGT (CVw, 13.8%; 95% CI: 12.6%-14.8%). AP was by far the most reliable of the five measurements (CVw, 6.7%; 95% CI, 6.4%-6.9%). Of those with initially elevated AST level, the proportion of persons with persistently elevated levels was 64%. Similarly, for ALT this proportion was 69%, for GGT 88%, for AP 83% and for total bilirubin 62%. Few people were reclassified as elevated on the 2nd exam after a normal result on the first exam (<5% for all tests). The results did not differ by gender, body mass index, level of alcohol consumption, or by laboratory evidence of hepatitis B or C infection. Conclusion: The usefulness of single measurements of liver tests in clinical practice and to screen large numbers of otherwise healthy subjects and/or monitor hepatic diseases may be limited by the low reliability of these measurements. If re-tested, over 30% of individuals with elevated AST, ALT or bilirubin levels will be reclassified as normal. GGT and AP are more reliable with ~15% of subjects being reclassified to normal after a second test. Clinicians should be aware of the relatively high within-person variability in common liver tests.
